Rutile occurs both as inclusions in garnet crystals and in the matrices of Late Precambrian metapelitic rocks in the Mica Creek area, British Columbia. Zr contents of these rutile crystals have been analyzed by electron microprobe. The Zr detection limit is 25 ppm (20 samples). Metamorphic grade ranges from staurolite-kyanite zone to K-feldspar-sillimanite zone. Temperatures are based upon experimental calibrations. Temperature (T) estimates for rutile inclusions in garnet range from 555 to 705°C (calculated at 7 kbar). T's for groundmass rutile range from <475 to 700°C. There is no apparent correlation of T with the metamorphic grade. In most samples there is no statistical difference between T's from inclusions and T's from matrix rutile. Many of these inclusion T's are simlar to those obtained from garnet-biotite geothermometry. Isopleths for garnet in isochemical phase diagram sections when compared to core garnet compositions yield T's which are much lower than those from Zr geothermometry. The isochemical phase diagram sections also suggest that garnet and rutile are not stable together except at high P-T. T's based upon Zr geothermometry for inclusions appear to be too high for the equilibrium growth of garnet at lower metamorphic grade. A study of Ti in quartz geothermometry for four samples (inclusions in garnet) yielded T's ranging from 417 to 553°C. Zr in rutile has been analyzed on two different microprobes and by laser ablation ICP-MS with consistent results. Other workers have found reasonable correlation between Zr T's and those based upon other methods. For the Mica Creek samples disequilibrium is a possibility but would require metastable growth of rutile with higher Zr contents. Most scenarios would predict T's which are too low rather than too high. Exchange of Zr between garnet and rutile inclusions during subsequent heating does not appear to be plausible. We suggest equilibrium at higher P-T between garnet and rutile inclusions than those suggested from garnet isopleths.

Fluid-absent melting of Phase D and the role of hydrous melts in the deep mantle

Sujoy Ghosh*[1], Max Schmidt[1]

[1]Dep. Earth Sciences, ETH Zurich, Switzerland, sujoy.ghosh@erdw.ethz.ch; max.schmidt@erdw.ethz.ch

The degree of hydration of and the amount of H_2O released from subducting slabs constrains the recycling and circulation of water in the Earth's interior. Water is transported into the Earth's interior via hydrous phases in descending slabs. Numerous high-pressure studies have determined the stabilities and role of several dense hydrous magnesium silicates (DHMS) at mantle conditions and H_2O-saturated conditions, mostly in MSH-model compositions. Among the DHMS, phase D is the one principally hosting water in the lower part of the transition zone (where slabs may travel along the upper/lower mantle boundary) and carrying H_2O from the upper to the lower mantle. The most likely state of a hydrated slab undergoing prograde metamorphism is that of fluid-absent but H_2O-present conditions at which hydrous phases destabilize through fluid-absent melting at their maximum temperature stability. In the present study, we constrain the fluid-absent melting relations of phase D and of phase D + olivine + enstatite in (i) MgO-SiO_2-H_2O system (ii) with Al_2O_3 and (iii) with Al_2O_3 + FeO added in proportions appropriate for the mantle. Stochiometric oxide mixtures of brucite and quartz of phase D composition were used as starting material. Multianvil experiments were carried out at 22-24 GPa and 1000-1800 ºC using 10/3.5 pressure assemblies.

Our data show that phase D decomposes to MgSi-ilmenite + stishovite + melt or MgSi-perovskite + stishovite + melt and indicate that phase D is stable along a slab geotherm to the top of the lower mantle for a range of H_2O contents. Melting temperatures are ~1400 ºC in the MSH system, 150 ºC higher with Al_2O_3 only, but similar to the MSH system with Al_2O_3+FeO. In all 3 systems, the melting temperature is almost constant with pressure. Melt compositions are strongly magnesian with Mg:Si ratio of 1.5-3.2. Furthermore, mass balance calculations of phase D composition experiments (with Al, Fe) suggest that the unquenchable melts contains ~ 23-32 wt% H_2O at the phase D-out, which fits well with EPMA analysis (difference of total to 100%). The data are used to determine the stability of phase D, the proportions of melt formed during melting, the composition of the partial melts and the variation in the melt composition at different pressure temperature conditions. Most interestingly, thermal relaxation to adiabatic temperatures of a slab traveling along the 660 km discontinuity, would lead to fluid-absent melting of phase D, thus producing a H_2O-rich magnesian melt.

THE PLAGIOCLASE AS ARCHIVE OF MAGMA ASCENT DYNAMICS: THE 2001-2006 ERUPTIVE PERIOD AT MOUNT ETNA

P.P. GIACOMOMI [1*], M. COLTORTI [1], C. FERLITO [2].

[1] Dipertimento di Scienze della Terra, Università di Ferrrara, Italy, pierpaolo.giacomoni@unife.it (* presenting author)

[2]Dipartimento di Scienze Geologiche, Università di Catania, Catania, cferlito@unict.it

ABSTRACT

Several studies are focused on textural and compositional features of plagioclase as an usefull tool to investigate magma chamber processes, ascent dynamics, and physico-chemical conditions. In particular water content, which plays a fundamental role in volcanic process, strongly affects plagioclase stability and, by conseguence, textural and compositional features. However, such reconstruction are usually biased by too many assumptions; particularly when dealing with past eruptions or remote volcanoes. Only few volcanoes provide an array of instrumental monitoring to constrain timing and modality of eruptive events. In this respect Mount Etna probably represents one of the most controlled volcano in the world and a great wealth of seismological and ground deformations data are available. In this work we present a textural and compositional study of plagioclases from lavas emitted during the 2001-2006 eruptive period on Mount Etna. Textural classification has been done on over 130 thin sections taking into account different portion of the crystals. This allow to recognize different types of core (ehuedral and rounded) and rims (dusty or with melt inclusion alignment) separated by oscillatory zoned overgrowth.

Oxygen fugacity in magmas has been calculated using the method of [1] and results has been used to reequilibrate the melts to mantle equilibrium, adding back the appropriate quantity of fractionated material. Water content of the melt has been estimated using the hygrometer of [2]. These data were used in the MELT model to estimate the plagioclase stability field and to calculate theoretic composition at different water content. Results were integrated with monitoring data acquired during the entire period under study with the aim to reconstruct magma ascent and storage conditions, as well as the mechanism of eruption triggering. Results indicate the 2001-2006 eruptive period involved magmas with quite similar major element composition but different dissolved H_2O. Complex zoning such as dusty areas and alignments of melt inclusions in outer portion of the phenocrysts suggest two different trigger mechanism respectively: i) magma input and mixing with a more basic and volatile-rich magma; ii) fracture migration that induce decompression of shallow magma batches.

Rates and mechanisms of lead(IV) oxide reductive dissolution

DANIEL E. GIAMMAR* AND YIN WANGAUTHOR

Washington University, Department of Energy, Environmental and Chemical Engineering, St. Louis, MO, USA, giammar@wustl.edu (* presenting author), yinwang@go.wustl.edu

The Pb(IV) oxides plattnerite (β-PbO_2) and scrutinyite (α-PbO_2) have very low solubility, but they can undergo reductive dissolution and release more soluble Pb(II). While PbO_2 solids are not common in nature, they can form in the presence of oxidants used for water disinfection and play a significant role in controlling lead concentrations in drinking water conveyed through lead pipes. Because PbO_2 is not stable in the absence of a strong oxidant, the dissolved Pb(II) concentrations achieved are governed by the kinectics and not the equilibrium of the dissolution reaction. The reductive dissolution of PbO_2 can be interpreted as a coupled process involving chemical reduction of Pb(IV) to Pb(II) at the PbO_2 surface followed by detachment of Pb(II) to solution.

The dissolution rates of plattnerite were measured as a function of water chemistry in continuously-stirred tank reactors that prevented the accumulation of reaction products and formation of secondary Pb(II) solids. Reaction rates were measured as functions of pH, a strong oxidant (hypochlorite) that might inhibit reductive dissolution, a reductant (iodide) that could accelerate the reduction of Pb(IV) to Pb(II), and a ligand (carbonate) with a high affinity for the Pb(II) formed during reduction.

PbO_2 is such a strong oxidant that soluble Pb(II) is produced even when water is the only possible reducant. The presence of hypochlorite at concentrations used in drinking water distribution systems strongly inhibited Pb release. The addition of iodide dramatically accelerated the dissolution of PbO_2 by driving the reduction of Pb(IV) to Pb(II) at the solid-water interface. The addition of dissolved inorganic carbon (DIC) to previously carbonate-free systems increased dissolution rates by facilitating the desorption of Pb(II) from the PbO_2 surface; however, once some DIC was present the dissolution rate was insensitive to further increases. The dissolution rate was higher at low pH, which could have been cuased by its effect on the overall electrochemical driving force for PbO_2 dissolution, impact on the kinetics of a rate limiting step, and control of iodide adsorption and Pb(II) desorption. A kinetic model similar to those used for the reductive dissolution of other metal oxides (i.e., iron and manganese oxides) was successfully fit to the experimental data. The data suggest that chemical reduction is the rate-limiting step for PbO_2 dissolution in the presence of iodide.

The reductive dissolution of PbO_2 present as a corrosion product on lead pipes can produce lead concentrations that exceed drinking water standards. Such reductive dissolution can occur for drinking water systems that switch their secondary disinfectant from hypochlorite to a weaker oxidant such as chloramines. While iodide was chosen in the present study as a model reductant, the reductive dissolution mechanism will likely be similar for natural organic matter, Fe(II), and Mn(II), which are more common reductants found in drinking water.

Isotopic evidence for sea ice and brine formation in the northern Labrador Sea at the terminations of Heinrich Events 1 and 2.

O. GIBB[1*], C. HILLAIRE-MARCEL[1], A. DE VERNAL

[1]GEOTOP-UQAM, Montreal, Canada, oliviagibb@gmail.com*

Reconstructions of sea surface conditions in the Northern Labrador Sea (HU2008-029-004PC) have been created using dinoflagellate cyst assemblages for the last ~35 cal ka BP. They demonstrate that the temperatures were near freezing, the salinity below 31, and the area was under close to permanent ice cover. There were however occurrences of the planktonic foraminifera *Neogloboquadrina pachyderma* sinistral (Npl). Since Npl requires salinity above 34 (e.g., [1]), its growth had to occur either deeper in the water column, if suitable salinities prevailed, or more likely, in brine canals in the sea-ice itself, as it does in modern sea-ice environments [2]. Similarly to previous studies (e.g., [3]), an isotopic shift of -2.5‰ occurs between the beginning and end of Heinrich Event 1 (H1), and a less dramatic -1‰ shift during H2. These light isotope excursions would typically be acknowledged as low-salinity pulses and higher sea surface temperatures. However the dinocyst data indicates this was not the case. As demonstrated by Hillaire-Marcel and de Vernal [4], the light $\delta^{18}O$ excursions are an effect of the foraminifera forming in isotopically light brines during sea ice formation. Perennial sea ice cover inferred from particularly low production of dinocysts occurred toward the end of the Heinrich events, concurrently with high abundance of ice rafted debris and Npl.

Application of X-ray absorption spectroscopy to characterize metal(loid) removal in passive treatment systems

BLAIR D. GIBSON[1*], MATTHEW B.J. LINDSAY[2], CAROL J. PTACEK[1], AND DAVID W. BLOWES[1]

[1]Earth and Environmental Sciences, University of Waterloo, Waterloo, ON, Canada, bgibson@uwaterloo.ca (* presenting author), ptacek@uwaterloo.ca, blowes@uwaterloo.ca

[2]Present Address: Earth and Ocean Sciences, University of British Columbia, Vancouver, BC, Canada, mlindsay@eos.ubc.ca

Introduction

Monitoring of the relative changes in dissolved metal concentrations and aqueous speciation modeling frequently are employed to evaluate the effectiveness of passive treatment systems for metal(loid) removal in mining environments. However, these methods do not provide mechanistic information on metal(loid) removal. Synchrotron-based X-ray absorption spectroscopy can provide information regarding the oxidation state and local coordination environment of the metal(loid) of interest on the reactive media, which can be used to determine if the metal(loid) removal mechanism involves sorption, oxidation/reduction, or precipitation reactions. This information is important for assessing treatment efficacy and the long-term stability of reaction products.

In this study, batch experiments were employed to evaluate the efficacy of different types of reactive media to induce removal of aqueous Se and Hg. For the Se experiments, 300 mg L^{-1} aqueous Se(VI) (from Na_2SeO_4) was allowed to react with granular Fe filings (GIF) and an organic carbon (OC) mixture consisting of a 1:1 (w/w) ratio of wood chips and crushed leaf mulch. For Hg, 4 mg L^{-1} aqueous Hg(II) (from $HgCl_2$) was allowed to react with GIF, granular activated carbon (GAC), attapulgite clay, and attapulgite clay pre-treated with two types of thiadiazole compounds [1]. Dissolved concentrations of Se and Hg were monitored over time, and X-ray absorption near edge structure (XANES) and extended X-ray absorption fine structure (EXAFS) spectroscopy methods were used to characterize the forms of metal(loid)s on the reactive media.

Results and Conclusion

After 5 days of reaction, Se(VI) removal was observed to be >90% in the presence of GIF and 15% with OC. Analysis with XANES spectroscopy suggested that removal in the presence of GIF was due to reduction of Se(VI) to insoluble Se(0), whereas removal with OC was due primarily to sorption of Se(VI). For Hg, treatment efficiency varied between the reactive media, ranging from 25% removal on untreated clay after 8 days of reaction to >99% removal on clay treated with 2,5-dimercapto-1,3,4-thiadiazole. Analysis with EXAFS spectroscopy indicated the presence of Hg-O bonding on GIF and GAC, suggesting Hg removal was due to binding with Fe corrosion products or to water sorbed to the surface of activated carbon. The presence of Hg-S bonding was observed in the presence of thiadiazole compounds, suggesting Hg was bound to thiol-functional groups on these compounds.

The mid-Cretaceous Canadian Cordillera: Paired orogenic belts or an Altiplano-esque Plateau deflated by deep crustal flow?

GIBSON, H.D.[1]*

[1]Simon Fraser University, Dept. Earth Sciences, Burnaby, Canada, hdgibson@sfu.ca (* presenting author)

The current configuration of the central and southern Canadian Cordillera clearly shows a pairing of highstanding orogenic welts, the Coast belt to the west and the Omineca belt to the east, separated by the intervening subdued topography of the Intermontane belt. How closely this reflects the Meoszoic orogenic architecture for the southern Canadian Cordillera is debatable, but it does bring to mind some important questions regarding the orogenic processes that shaped the southern Canadian Cordillera.

The last major orogen-wide compressional event within the southern Canadian Cordillera occurred in the mid- to Late Cretaceous time, coinciding with the final closure of a marginal basin and attendant accretion of the Insular terranes. Plutons, contractional deformation and high-grade metamorphism that attest to this orogenic event are most obviously manifest in the southern Coast and Omineca belts, and provide evidence for crustal thicknesses on the order of 55-65 km, similar to the average thickness of the Altiplano plateau. So, was there a continuous, high-standing (~4-5 km above sea level) plateau across the width of the southern Canadian Cordillera, or was there an intervening low-lying area of subdued topography much like there is today, which might suggest a paired-system of orogenic belts inherited from Mesozoic orogeny? If so, how would such a system operate?

The displacement along Paleogene strike-slip faults needs to be restored in order to assess the mid- to Late Cretaceous crustal architecture of the southern Canadian Cordillera. This places the Bowser basin in the intervening region with subdued topography whose crustal thickness was on the order of 40-45 km, compared to the flanking 55-65 km welts on either side of it. This implies that the crustal architecture for the mid- to Late Cretaceous time was dumb-bell shaped in cross-section, akin to lithospheric-scale boudinage. The flanking welts would represent paired-orogenic belts characterized by thick-skinned deformation, high-grade metamorphism, anatectic melting and plutonism that were separated by the Bowser basin with its classic thin-skinned Skeena fold and thrust belt. How did the stress that was driving the Coast belt orogen nearest the convergent margin transfer to the east across the width of the orogen to drive the thick-skinned deformation and substantial crustal thickening within the Omineca belt without similarly affecting the intervening crust within the Intermontane belt?

Alternatively, could there have been an Altiplano-style plateau spanning the width of the southern Canadian Cordillera? If so, could the apparent thinning of the crust within the central part of the plateau have been the result of deflation related to general non-coaxial flow within its deepest levels? In this scenario, the general non-coaxial flow, which would include a significant flattening component, effectively evacuated material out from beneath the plateau, perhaps accentuating thickening on its flanks, leaving the appearance of the paired-orogenic belts we see today.

Hydrogeochemical setting of the Northern Athabasca Oil Sands area

J.J. GIBSON[1,2*], Y. YI[1,2], S.J. BIRKS[1,2], M.C. MONCUR[1], J.W. FENNELL[3], K.TATTRIE[1]

[1]Integrated Water Management, Alberta Innovates-Technology Futures, Victoria & Calgary, Canada, john.gibson@albertainnovates.ca (*presenting author)

[3]Worley Parsons, Calgary, Canada, jon.fennell@worleyparsons.com.

Introduction

The oil sands of Northern Alberta represents an important oil reserve for Canada and the world. These vast hydrocarbon deposits have been exposed to the surface via long-term erosion by the Athabasca River and its tributaries. This geological evolution has led to a complex hydrogeological system, which features numerous pathways connecting the surface and subsurface hydrologic systems. Here, we present a study based on data and information collected from several river sampling campaigns along the main channel of the Athabasca River, including geochemical and isotopic signatures in formation water, that shed light on the natural hydrogeological setting of the Northern Athabaca Oil Sands Area.

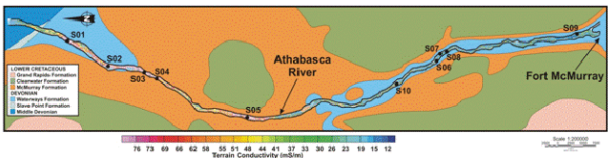

Figure 1: Terrain electrical conductivity of a 125-km reach of the Athabasca River from Fort McMurray to the Firebag River overlain on a map of bedrock geology. Zones of elevated terrain conductivities indicate potential connections between surface water and groundwater, and these areas were targeted for groundwater sampling for a full suite of geochemical and isotopic analyses to characterize and trace the origin and evolution of groundwater discharging to the river.

Results and Discussion

Electrical conductivity surveys reveal large areas with elevated conductivity, reflecting both variation in geologic substrate (e.g. evaporites), as well as variable salinity of inflowing waters in seeps and an array of groundwater springs. The geochemical and isotopic composition of these groundwater inflows are similar to those found in the McMurray Formation and Devonian Formation waters. The distribution of the seep geochemistry and some of the bulk river chemistry are related to changes in geology along the reach of the Athabasca River studied. The results of this investigation provide insight into the geochemical and isotopic evolution of riverine water quality, specifically the significant influence of natural groundwater sources of salinity and organics to the Athabasca River.

Assessing the health effects of atmospheric particulate matter

RETO GIERÉ[1]

[1] Universität Freiburg, Geowissenschaften, 79104 Freiburg, Germany (giere@uni-freiburg.de)

Atmospheric particulate matter (PM) is ubiquitous in the atmosphere and is generated in various environments through natural processes and human activity. Individual particles display a wide range of physical, chemical, structural and surface properties, which depend on source, chemical reactions, and transport under variable atmospheric conditions [1]. Several epidemiological and toxicological investigations have linked airborne PM with adverse effects on human health, both acute and chronic. Effects associated with PM exposure include chronic obstructive pulmonary disease (COPD), exacerbation of asthma, fibrosis, slower lung development in children, and lung cancer, but also an increase in cardiovascular diseases [2]. The inhaled fine particles ($PM_{2.5}$) can migrate to the alveoli in the deep lung, where they remain for long periods of time and interact with lung fluid and tissue. The deepest part of the lungs, thus, acts a special type of active sampler for atmospheric dust. The finest PM fraction may translocate to epithelial and interstitial sites and possibly to extrapulmonary organs. Inhaled coarse particles, on the other hand, are retained in the upper part of the respiratory tract, but there is increasing evidence that coarse particles may also produce adverse health effects [3].

Within the lung, the inhaled PM interacts with lung fluid and tissue, stimulating various types of biological and biochemical responses (e.g., immune defense reactions, inflammation, cytokine release). These reactions to external stimuli are still poorly investigated, and their relationship with, and dependence on, specific PM properties are largely unknown. To improve our knowledge on the health effects of PM, a close collaboration between diverse scientific disciplines is crucial. Moreover, it is essential to characterize single particles in detail in order to perform meaningful experiments designed to improve our currently poor knowledge on the interaction between atmospheric PM and the respiratory tract.

This presentation will discuss various approaches to assessing the health impacts of PM. It will describe experimental results obtained from *in-vitro* stimulation of lung cells with diverse types of PM, which have been found to be present in ambient air (magnetite, black toner dust, various metal sulfates, and tire-wear particles). This presentation will also report results from investigations on lung tissue samples and brochoalveolar lavage (BAL) fluids.

Schwertmannite formation in acid mine drainage in NE Viet Nam

RETO GIERÉ[1*], THI BICH HOÀNG-HÒA[1], RAUL E. MARTINEZ[1], AND RICHARD WIRTH[2]

[1] Universität Freiburg, Geowissenschaften, 79104 Freiburg, Germany (giere@uni-freiburg.de)

[2] GeoForschungsZentrum Potsdam, Section 4.1, Telegrafenberg C120, 14473 Potsdam, Germany

The province of Quang Ninh in northeastern Viet Nam is one of the largest coal mining districts of the country, hosting reserves estimated at 10 Gt. The coal is mostly anthracite and is mined both in open pits and underground. This study focuses on acid mine drainage from the Coc Sau open-pit mine near the town of Cam Pha. The mine is approximately 3 km in diameter and has an orange-colored lake in the center, which drains through a tunnel into a creek. After flowing for ~4 km through the densely populated town, the acid mine waters discharge into the ocean.

The drainage waters have a pH of 2.4±0.4, a temperature of 30.3 ºC, and an Eh of 0.63±0.02 V under normal conditions, but after major rain storms the pH may be as high as 7.2±0.1, with an associated Eh of 0.29±0.05 V. The low-pH water contains the following major components (in mg/L): Fe = 46±18, SO_4^{2-} = 850±100, Al = 7±2, Mg = 76±3, and Ca = 66±18.

The creek bed and the contained pebbles are covered by a bright orange crust. This crust consists primarily of schwertmannite, quartz and sheet silicates (mostly kaolinite and illite) in the outer, highly porous part, whereas the inner part, directly on the substrate, consists of mostly ferrihydrite and sheet silicates. Scanning electron microscopy revealed the typical appearance of schwertmannite, i.e. small (usually <1µm across), spherical to ellipsoidal aggregates resembling sea urchins, and further suggested that schwertmannite also forms crusts on, and is intergrown with, sheet silicates. This suggestion was corroborated by transmission electron microscopy, which has shown that the schwertmannite aggregates in many cases contain a core of sheet silicate. Selected area electron diffraction allowed for unequivocal identification of schwertmannite, but the typical needle-like features (~200 nm long) are in many cases amorphous and therefore not whiskers.

In order to construct an Eh-pH diagram showing the stability fields for schwertmannite and ferrihydrite, we calculated the activity of the major chemical components using the extended Debye-Hückel equation. The ionic strength of the system (I = 0.016 M) was computed from the water conductivity [1]. Based on the available thermodynamic data, including a logK_{sp} value of 1.2±0.5 for schwertmannite with the ideal formula $FeO(OH)_{3/4}(SO_4)_{1/8}$ [2], a plot of Eh *vs.* pH was generated showing a schwertmannite field that is consistent with the observed conditions of our low-pH water samples. The diagram also coincides with an Eh-pH diagram constructed with a logK_{sp} of 0.88±0.01 for schwertmannite with the formula corresponding to $FeO(OH)_{0.738}(SO_4)_{0.131}$ [3].

At present, we do not understand yet, why the innermost part of the crust, directly on the substrate, consists mostly of ferrihydrite.

Structural and chemical studies of the pyrite (001) surface

B. GILBERT[1,*], P. J. ENG[2], D. SINGER[1], J. F. BANFIELD[3] AND G. A. WAYCHUNAS[1]

[1]Lawrence Berkeley National Laboratory, Earth Sciences Division, Berkeley, USA, bgilbert@lbl.gov, gawaychunas@lbl.gov. (* presenting author)

[2]University of Chicago, Chicago, USA, eng@cars.uchicago.edu

[3]University of California – Berkeley, Dept. Earth & Planetary Science, Berkeley, USA, jbanfield@berkeley.edu.

Pyrite, FeS_2, is a widespread and important sulfide mineral. Pyrite is thermodynamically stable under reducing conditions and in saturated sediments provides surfaces for the adsorption of aqueous species. When exposed to oxidizing environments, for example through mining activities, pyrite oxidation leads to the generation of low pH solutions termed acid mine drainage (AMD). The impact of AMD on environmental health is a global concern.

Detailed understanding of the reactivity of pyrite surfaces requires knowledge of their atomic structure under relevant conditions. Many groups have studied the surface chemistry of pristine and oxidized pyrite surfaces but the structure of a hydrated surface has never been experimentally determined. We have employed the crystal truncation rod (CTR) method and complementary surface-sensitive techniques in order to determine the structure of the water—pyrite (001) interface and to establish how adsorbates interact with this surface.

We developed an anaerobic chemical–mechanical polishing method that creates low-roughness pyrite (001) surfaces shown by atomic force microscopy (AFM) to be dominated by irregularly shaped (001) terraces. We studied the structure of the hydrated pyrite (001) surface using the CTR method, obtaining reproducible results from three crystals. Optimal fitting of the CTR data requires the incorporation of two structurally distinct termination surfaces that differ in the coverage, and likely the chemical speciation, of surface sulfur atoms. In each case, surface iron atoms and disulfur groups are significantly displaced from bulk positions.

The adsorption of aqueous metal ions provides a complementary approach for assessing the chemical speciation of sites on the (001) surface. We observed modulation in the CTR scattering patterns following exposure to Fe^{3+} and Pb^{2+} ions, confirming that the termination surface is accessible and chemically reactive. Grazing incidence extended X-ray absorption fine structure (EXAFS) studies of surface-adsorbed Pb^{2+} revealed at least two near-neighbor distances consistent with a fraction of lead atoms adsorbing via inner-shell interactions with surface sulfur sites.

Sorption of Cr(VI) on Mineral Assemblages of Goethite with Clays and Al-Oxides

ANN M.GILCHRIST[1*], CARLA M. KORETSKY[1]

[1]Western Michigan University, Kalamazoo, MI, USA
ann.m.gilchrist@wmich.edu (* presenting author)

Anthropogenic activities have caused toxic Cr(VI) contamination of many natural systems. Cr(VI) travels readily in aqueous solution but can be impeded by sorption by reactions with Fe-bearing solids. Subsurfaces are not homogeneous, yet most surface complexation models (SCM) are developed for simple, single substrate systems, and do not account for mineral-mineral interactions. The goal of this study is to measure sorption of Cr(VI) on mineral assemblages of goethite, kaolinite, montmorillonite, γ-alumina, hydrous manganese oxide (HMO), and hydrous ferric oxide (HFO) as a function of pH and pCO_2, and to compare measurements to predictions from SCMs developed for single solid systems.

Goethite was synthesized by heating a mixture of KOH and $Fe(NO_3)_3 \cdot 9$ H2O at 70°C for 60 hours [1]; montmorillonite (SWy-2) and kaolinite (KGa-1b) were obtained from the Clay Minerals Society; γ-alumina (γ-Al_2O_3) was purchased from Inframat Advanced Materials; HMO was synthesized by alkametric titration [2] and 2-line HFO was synthesized according to [1]. Synthesized solids were confirmed by XRD and surface area measurements of all solids were completed using 11-point N_2BET analysis.

Adsorption edges were measured over a pH of 3.5 to 10, in open atmosphere or under 0% pCO_2. Binary mixtures of solids were used based on equal surface area (~5 g/L total solid) with 10^{-5} M Cr(VI) and 0.01 M $NaNO_3$. Batch slurries of Cr(VI), $NaNO_3$, and solids were equilibrated for ~1 hr at circumneutral pH. The pH was then lowered to 3.5 by addition of HNO_3, and then titrated upward with removal of ~60 mL aliquots of slurry at each ~0.5 pH increment. After 24 hr, 48 hr, 1 week and 2 weeks of mixing, ~15 mL of slurry was removed from each aliquot and the pH rechecked. Each slurry sample was centrifuged, the supernatant syringe-filtered (0.45 μm) and tested for Cr(VI) using the diphenylcarbazide method.

In all systems containing goethite sorption is near 100% below pH ~6. The sorption edge spans from 6-9 pH with <10% Cr(VI) sorbed at pH >9. The pH at which 50% of Cr(VI) is sorbed is ~6.8 for goethite-montmorillonite and increases to ~7.1 for goethite-kaolinite and ~7.7 for goethite-γ-alumina. Edges for the goethite-clay mixtures appear to be dominated by sorption on goethite, whereas mixtures of goethite and γ-alumina result in edges that are intermediate between those obtained for the pure end-member solids; this will also be assessed using component additivity surface complexation modeling.

Adsorption is rapid for goethite-montmorillonite, goethite-γ-alumina and goethite-kaolinite combinations with little change in sorption with increasing aging from 24 hrs to 2 weeks. All systems exhibit little variation in sorption under atmospheric compared to 0% pCO_2 conditions.

Noble gas and C stable isotopes quash fears over CO_2 storage leaks at Weyburn

STUART GILFILLAN[1*], R. STUART HASZELDINE[1], GEORGE SHERK[2], AND ROBERT POREDA[3]

[1]Scottish Carbon Capture and Storage, University of Edinburgh, UK. stuart.gilfillan@ed.ac.uk (*presenting author:)
[2]International Performance Assessment Centre for Geologic Storage of CO_2 (IPAC-CO_2), Regina, Saskatchewan, Canada.
[3]Department of Earth and Environmental Sciences, University of Rochester, New York, USA.

In January 2011 it was extensively reported that the Kerr family had been forced to move from their property located above the Weyburn-Midale Monitoring and Storage Project in Saskatchewan, Canada. A geochemical consultant from Petro-Find GeoChem Ltd., who was hired on behalf of the Kerr's, reported measurements of $\delta^{13}C$ (CO_2) isotope values in soil gases rich in CO_2 which were similar to those of the CO_2 injected into the deep oil reservoir. The Petroleum Technology Research Centre (PTRC), who are responsible for the environmental monitoring of the Weyburn CO_2-EOR and storage operation, published a detailed response correctly stating that Petrofind had not taken the similar baseline $\delta^{13}C$ (CO_2) isotope measurements conducted prior to the injection into account. Also as $\delta^{13}C$ (CO_2) is not a unique tracer, there were several other natural sources that could account for the measured values. Whilst this response went some way to addressing the public perception fears raised by the alleged CO_2 leakage claims, it was clear that more research was required to re-establish confidence in the safety and security of CO_2 stored at Weyburn. This was imperative for both the project itself and the future of CO_2 storage. IPAC-CO_2 undertook a detailed independent incident response protocol focused on the near surface soil gases, the noble gas composition of the shallow groundwaters and a hydrogeological analysis.

Noble gases are extremely powerful tracers of source and the subsurface processes that act on CO_2. They have recently proved to be effective at tracing the migration of natural mantle derived deep CO_2 up a fault above the St. Johns Dome-Springerville CO_2 reservoir in Arizona [1]. A clear component of the helium fingerprint observed in the gaseous CO_2 contained in the deep reservoir could be traced in waters from both the groundwater wells and the springs emerging at the surface above the reservoir.

Here we use similar methodology to investigate the alleged leakage and we report noble gas and carbon stable isotope measurements from four groundwater wells surrounding the Kerr quarter, near Goodwater in Saskatchewan. We compare these to the noble gas and carbon isotope composition measured from fluids sampled from a production well and CO_2 and water from enhanced oil recovery injection wells associated with the Weyburn-Midale oil field, located near to the Kerr quarter. To determine if migration of dissolved CO_2 from the Weyburn oil field is responsible for the alleged CO_2 anomaly, we compare the noble gas and carbon stable isotope tracers in the water and CO_2 injected into the oil field, and the fluids produced from the field, with those measured in the groundwater well waters.

We find no evidence in any of the noble gas data that there is any presence of deep crustal derived noble gases within the groundwaters surrounding the Kerr quarter. The absence of crustal derived noble gases derived from depth means that there is no evidence of the migration of CO_2 from the Weyburn oil field into the groundwater on the Kerr quarter or surrounding area.

Sulfur cycling in shallow-sea hydrothermal vents, Milos Greece

WILLIAM P. GILHOOLY III[1*], DAVID FIKE[2], JAN AMEND[3], GREG DRUSCHEL[1] AND ROY PRICE[3]

[1]Dept. of Earth Sciences, Indiana University-Purdue University Indianapolis, Indianapolis, USA, wgilhool@iupui.edu (* presenting author); gdrusche@iupui.edu

[2]Dept. of Earth and Planetary Sciences, Washington University in St. Louis, St. Louis, USA, dfike@levee.wustl.edu

[3]Earth Sciences and Biological Sciences, University of Southern California, Los Angeles, USA, janamend@usc.edu; royprice@usc.edu

Milos is a volcanic island positioned along the Southern Aegean Volcanic Arc. Shallow-sea (5 m) hydrothermal venting is extensive throughout our study area, Paleochori Bay. Pore fluids exibit elevated temperatures (115°C), acidic conditions (pH 5), dissolved sulfide (3 mM), and either dilute or elevated chloride (1.5x Mediterranean seawater). The shallow hydrothermal vents offered an ideal opportunity to target microbial processes that presumably transition from sulfide delivered with volcanic gases to sulfide produced by dissimilatory sulfate reduction in background sediments. Seafloor vent features include large (> 1 m^2) white biofilms containing elemental sulfur and orange/yellow patches of arsenic-sulfides. We investigated three patches of colored seafloor, a non-vent area as a control site, and a brine. Pore waters, push-cores, surface films, and water column samples were collected by SCUBA from seafloor patches and background sediments. One goal of the study was to measure $\delta^{34}S$ spatial variability along environmental gradients that included volcanic vents and 'normal' ocean bottom.

We observed strong geochemical spatial patterns across each patch of colored seafloor. Temperature profiles within the upper 20 cm of the sediments ranged 35 to 111°C. Pore water sulfate concentrations (ranging 8 to 25 mM) and $\delta^{34}S$ values (ranging +17.5‰ to +21.4‰), show a clear decrease toward the center of each hydrothermal feature that coincided with maximum measured temperatures. We interpret the inverse relationship between temperature and sulfate $\delta^{34}S$ as a mixing process between oxic seawater and anoxic magmatic inputs. To better constrain this relationship, we collected endmember samples of seawater and vent gas sulfide. The $\delta^{34}S$ values of pore water sulfate extracted from low temperature (< 60°C) sediments along the fringe of the patches were identical to seawater ($\delta^{34}S$ = +21‰). In contrast, hydrogen sulfide in the free gas sampled from all study sites had uniform values, $\delta^{34}S$ = +2.5 ± 0.28‰ (n = 4) that were nearly identical to pore water sulfide, $\delta^{34}S$ = +2.7 ± 0.36‰ (n = 21). The relationship between the isotopic composition of dissolved sulfur species suggests the oxidation of dissolved sulfide by the entrainment of oxic seawater potentially mixed an isotopically light pool of secondary sulfate with the ambient pore water sulfate pool. An isotopic mass balance model demonstrates that the data plot along a conservative mixing array between seawater and a chloride rich, sulfidic fluid. Any biological sulfur cycling potentially operating within these hydrothermal systems is masked by abiotic chemical reactions.

INTERPRETING THE TRACE METAL RECORDS OF ANCIENT EPEIRIC SEAWAYS: LESSONS FROM THE TOARCIAN (JURASSIC) BLACK SHALES OF EUROPE

[4]Department of Earth Sciences, University of Oxford, UK

There is an ongoing discussion concerning the global-versus-local origins of trace metal records expressed in sedimentary successions from ancient epicontinental (epeiric) seaways. Properly deciphering these records is of considerable importance because they factor prominently in our understanding of the redox history of the Earth surface environment. Particularly useful and contentious examples of this debate are the black shales deposited in the north European epicontinental seaway (NEES) during the Toarcian Stage of the Early Jurassic. Despite the fact that these marine shales are extremely rich in organic matter and sedimentary sulfides, some show little to no enrichment beyond crustal abundances of many redox-sensitive elements (e.g., Cu, Mo, Ni, V, Zn, U). As these organic-rich rocks have been linked to an interval of widespread marine anoxia/euxinia — the Toarcian Oceanic Anoxic Event (T-OAE) — the muted enrichments have consequently been purported to reflect diminished global seawater inventories of these elements. Conversely, some workers attribute the lack of trace metal enrichment to restriction of the seaway from the open ocean.

In this study, we present a variety of geochemical data from various locations in the northern Europe to explore the character of the Toarcian trace metal record. High-resolution stratigraphic iron and sulfur redox proxy data from within the seaway (Fe/Al, Fe_{HR}/Fe_{total}, Fe_{py}/Fe_{HR}, $\delta^{34}S_{pyrite}$) reveal variable redox conditions and also suggest hydrographic restriction of the seaway, both of which likely played roles in the trace metal depletions. Furthermore, the trace metals records show higher enrichments at locations more proximal to the open ocean, also pointing to restriction within the NEES. However, all the study localities record a temporal pattern of subdued metal enrichment and rates of metal accumulation, which together suggest a global marine depletion during the OAE. Perhaps not surprisingly, therefore, ancient trace metal records of organic-rich rocks contain both global and local features, which can be deciphered through careful integration of parallel geochemical and sedimentological data.

Variability of ^{13}C-^{14}C in soil CO_2: Impact on ^{14}C groundwater ages

The ^{14}C age correction models for groundwater use generally an input function that depends on the carbon isotopic composition (^{13}C and ^{14}C) of the soil CO_2. However, in most cases the activity ($A^{14}C$) of atmospheric CO_2 is directly used as input function without considering processes occurring in soil and leading to significant isotopic changes between the composition of atmospheric CO_2 and of soil CO_2 [1][2]. We present here the role of these processes as well as the associated isotopic changes and their impact on the calculation of the age of groundwater. Our approach is based on the use of experimental data from two sites (Fontainebleau sands and Astian sands, France) and its interpretation by a distributed model [3].

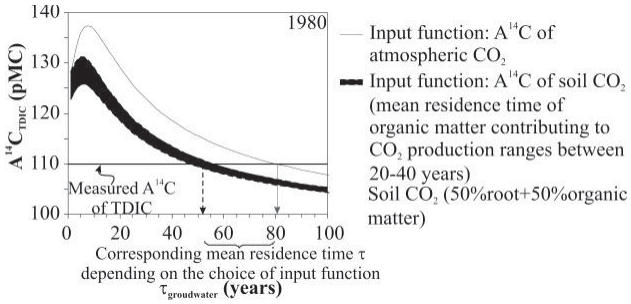

Figure 1: Calculated mean ages of groundwater with respect to different input function; case of a theoretical sampling in 1980.

Since 1950, the evolution of the $A^{14}C$ in soil CO_2 reflects the competition between the fluxes of root derived-CO_2 and organic matter derived-CO_2 due to the residence times of organic matter in the soil. We demonstrate that a mean ^{14}C groundwater age based purely on the ^{14}C atmospheric data may lead to significant biases [2]. For example, a measured $A^{14}C$ of 110 pMC in 1980 corresponds to a mean age of 50±5 or 80±2 y depending on the choice of the input function (Fig. 1). Moreover, the analytical $\delta^{13}C$ of soil CO_2 showed large seasonal variations. Therefore, for dating modern groundwater, a systematic sampling of soil CO_2 has to be integrated into numerical simulations to define ^{13}C-^{14}C content at the water table [4].

What we do and don't know about microbial mercury methylation

CYNTHIA C. GILMOUR[1*], JUDY WALL[2], REMY GUYONEAUD[3] AND DWAYNE ELIAS[4]

[1]Smithsonian Environmental Research Center, gilmourc@si.edu

More than 40 years after the discovery of the Hg methylation process in sediments, we still don't know why some bacteria are capable of methylmercury (MeHg) production and others are not. This paper will present an overview of our understanding of those processes, taken from the recent literature and ongoing research in our groups.

The intimate and complex relationship between mercury and sulfur is a dominant feature of mercury's biogeochemical cycle. However, while sulfate- and iron-reducing bacteria (SRB and FeRB, respectively) are implicated in MeHg production, only a subset of these organisms have the ability to produce MeHg. Other than the observation that most methylators have membership in the *Deltaproteobacteria* , there is no obvious physiological or genetic trait that is common. Recent data suggesting net MeHg production in novel environments, like surface ocean waters, suggest that the diversity of Hg-methylators may be broader than we realize. However, to date, and with modern analytical methods, Hg methylation has only been demonstrated within the *Deltaproteobacteria*.

The earliest work on Hg methylation mechanisms focused on intracellular methylases. Methylcobalamine was identified as the proximate methyl transfer group in one *Desulfovibrio*, but the proposed pathway is also present in many non-methylating SRB and FeRB. The sulfate-reducing apparatus in SRB does not appear to play a direct role in methylation, although the sulfide and other reduced sulfur compounds produced by SRB have dramatic effects on Hg bioavailability to cells

Stable isotope fractionation suggests that some portion of the Hg methylation pathway is enzymatic, but whether that portion is uptake, methylation or even export is unknown. Cell-free protein extracts of methylators exhibit low levels of methylation not seen in extracts of non-methylators. Denaturation of proteins eliminates the activity detected confirming the apparent enzymatic nature of the catalyst. Importantly, Hg-methylators release MeHg from cells very rapidly, and perhaps as a part of a larger organic complex. SRB (and FeRB) also demethylate MeHg, sometimes very rapidly. These organisms do not contain the *mer* operon and the mechanism of demethylation remains a mystery.

More recently, Hg transport has emerged as a potentially distinguishing characteristic of some Hg-methylators. Certain Hg-thiol complexes are highly bioavailable to methylators Nanoparticulate HgS, bound up in organic colloids, is also bioavailable to Hg methylators. However, the uptake mechanism(s) for both remain uncertain. Progress on understanding MeHg production in the environment depends on a fuller understanding of Hg methylation pathways in bacteria. The recent completion of full genome sequences for a number of Hg-methylating SRB may help solve this mystery through phylogenetic comparisons and genetic approaches.

Geochemical characterization of the initial phase of El Hierro eruption

DOMINGO GIMENO[1*], MERITXELL AULINAS[1] AND GUILLEM GISBERT[1]

[1]Dpt. Geoquímica, Petrologia i Prospecció Geològica, Universitat de Barcelona, Spain domingo.gimeno@ub.edu (* presenting author), meritxellaulinas@ub.edu, ggisbertp@hotmail.com

Ongoing submarine eruption at El Hierro]

A submarine eruption close to the La Restinga village (south of El Hierro island, Canary Archipelago, Spain) started october the 13th 2011 and is still (1st february 2012) ongoing. During some weeks the eruption was manifested by a discoloured plume (green) of dissolved gas (and probably suspended fine-sized particles) marking the site of submarine vents on the sea surface, and by the punctual emission of a rare type of decimetre to metre-sized buoyant pyroclasts, ovoid in shape. At the moment of emerging, pyroclasts crack or explode producing small steam plumes as a consequence of cooling by water. The initial phase of eruption provided mingled massive bombs (the so-called "restingolites") while successively the buoyant pyroclasts became hollow balloons, exclusively basic in composition.

Rhyolite-basanite composite mingled pyroclasts

"Restingolite" pyroclasts are formed by two parts intimately mingled: a white microvesiculated pumice, rhyolitic in composition and a deep green-black glassy basanite with porphyritic (phenocrysts < 3 %) and locally macrovesicular textures. The basanite constitutes the skin of the pyroclasts. while the inner part is formed by planar pumitic discontinuous plastic fragments roll-wrapped with black partings of basanite. Locally, the basanite clearly looks vitreous with concoidal fracture (sideromelane). Under the stereomicroscope, the basanite and rhyolitic glass are sinterized at their contact along planar surfaces, without trace of substantial mixing. The whole pyroclast is very friable, pulling apart as fragments with thin basanitic crust and centimetre thick of pumitic rhyolite; this provides pieces with the appearance of coconut fragments.

Trace element geochemistry and isotopic geochemistry gives evidence of an unequivocal magmatic character for both materials. In fact, the $^{143}Nd/^{144}Nd$ isotope ratios of the pumitic rhyolite and the roll-wrapped basanite are very close (0.512926 ± 0.000005 and 0.512975 ± 0.000007, respectively) and similar to the Nd isotopic data reported in literature for El Hierro magmas. $^{87}Sr/^{86}Sr$ of the basanite component is 0.702947 ± 0.000006 whereas alkaline rhyolite show higher ratios (0.706040 ± 0.000005) the latter indicating an interaction with hydrothermal fluids prior to eruption. Moreover, Nb/Zr ratio of the rhyolite component is close to the ones dispayed by oceanic islands rhyolitic peralkaline rocks [1].

This research has been developed at the Serveis Científicotecnics (SCT) belonging to the Universitat de Barcelona (UB) (Spain), while isotope data were kindly provided by CAI (Centro deGeocronología y Geoquímica Isotópica) from the Universidad Complutenese de Madrid (Spain)

New insight into long-term dissolution rates of borosilicate glasses

S. GIN, P. FRUGIER*, F. ANGÉLI, C. JÉGOU, N. GODON, Y. MINET

Commissariat à l'Énergie Atomique (CEA), DEN - Marcoule, 30207 Bagnols-sur-Cèze, France stephane.gin@cea.fr (* presenting author)

Ten borosilicate glass compositions were leached at 90°C for up to 14 years under static conditions in deionised water, and then characterized by SEM, TEM and XRD in order to establish a correlation between the glass composition and the long-term rate. Within a ternary sodium borosilicate glass, some of the key elements present in nuclear glasses (Al, Ca, Zr, Ce) have been progressively incorporated. A qualitative inverse correlation between the forward and residual rates of these glasses has been observed. This unexpected result is related to the effect of gel reorganisation on the diffusive properties of the passivating layer. No simple relations was found between the residual rates and the solution composition. A first-order rate law based on silica fits only the first few weeks, but a large deviation is observed thereafter. In most of the experiments, no real saturation occurs even during the residual rate regime: the silica concentration slowly increases towards saturation with respect to amorphous silica. The role of some glass components is examined. Glasses containing a hardener element (Al or Zr) and Ca have lower residual rates than those containing only one of these two categories of elements. the detrimental effect of precipitation of silicate minerals on the residual rate is also evidenced. Finally, the 6-oxide glass, called CJ4 in this study, as well as the more complicated CJ5 and CJ6 glasses are good analogues of the actual nuclear glass. CJ4 glass has been selected at an international level as a reference glass for a common understanding of glass corrosion mechanisms.,

In conclusion, the residual rate strongly depends on the glass composition. This rate depends on the transport properties of transient amorphous layers formed by glass hydration and in situ reorganization.

Abstract

In the environment, chemical reactions at the mineral/water interface occur over a range of temporal scales, ranging from microseconds to years. Many important mineral surface processes (e.g., adsorption, oxidation-reduction, precipitation) are characterized by a rapid initial reaction on time-scales of milliseconds to minutes, and are often limited by the formation of secondary mineral phases. Knowledge of these initial reaction rates combined with detailed characterization of secondary phases is critical to determining chemical rate constants, and reaction mechanisms.

Here we describe the reactions controlling the oxidation of As(III) by δ-MnO_2 (a poorly crystalline form of hexagonal birnessite) over time-scales rangin from sub-second to hours. Initial As(III) oxidation rates (< 30 s) were measured using batch reactions and quick-scanning X-ray absorption spectroscopy (Q-XAS). Longer-term reaction dynamics were examined using a combination of column and stir-flow reactors combined with molecular-scale characterization of the resultant solid-phases with both Q-XAS and traditional XAS. While the aqueous As(V) and As(III) concentrations were determined using LC-ICPMS analysis.

Q-XAS studies reveal that As(III) oxidation occurs most rapidly during the initial 30 seconds of reaction, followed by slow oxidation over the next several minutes, and that traditional analysis (i.e., ex-situ analysis of $As(III/V)_{aq}$) may underestimate As(III) oxidation rates due to As(V) removal from solution due to sorption on the HMO mineral surface.

In column and stirred-flow experiments, As(III) oxidation by δ-MnO_2 is also initially rapid but slows appreciably after several hours of reaction. Mn(II) is the only reduced product of δ-MnO_2 formed by As(III) oxidation during the initial, most rapid phase of the reaction. However, it appears that observed Mn(III) is a result of conproportionation of Mn(II) sorbed onto Mn(IV) reaction sites rather than from direct reduction of Mn(IV) by As(III). The only evidence of arsenic (As) sorption during As(III) oxidation by δ-MnO_2 is during the first 10 h of reaction, and As sorption is greater when As(V) and Mn(II) occur simultaneously in solution. Our findings indicate that As(III) oxidation by poorly crystalline δ-MnO_2 involves several simultaneous reactions and reinforces the importance of studying reaction mechanisms over multiple time-scales with multiple techniques.

Photodemethylation: a significant actor in the methylmercury budget of Arctic freshwater ecosystems

CATHERINE GIRARD[1*], MARC AMYOT[2]

[1]CEN, Université de Montréal, Département de sciences biologiques, Montréal, Canada, catherine.girard.7@umontreal.ca (* presenting author)

[2]GRIL, Université de Montréal, Département de sciences biologiques, Montréal, Canada, m.amyot@umontreal.ca

Results of field experiments in the Arctic

Photodemethylation of monomethylmercury (MMHg) into inorganic mercury (Hg) has recently been shown to play an important part in the mercury budget of aquatic ecosystems. The objective of our project was to assess photodemethylation potential as well as its chemical drivers in Arctic lakes and thermokarst ponds. In 2008-2011, *in situ* experiments were conducted on Bylot and Cornwallis Islands (Nunavut) to determine which natural compounds drove the process. After week-long incubations of natural water exposed to sunlight, we observed significantly lower levels of MMHg (losses of 34-63%), and the use of light filters showed that short wavelenghts of solar radiation (<410 nm) were most effective at mediating photodemethylation. The process appears to be abiotic, being unnaffected by filtration (0.45 μm). Furthermore, samples amended with sulfur-rich molecules (thiols), chlorides as well as reactive oxygen species producers and scavengers showed that the presence of glutathione, singlet oxygen and chlorides accelerated photodemethylation.

In 2011, another experiment was conducted during which solar radiation was obstructed (98,7% of radiation from 200-750 nm) from a thermokarst pond on Bylot Island to measure the impact of photodemethylation on the pond's total MMHg budget. Monitoring was conducted over a 14-day period, during which time Hg levels remained stable, indicating that the total Hg budget was unaffected. However, MMHg levels fluctuated significantly, with changes in water chemistry occuring concurrently. Hence, the absence of solar radiation induced significant changes in the MMHg budget of the thermokarst pond.

Conclusions

We conclude from both sets of experiments that photodemethylation is a major degradation pathway of MMHg in Arctic thermokarst ponds and lakes, and that it has the potential to significantly affect MMHg budgets in northern aquatic ecosystems. Our results show that the process is most effectively mediated by UV radiation, and that sulfur-rich compounds and singlet oxygen play a significant role in the *in situ* degradation of MMHg via solar radiation.

HOT-WIRED: THE ROLE OF EXTRACELLULAR ELECTRON TRANSFER IN SUSTAINING PRIMARY PRODUCTION BY HYDROTHERMAL VENT MICROBES

PETER R. GIRGUIS[1*] AND MARK NIELSEN[1]

[1]Harvard University, Cambridge, USA, pgirguis@oeb.harvard.edu*

Introduction

Microbes have evolved a variety of metabolic strategies to flourish in the absence of oxygen (e.g. sulfate reduction, methanogenesis). Recent studies of extracellular electron transfer (or EET) have further expanded the repertoire of metabolic capacities that facilitate life in anaerobic environments. EET is a process whereby microbes shuttle charge to or from solid phase electron acceptors or donors. EET was first described in iron-reducing proteobacteria by Lovley and Philips (*1*), which use iron oxides as terminal electron acceptors for respiration. In recent years is has become apparent that EET is quite widespread, and studies have shown that a diversity of microbes are capable of EET, and that EET is coupled to an equally diverse number of metabolic modes.

Microbial EET at hydrothermal vents

At hydrothermal vents, EET may enable microbes in anaerobic milieus to remotely access dissolved oxidants in the overlying seawater through the semi-conductive metal sulfides cross redox gradients. Here we present laboratory and *in situ* experiments that support this hypothesis, revealing that hydrothermal vent microbes employ and depend upon EET to access spatially remote oxidants via semi-conductive pyrite. To simulate the physical and electrochemical conditions in vent sulfides, we constructed a two-chamber flow-through bioelectrochemical reactor in which a pyrite electrode was enclosed in one chamber and subject to simulated hydrothermal conditions. Substantial electroactive biofilms formed on pyrite in electrical continuity with oxygenated water. Phylogenetic and metagenomic analyses revealed a diversity of autotrophic and heterotrophic archaea and bacteria, markedly different in composition from the control (pyrite without electrical continuity). Stable carbon isotopic tracer experiments further reveal differences in carbon fixation among communities in and out of electrical continuity with oxygen. The data presented here reveal that microbial communities use conductive minerals such as pyrite to enable the reduction of spatially remote oxidants. Thus EET, by enabling sustained access to terminal electron acceptors while maintaining the functioning of strictly anaerobic metabolisms, may alleviate the limitation of oxidants commonly associated with anaerobic environs.

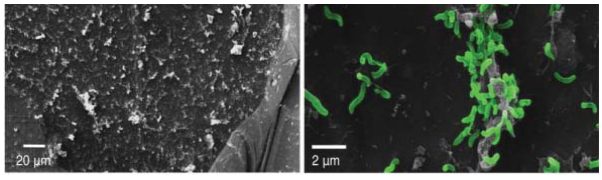

Figure #1: SEM image of electroactive biofilm, and SEM image with false color added to microbial cells to provide contrast.

Subduction-related fluids influence on the Oligo-Miocene transitional magmatism of the Sulcis area (SW Sardinia, Italy)

GUILLEM GISBERT[1]*, DOMINGO GIMENO[1], MERITXELL AULINAS[1]

[1]Universitat de Barcelona, Facultat de Geologia, Barcelona, Spain, ggisbertp@hotmail.com (* presenting author), domingo.gimeno@ub.edu ,meritxellaulinas@ub.edu

The Sardinia-Corsica microplate was involved in Oligo-Miocene times in a SE-ward drift and counterclockwise rotation from the European margin in western Mediterranean to its current position. This movement was caused by the roll-back play of a NW-ward subducting oceanic plate under this margin and produced the detachment of this microplate from the continental margin and the openning of the Liguro-Provençal basin. As a result of the subduction abundant calc-alkaline magmatism of orogenic affinity occurred, mostly in the western sectors of Sardinia. In the final stages of the Miocene subduction and magmatism, coinciding with an increase in extensional tectonics, in the Sulcis area magmatism shifted from typical orogenic andesites to more evolved products of transitional character, ranging from trachydacites to rhyolites, with the relevant presence of peralkaline magmas (comendites), which were emplaced mostly as widespread ignimbrites reaching up to 20 km^3 in volume and forming a pile over 200 m thick.

The present work is focused on the study of the evolved rocks of the Sulcis area. Literature was reviewed for data, and new sampling was done. Major and trace elements whole rock XRF and ICP (-OES and MS) analyses were done on over 200 new samples covering the whole sequence, as well as Sr, Nd and Pb isotopes on a selection of 26 samples. Mineral chemistry (EMP) was done on a selection of representative samples.

Trace elements and isotope ratios reveal that magmas were originated in a mantle wedge metasomatised by fluids released by the subducting slab which were both hydrous fluids from the oceanic crust and overlying sediments, and sediment partial melts. It is also evidenced that the mantle beneath Sardinia had an original EMI signature which was subsequently modifyed by the Central Atlantic Plume event in Cretaceous times (to get a more EAR-like signature) and finally by the subduction fluids. Isotopes show that fluid influence progressively decreased with time and that assimilation processes during magma evolution were scarce. The transitional character of this magmatism was caused by the increased extensional setting, which controlled magma alkalinity and favoured melting of mantle wedge sectors with less slab-released fluids. Magma evolution in the upper crust was dominated by fractional crystallisation of magmas with slightly different initial alkalinity, producing subparallel evolutionary trends. The peralkaline magmas were originated by the evolution of the more alkaline magmas, with participation of the plagioclase effect and the resorption of cumulate amphibole, which further favoured it.

Reactivity of detrital silicates and carbon storage in the ocean margins

S.R. GISLASON[1*], E.H. OELKERS[1,2], M.T. JONES[1], D. WOLFF-BOENISCH[1], H.A. ALFREDSSON[1] AND K.G. MESFIN[1]

[2]Géosciences Environnement Toulouse , GET/CNRS, Université de Toulouse, Toulouse, France (oelkers@get.obs-mip.fr)

A recent survey of chemical denudation of continental silicates at the global scale suggests that riverine particulate material-seawater interaction may be essential to the feedback between weathering and atmospheric CO_2 content/climate over geological timescales [1]. Moreover substantial evidence indicates that this pariculate material is reactive once it arrives in the coastal oceans, in part due to its high surface area [2,3]. This study explores the possibility of using the detrital silicate material, located at the continental and volcanic island margins for carbon storage via *in-situ* mineral carbonation.

Continental margin silicate sediments offer a number of advantages to potential carbon storage efforts. In addition to the large surface area of reactive solids, they have subtantial porosity available for carbonate mineral precipitation. The carbonation of silicate sediments can be enhanced by injecting CO_2 fully dissolved in water, which in turn limits the risk associated with buoyancy. The CO_2 dissolution requires large water volumes that may not be available on land. Moreover, public acceptance of ocean sediments storage may be easier than for land storage.

Of particular interest is the carbonation of basaltic and ultramafic sediments [4,5], which comprise a significant proportion of the particulate material transported to the oceans. Natural analogues, laboratory experiments, and reactive transport models suggests that such material is readily transformed into carbonates at low temperature and high CO_2 partial pressure [e.g. 6]. Laboratory experiments suggest that seawater/basaltic sediment interaction is particularly well suited for long-term CO_2 storage [7].

Controls of polysaccharide chemistry on kinetics and thermodynamics of calcium carbonate nucleation

ANTHONY J. GIUFFRE[1*], LAURA M. HAMM[1], AND PATRICIA M. DOVE[1]

[1]Department of Geosciences, Virginia Tech, Blacksburg, USA, giuffre@vt.edu (* presenting author)

Living organisms produce skeletal structures within a complex matrix of organic macromolecules. These compounds are proposed to actively guide the nucleation and growth of crystalline structures into the organic-inorganic composites we know as biominerals. Good examples are seen in calcareous algae and stromatolite-forming cyanobacteria. An extensive effort has investigated the influence of proteins on calcium carbonate ($CaCO_3$) mineralization. The polysaccharides, however, have received little attention despite their near-ubiquitous occurrence in mineralized tissues and intimate associations with proteinaceous compounds of the organic matrix.

The polysaccharides found at sites of microbial mineralization have complex monosaccharide sequences with various carbohydrate stereochemistries and functionalities (carboxylated, acetylaminated, sulfonated, methylated). This study tests the hypothesis that polysaccharides influence the rate of calcite nucleation by systematic and predictible differences in their chemistry. Using high purity polysaccharides with regular monomer sequences as simple model compounds for more complex macromolecules, we quantify the effect of functional group chemistry (chitosan, hyaluronic acid, heparin, alginic acid) and monomer sequencing (two stereoisomers of alginic acid) on the kinetic and thermodynamic barriers to $CaCO_3$ formation. Substrates were prepared by electrodeposition of these polysaccharides as thin gel-like films onto gold-coated silicon wafers. Using a flow-through cell, heterogeneous nucleation rates of calcite were measured for a suite of supersaturation conditions.

The kinetic measurements show rates of calcite nucleation are dependent on polysaccharide functional group chemistry and monomer sequence. Analysis of the data indicate the kinetic and thermodynamic barriers to nucleation are correlated with surface charge as the number of carboxyl groups per monomer of polysaccharide. Nucleation rates are also correlated with independent measurements of surface free energy of the polysaccharide substrates. These findings indicate polysaccharides may have active roles in promoting the formation of calcite and suggest their presumed function as inert framework molecules should be revisited.

The use of coupled image analysis and laser-ablation ICP-MS in fission track thermochronology

ANDREW GLEADOW*, BARRY KOHN, RAUL LUGO-ZAZUETA AND ABAZ ALIMANOVIC

School of Earth Sciences, University of Melbourne, Victoria 3010, Australia, gleadow@unimelb.edu.au (* presenting author)

Strategies for the interpretation of fission track data from natural minerals, especially apatite, and the quantitative techniques for forward modeling of thermal histories based on data, have advanced enormously over the past two decades. However the actual techniques used to acquire these data have changed little in this time. Moreover the limitations of that data in terms of both quality and quantity are now providing significant constraint on the further development of fission track thermochronology. Two very important technological developments are currently taking place in fission track analysis that are likely to transform the practice of this technique, and are likely to lead to significant improvements in data quality, inter-user consistency and the efficiency of data acquisition.

The first of these is the emergence of autonomous microscopy and automatic image analysis for the recognition and counting of fission tracks in minerals such as apatite [1], along with new tools for the enhanced measurement of fission track lengths. The second is the adoption of Laser-Ablation ICP-Mass Spectrometry for direct determination of ^{238}U abundances in the same mineral grains, in place of the conventional method using neutron induced fission tracks to measure ^{235}U as a proxy.

Switching from the conventional external detector method to using image analysis and LA-ICP-MS means that a new set of analytical and calibration issues must be addressed. These include practical matters such as transfer of grain coordinates from the microscope to the ablation stage, avoiding ejection of etched grains from the mount during laser ablation, and choice of the most appropriate ablation pattern to adequately sample the ^{238}U distribution. In addition a number of analytical strategies such as optimising instrument settings and developing suitable matrix-matched standards must also be resolved. Working solutions to all of these issues have now been developed.

Limitations of the conventional method for fission track analysis include: laborious and demanding procedures, limited counting statistics, and extremely long sample turnaround times due to the required neutron irradiation (typically several months), as well as safety issues due to the handling of irradiated materials. In contrast, the new approach using automated image analysis and LA-ICP-MS can produce better counting statistics, reduced demands on the analyst and dramatically improved sample turn-around times. In addition only one track density need be measured instead of three with the conventional method. Further, the combination of LA-ICP-MS and fission track data opens the potential for routine double-dating using both U-Th-Pb and FT systems, or even triple dating with (U-Th)/He analysis on the same grains . These advances mean that more data can be collected, with greater consistency and much more rapidly, providing higher quality input for thermal history modelling.

There is considerable interest in stimulating microbial methanogenesis from coal *in situ*, but limited information available on the interactions of the metabolic groups of organisms involved in this process. In most freshwater systems with sufficient sulfate, sulfate reducing bacteria (SRB) will outcompete methanogens for available acetate and H_2 due to their higher substrate affinity and growth yields . However, SRB can function both as fermenters and syntrophically with methanogens in the absence of sulfate , so their role in coal degradation may depend entirely upon reservoir conditions. In this study we examined the role of SRB in methanogenic coal degradation experiments through the use of variable sulfate concentrations (50 μM – 1mM) and metabolic inhibitors (5 mM molybdate for SRB). We hypothesized that with increasing sulfate concentrations SRB would outcompete methanogens for both the acetate and hydrogen resulting from coal fermentation, and that the absence of sulfate, or presence of molybdate, would enhance methanogenesis relative to the uninhibited, sulfate-amended experiments. Results from these experiments suggest that SRB did not outcompete methanogens for available acetate or hydrogen. Roughly 4-6 μmol sulfate was consumed in each experiment amended with sulfate, regardless of its starting concentration. Experiments performed with molybdate and in the absence of sulfate did not produce more methane than experiments amended with up to 1mM sulfate, suggesting that SRB did not compete with methanogens for the same substrate. Changes to the microbial consortium were montitored using qPCR for the mcrA and dsrA genes for methanogens and SRB, respectively, as well as by phospholipid fatty acid (PLFA) and phospholipid ether lipid (PLEL) analysis. Stable carbon isotope analysis of the microbial phospholipids will help to elucidate carbon flow pathways in these experiments as well. Results from this work help elucidate the microbial carbon transformation pathways that might stimulate in situ methanogenesis from coal.

Benthic Iron flux in the Arctic Ocean

CHARLES GOBEIL [1*] AND ROBIE W. MACDONALD

[1]IRS-ETE, Université du Québec, Québec, Canada, charles.gobeil@ete.inrs.ca (* presenting author)
[2]Department of Fisheries and Oceans at IOS, Sidney, Canada, robie.macdonald@dfo-mpo.gc.ca

Between 1990 and 2007, sediments box cores were recovered within the Arctic Ocean at locations spanning shallow to deep water (40-4200 m), and analyzed for total Fe and S, operationally-defined fractions of Fe and S, other inorganic components and organic C. Cores from the basins (defined as depth > 1000 m) are characterized by the lowest concentrations of organic C, undetectable levels of pyrite, and high concentrations and inventories of Fe oxihydroxides (Fe soluble in a dithionite solution at pH 4.8). In contrast, cores from the arctic continental shelves and slopes exhibit relatively higher levels of organic C, detectable concentration of pyrite, and significantly lower levels and inventories of Fe oxyhydroxides. Using these data to determine the sediment sink and relying on literature values for physical transport of material in and out of the polar ocean, we have constructed a budget for highly reactive Fe (FeHR), defined as Fe oxihydroxides plus pyrite-Fe, for the whole Arctic Ocean. This budget reveals that most FeHR comes from rivers and coastal erosion and that almost all of it is trapped within the Arctic Ocean. The amounts of FeHR accumulating in shelf, slope and basin sediments represents 36%, 22% and 33% of its total input, respectively, with pyrite-Fe representing less than 20% of total burial of FeHR in shelf and slope sediments. This budget, combined with the fact that the proportion of FeHR relative to total Fe (FeT) is significantly higher in basin sediments (FeHR/FeT = 0.30±0.03) than in shelf sediments (FeHR/FeT = 0.19±0.07), implies that authigenic pyrite is not a substantial sink for Fe in the Arctic Ocean and that a significant fraction of the Fe recycled as a consequence of Fe oxyhydroxides reduction during the anaerobic metabolism of organic matter in shelf sediments is eventually exported towards the Arctic Ocean interior. Considering that the large-scale distribution of FeHR in the arctic marine sediments is strongly dependent of organic matter metabolism in shelves and that the Arctic Ocean presently contains as much as 50% shelf area, but loses most of that when global sea level falls by ~120 m during glacial maxima, we argue that sea-level fluctuation is a major factor influencing the biogeochemical cycle of Fe in the Arctic Ocean.

Climate change: the future of continental weathering

YVES GODDÉRIS[1*], EMILIE BEAULIEU[1], YANNICK DONNADIEU[2], DAVID LABAT[1], CAROLINE ROELANDT[3]

[1]Géosciences Environnement Toulouse GET, CNRS, Observatoire Midi-Pyrénées, Toulouse, France, yves.godderis@get.obs-mip.fr
[2]LSCE, CNRS, Gif sur Yvette, France, yannick.donnadieu@lsce.ipsl.fr
[3]Geophysical Institute, University of Bergen, Bergen, Norway, caroline.roelandt@gfi.uib.no

Continental weathering has been considered for long as a key process in the global carbon cycle at the geological timescale. Conversely, the evolution of the CO_2 sink by weathering is neglected in all studies dealing with the future of our climate, because weathering is considered as a slow process, almost inert at the secular time scale. However, recent data surveys have demonstrated the potential high sensitivity of weathering to the ongoing climate and land use changes[1,2].

According to future anthropogenic emission scenarios, the atmospheric CO_2 concentration may double before the end of 21st century, resulting in a global warming more than 6°C in the worse case. The global temperature increase will promote changes in the hydrologic cycle through redistributions of rainfall patterns and continental vegetation cover[1,2]. All these changes will impact the chemical weathering of the continental rocks. To evaluate these impacts, we use a process-based model of the chemical weathering of the continental surfaces (B-WITCH[3], spatial resolution 1°x1°) forced by models describing the atmospheric general circulation and the dynamic of the vegetation under increased atmospheric CO_2. We focus on the arctic environment where land use changes can be neglected while the climate change is expected to be important (the Mackenzie watershed)[4]. We calculate that the CO_2 consumption flux related to weathering processes (including carbonate and silicate dissolution) may increase by more than 50% for an atmospheric CO_2 doubling for one of the most important arctic watershed: the Mackenzie River basin. 40% of this increase is directly related to the warming (1.4 to 3°C warming over the watershed) and to the rainfall increase (averaged increase of 7%). But the remaining 60% are due to the direct CO_2 impact on the vegetation. Indeed, under higher CO_2 pressure, plants close their stomata, limiting the evapotranspiration and the fertilization effect promotes below ground CO_2 respiration[4]. Our study stresses the potential role that weathering may play in the evolution of the global carbon cycle over the next centuries.

The effect of surface chemistry on dissolution rates of CaF_2 suggests a new dissolution mechanism

JOSÉ R. A. GODINHO[1*], SANDRA PIAZOLO[1,2] AND LENA Z. EVINS[3]

[1] Department of Geological Sciences, Stockholm University, Stockholm, Sweden; jose.godinho@geo.su.se (* presenting author)
[2] GEMOC ARC National Key Centre, Department of Earth and Planetary Sciences, Macquarie University, Sidney, Australia; sandra.piazolo@mq.edu.au.
[3] Swedish Nuclear Fuel and Waste Management Co, Stockholm, Sweden. lena.z.evins@skb.se

We investigated how during dissolution differences in surface chemistry affect the evolution of topography of CaF_2 pellets with a microstructure similar to UO_2 spent nuclear fuel [1]. 3D confocal profilometry and atomic force microscopy were used to quantify retreat rates and analyze topography changes on surfaces with different orientations as dissolution proceeds up to 468 hours. A $NaClO_4$ (0.05 M) solution with pH 3.6 which was far from equilibrium relative to CaF_2 was used.

Measured dissolution rates depend directly on the orientation of the dissolving surfaces. The {111} is the most stable plane with a dissolution rate of (1.2 ± 0.8) x10^{-9} mol.m^{-2}.s^{-1}, and {112} the least stable plane with a dissolution rate 33 times faster that {111}. Dissolution rates were found to be correlated to surface orientation which is characterized by a specific surface chemistry and therefore related to surface energy. It was proposed that every surface is characterized by the relative proportions of the three reference planes {111}, {100} and {110}, and by the high energy sites at their interceptions.

Based on the different dissolution rates observed and ab initio simulations we propose a dissolution model to explain changes of topography during dissolution [2]. Surfaces with slower dissolution rate, and inferred lower surface energy, tend to form leading to an increase of roughness and surface area. This adjustment of the surface during dissolution suggests that dissolution rates during early stages of dissolution are different from the later stages. The time-dependency of this dynamic system needs to be taken into consideration in geosciences and the nuclear waste disposal management when predicting long-term dissolution rates.

Application of Light Isotopes as a Tool for Watermasses tracing – Results of South Atlantic JC-057 Cruise

JOSÉ MARCUS GODOY[1,2*], MARIA LUIZA GODOY2, EDNO CAMPOS[3]

[1]Pontificia Universidade Catolica do Rio de Janeiro, Rio de Janeiro, Brazil, jmgodoy@puc-rio.br (* presenting author)
[2]Instituto de Radioproteção e Dosimetria, Rio de Janeiro, Brazil, malu@ird.gov.br
[3]Universidade de São Paulo, São Paulo, Brazil, edno@usp.br

Introduction

As part of the JC-057 cruise, filtered seawater samples were collected from 18 stations at 24 different depth. The samples were directly measured using a L-1102i PICARRO water analyzer (cavity ring down spectrometer, CRDS).Each sample result represents the mean value of four different injections, and for a batch of each six samples a standard and a test sample were measured. Typical combined uncertainty is 0.7‰ for δ(D) and 0.2‰ for δ(^{18}O).

The obtained results shown that light isotopes values are valuable tools to identify watermasses. An example of the obtained output is shown in Fig 1, where is possible, for example,to identify different water masses as, for example, South Atlantic Central Water (SCAW) at the surface and the North Atlantic Depth Water (NADW), at intermediary depth, starting at a latitude of about 40°C. Interisting also to note is the inflow of a botton water mass at 45° S. Good correlation to salinity[1] (Fig. 2) and nutrients, as fosfate, was observed, in particular, of δ(D) values.

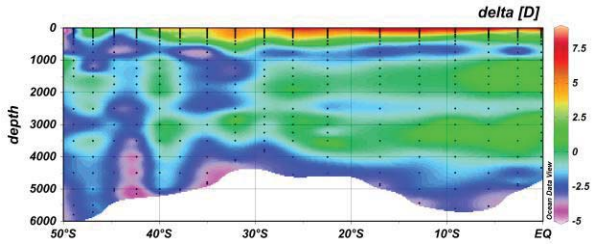

Figure 1: Isoplot of δ(D) values

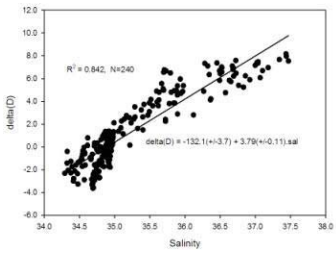

Figure 2: δ(D) and salinity relationship

Conclusions

On a very simple way, applying CRDS, it was possible to trace the different water masses acting at the South Atlantic at long the South American coast.

Characterization of S-containing concretions from the North Sea

JOERG GOETTLICHER[1]*, RALPH STEININGER[1]

[1]Karlsruhe Institute of Technology, Institute for Synchrotron Radiation, ANKA, Eggenstein-Leopoldshafen, Germany, joerg.goettlicher@iss.fzk.de (* presenting author)

Sulfur containing concretions can be found from time to time on the German North Sea shore, e.g., on the beach of the island Juist. They show grey to black and yellow to red-brown colors (Fig. 1). Macroscopically they consist of cemented sand intergrown with shell fragments. Because of the red brown colors Fe might be present.

So far, a few of them have been investigated by X-ray powder diffraction and additionally with X-ray absorption spectroscopy (SUL-X beamline, ANKA) at the S K-edge to determine the chemical form of sulfur. The latter technique has been applied because the grey black colored parts may indicate iron sulfides. XANES spectra have been processed with the Athena program [1]. From the X-ray diffractograms quartz (SiO_2), calcite ($CaCO_3$) and calcium sulfate hydrate have been identified. Two sharp reflections (at d values of 3.24 and 3.19 Å) could not yet been assigned. And there are no reflections left that indicate an iron oxyhydroxide or iron sulfide phase because their amounts might be too small or they are not or not well crystalline. Peaks from the S K XANES spectra of the brown parts have been assigned to sulfate (≈ 2481.4 eV, close to the calibration energy of sulfate in scotch tape) and to elemental sulfur (2471.6 eV) by comparison with a spectrum of elemental sulfur (Fig. 2). Brown-black parts show additionally a peak at about 2477.6 eV which is close to S^{4+}. In the grey-black areas mono-sulfide (S^{2-}) has been identified by comparison with a spectrum of pyrrhotite ($Fe_{1-x}S$).

Because of the intergrowth with shells the location of the iron, sulfide, elemental S and sulfate containing concretions may take place on the sea floor. One possibility could be that around a nucleus in the tideland concretions of sand and shells are forming, where Fe and reduced sulfur are delivered from the sediment to form iron mono-sulfides around the quartz grains and shells that partially oxidize to elemental sulfur and sulfate. Fe K XANES spectroscopy is planned to get more information of the Fe mineral phase.

Figure 1: Fe- and S-containing concretion (scale in cm).

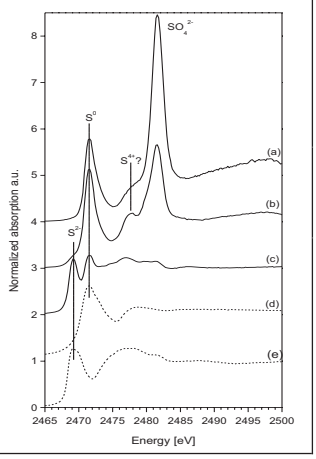

Figure 2: S K XANES spectra of a brown (a), brown-black (b) and grey-black part (c) of the sample compared to reference spectra of elemental S (d) and pyrrhotite (e).

MULTI-ISOTOPE TRACING OF ATMOSPHERIC EMISSONS FROM AN ALUMINUM SMELTER

JULIEN GOGOT[1*], ANDRÉ POIRIER[1], AND AMIEL BOULLEMANT[2]

[1]GEOTOP-UQAM, Science de la terre et de l'atmosphère, poirier.andre@uqam.ca julien.gogot@gmail.com (* presenting author)

[2]Rio Tinto, Australia, QRDC, amiel.boullemant@riotinto.com

Evaluating the net contribution to atmospheric fine particulates of an aluminium smelter is a challenge. For the first time here, we combine osmium (Os) and lead (Pb) isotopes as tracers of the atmospheric emissions from an aluminum smelter in Saguenay (Canada). This smelter reduces alumina (extracted from bauxite) into metallic aluminum using carbonaceous anodes. These anodes are consumed during the electrolytic process and produce atmospheric emissions (mainly CO_2) during reaction with Al_2O_3. Anodes are made of petroleum coke, which is characterized by isotopic compositions of lead and osmium that are significantly differents from other typical anthropogenic sources [1]. These metal's isotopic compositions are transfered into particulate matter emitted along with gases from the smelter process, and can then be traced in the environment. In the immediate surroundings of the aluminum smelter (i.e. on the industrial property) we observed a high Os content in surface deposits, which gradually decrease away from the factory, down to average eroding continental crust at the sampling point closest to the boundary of the industrial property (Fig. 1). For this study, we will compare these findings with Pb isotope results obtained on the same set of samples; Pb stable isotopes systematics being a powerful tool in environmental studies.

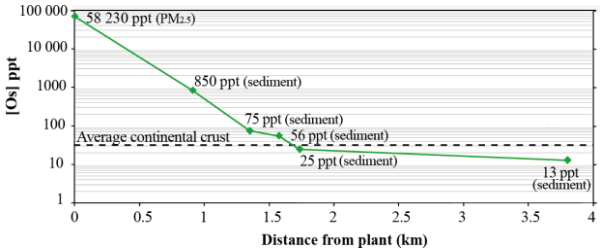

Figure 1. Decrease of osmium content in the near environment of the aluminum smelter.

RECONSTRUCTION OF TRACE METAL CONTAMINATION IN COASTAL SEDIMENTS FROM CAPE CORSICA (FRANCE) DURING ANCIENT TIME

JEAN-PHILIPPE GOIRAN[1] NATHALIE FAGEL[2], CLAIRE HALLEUX[2], LUCIE LEFEBVRE[2], PASCAL ARNAUD[3] AND GILLES DE LA BRIERE[4]

[1]UMR 5133 Archéorient, MOM, CNRS, Lyon, France, jean-philippe.goiran@mom.fr (* presenting author)
[2]AGEs, Argiles, Géochimie et Environnement sédimentaires, Université de Liège, Liège, Belgium, nathalie.fagel@ulg.ac.be; Claire.Halleux@student.ulg.ac.be, Lucie.Lefebvre@student.ulg.ac.be
[3]UMR 5189 HISOMA, MOM, Université Lyon 2, Lyon, France Pascal.arnaud@mom.fr
[4]Commission Régionale d'Archéologie Sous-Marine, France gilles.delabriere@wanadoo.fr

The Mediterranean margins were characterised by intense maritime commercial exchanges since Antiquity. We conduct a sedimentological (mineralogy, fossil assemblages, C/N ratio, organic content) and geochemical (trace element concentration, Pb isotope composition) study of lagoon sediments from Cala Francese, a Roman archeological site from Cape Corsica that may have been an ancient harbour. Aims are to reconstruct history of environmental contamination in trace metals over the historical period and, to propose a paleoenvironmental reconstruction. The sedimentary column of core CF10-III is divided in 3 units: an upper clayey unit (0-80cm); a median sandy clayey unit with abundant marine plant (posidonia) remains (80-160 cm) and a lower sandy and gravelly unit (160-220 cm). Radiocarbon ages performed on macroremains in an adjacant core CF10-II suggest that the sedimentary column covers the last 6000 years, with a late Roman age (210-350 AD) obtained at 140-160 cm. In core CF10-III, Pb concentration remains low in the lower unit (10 ppm), it ranges between 30-40 ppm in the intermediate unit and then increase from 60 cm (>115 ppm). A major shift in Pb isotopic composition is observed at 60 cm, with a decrease of $^{206}Pb/^{207}Pb$ ratios from 1.193 to 1.187. Both $^{206}Pb/^{207}Pb$ and $^{208}Pb/^{206}Pb$ ratios are consistent with Pb Roman signatures [1]. A marked Zn-enrichment (from 4 to 80 ppm) is observed at 40-60 cm. Such drastic changes in trace metal content and Pb isotopic signature of sediments is consistent with Human perturbations of the environment during the Roman period. Further investigations are in progress in order to define the sediment deposition conditions and in particular to date the marine-continental transition.

[3]IRD, Laboratoire Hydrosciences Montpellier, CNRS-IRD-UM1 34095 Montpellier Cedex 05, France

20d. Metals and human health

Located on the Bolivian Altiplano at 3750 m.a.s.l., Oruro is a mining city with a population of 200 000. The volcanic dome on which lies the city is exploited since centuries for its polymetallic ores (Sn, Ag, Zn, Cu, Pb, Sb, Au) and smelting activities (Sn, Sb) are developed in the direct vicinity of the town, and process half of Bolivia's Sn ore.

An interdisciplinary project (ToxBol) aiming at studying the origins and impacts of trace metal contamination on the environment, human health and society was initiated in 2006 in Oruro. Previous studies have shown differences in polymetallic contents between exposed and non exposed area in children's hair[1] and atmosphere[2]. Correlations were found between air particles and children's exposure except for Pb that show relative low contamination in atmosphere in comparison with children's hair content.

Dusts from football fields were collected in mining and smelting districts. Particles were separated into 5 granulometric fractions: 2000-200 (coarse sand), 200-50 (fine sand), 50-20 (coarse loam), 20-2 (fine loam) and <2 µm (clay). Bulk samples and fractions were analyzed to characterize geochemical and mineralogical dust properties. Bioaccessibility of trace metals was measured on each subsample following the UBM stomach phase procedure[3].

Results and Conclusion

Bulk samples were highly contaminated, especially in the smelting environment with up to 16000 µg/g Pb. Clay fraction was globally the most concentrated in trace metals. Bioaccessibility in bulk sample was different according to the environment: Cd>Pb>Zn>As>Sb=Sn (i.e., 84% to 1%) in smelting district and Cd>Zn>Pb=As>Sn=Sb (i.e., 86% to 1%) in mining district. Highest difference was observed for Pb (62% of bioaccessibility in mining and 13% in smelting bulk dust). Trace metals in smelting environment were globally more bioaccessible in fine sand than in clay. In mining district, fine loam and clay show the highest trace metals bioaccessibility.

Observed differences can be partly explained by mineralogical speciation of trace metals. Exposure doses of particles ingestion for children playing on the field were calculated, and show possible metal absorption higher than those recommanded by WHO.

Mo isotopes are employed as a palaeoredox indicator, particularly in terms of quantifying the spatial extent of different redox conditions [e.g. 1]. However, the controlling factors on Mo cycling and isotopic fractionations under distinct redox conditions remain poorly understood. Mn and Fe (oxyhydr)oxides, Fe-sulphides, and organic mater have all been proposed to exert an influence on Mo isotope fractionations during diagenesis [2, 3]. To evaluate past ocean redox conditions it is necessary to understand the controls on redox sensitive element and isotope cycling in modern sedimentary environments, as well as the degree of Mo fractionation during Mo uptake by different substrates.

Sediment cores from Danish and Swedish waters were investigated for this purpose. The redox chemistry ranges from Mn- to Fe-rich to sulphidic sediments and pore-waters. An examination of dissolved and particulate Mo isotope measurements with porewater and solid phase Mn, Fe and sulphide characterization, reveals that adsorption and desorption processes heavily influence the porewater δ^{98}Mo values. The highest δ^{98}Mo values, converging towards the global modern seawater (~2.3‰), are recorded in highly sulphidic sediments. Our results suggest that for modern anoxic marine sediments, where deposition occurs beneath an oxic to suboxic water column, sedimentary δ^{98}Mo is dominantly controlled by the relative availability of Mn and Fe (oxyhydr)oxides, and the production of dissolved sulphide [4].

A mechanistic investigation of the isotopic fractionation of Mo during different mineral uptake pathways was also employed. The focus here is on fractionations during redox transformations involving iron-based phases, including those upon Mo interaction with Fe oxides and their sulphide-promoted reductive dissolution. This is a key process affecting Mo cycling in the environment. Preliminary results exhibit species dependant fractionations. The findings add to our understanding of Mo isotope fractionations during syn- to early-diagenesis and their relation to the interpretation of Mo isotope data for ancient sediments.

On the evolution of Earth's "Geo-bio" atmosphere

COLIN GOLDBLATT[1*]

[1] School of Earth and Ocean Sciences, University of Victoria, PO Box 1700 STN CSC, Victoria, BC Canada V8W 2Y2 czg@uvic.ca (* presenting author)

On of the first predictions of Gaia hypothesis was that the biota exerted dominant control of evolution of the composition of Earth's atmosphere - including for the major atmospheric constituents, oxygen and nitrogen [1]. Here we review this in light of four decades of study. We argue that, other than water vapour (which is controlled by temperature) and the noble gases, all constituents of the atmosphere are controlled by a mix of geological and biological processes. In particular, recent work on nitrogen has shown that there is more nitrogen buried in the mantle than there is in the atmosphere. This is not primordial, but grew from the subduction of biologically fixed NH_4^+ [2]. It is evidence of both the biological contamination of the mantle, and billion-year timescale, non-steady state interaction of life and the atmosphere. By contrast, cycles of other gases range from years (methane) to millions of years (CO_2 via carbonate silicate weathering), and others display strongly non-linear behaviour (oxygen [3]). Can one weave these timescales together to a coherent narrative of coupled geosphere-atmosphere-climate interaction through the history of life on Earth?

Scaling of Ecological and Critical Zone Processes in the Prairie Pothole Region, USA and Canada

MARTIN GOLDHABER[1*], CHRISTOPHER MILLS[2], CRAIG STRICKER[3], DAVE MUSHET[4], JEAN MORRISON[5]

[1]USGS, Denver CO, USA, mgold@usgs.gov (*presenting author)
[2]USGS, Denver CO, USA cmills@usgs.gov
[3]USGS, Denver CO USA, cstricker@usgs.gov
[4]USGS, Jamestown ND, USA, dmushet@usgs.gov
[5]USGS, Denver CO, USA, jmorrison@usgs.gov

The Prairie Pothole Region (PPR), occupying 715,000 km^2 of the north central U.S. and S. central Canada, is a vital ecosystem in North America. It contains >10 million wetlands that are habitat for shore and migratory birds. The wetlands are underlain by glacial till and are internally drained within discrete, km-scale basins. We studied the geochemistry of sediments, wetland water, and groundwater in the 92 hectare Cottonwood Lakes area (CWLA) of North Dakota, USA. The CWLA has upland groundwater recharge wetlands with TDS ~150 mg/kg (Ca-HCO_3 dominant), and a discharge wetland at a local topographic low only 200m distant with TDS>3000 mg/kg (Mg-SO_4 dominant). Groundwater and wetland chemistry is controlled by critical zone oxidation of marine shale-derived pyrite in the upper glacial till (mean $\delta^{34}S$ of unoxidzed till=-19.9‰). A sample of the underlying marine shale has $\delta^{34}S$ value of -16.5‰. Oxidation produces an upper iron oxide rich brown zone in the till (mean depth 6.1m) supplying mobile and isotopically light SO_4 ($\delta^{34}S$ from -18.2 to -7.5‰) to the local discharge area. Dissolution of dolomite in the till is the source of Mg. Thus, critical zone oxidation processes dominate wetland water composition, which in turn is a primary control on ecology.

The same combination of upland recharge areas and local discharge areas occurs at a range of scales throughout the PPR. Information from nearly 500 well logs from a 10^3 km^2 area surrounding the study site document oxidation of surface till to an average depth 7.8m. Comparison of CWLA geochemistry with that of literature data from 178 wetlands in this same surrounding area both document the progressive formation of SO_4 with increasing salinity. Thus, geochemical processes identified in the CWLA are likely occurring across a much larger area. Furthermore, based on our analysis of literature data, the same wetland geochemical trends occur in >300 wetlands in southern Canada.

The broad regional impact of critical zone pyrite oxidation on ecology is reflected in two published studies on the S isotope composition of juvenile mallard feathers througout North America. These feathers are isotopically light ($\delta^{34}S$ from -5 to -16‰) in the PPR in contrast to other mallard migration corridors ($\delta^{34}S$ from -2 to +13‰), reflecting the pyrite source for sulfur in PPR breeding ground waters. We conclude that critical zone oxidation of glacial till is a key control on geochemistry and biology in the PPR ecosystem.

Multi-proxy investigation of paleoredox indicators in a permanently euxinic, low sulfate lake

M. GOMES[1*] AND M.T. HURTGEN[1]

[1]Department of Earth and Planetary Sciences, Northwestern University, Evanston, IL, USA (* correspondence: maya@earth.northwestern.edu)

Many paleoclimate investigations require knowledge of the redox state of the ocean-atmosphere system at the time of sediment deposition. This is an essential question because it has implications for what chemical reactions are favored or suppressed in a given system and, importantly, what kinds of organisms could have lived during the time period studied. Yet, it can be very challenging to conclude with certainty whether or not a system was oxic, and could therefore support animal life. Geochemical signatures of sulfur (S) and iron (Fe) preserved in marine sediments have been utilized as paleoredox indicators because they are redox sensitive elements that are transformed as organic matter is degraded in sediment. Many of these proxies have been developed and calibrated using empirical and experimental studies of the modern, high sulfate (~28mM) ocean. However, sulfate concentration in the ocean has varied widely through Earth history from a low of <200μM to the high modern value of 28mM [1].

In this study we examine Fe speciation, S isotopes, and elemental ratios in a modern low sulfate (~275-330μM) system with permanently euxinic (i.e. anoxic and sulfidic) bottom waters. We investigate both a shallow site with oxic overlying water and a deep site with euxinic overlying water. Given the current paradigm of these paleoredox proxies, the S-Fe geochemistry preserved at these disparate sites would lead to interpretations of redox state that are different than what is observed in the modern system. We hypothesize that this is due to the small size of the sulfate reservoir and differences in sedimentation patterns between the two sites. Because sulfate levels are low and organic carbon availability is high, a relatively large fraction of the sulfate reservoir is quickly consumed during early diagenesis resulting in sediment S-Fe geochemistry that would lead to incorrect interpretations of the redox state of the environment. This investigation and future studies in low-sulfate systems are imperative towards improving our understanding of how the redox state of the ocean-atmosphere system varied during long periods of Earth history when marine sulfate levels were much lower than they are in the modern ocean.

Anaerobic reduction of adsorbed X-Ferrihydrite (X = 0, AsO_4 and MoO_4) at pH 8 and 10

MARIO A. GOMEZ[1*], AND JIM HENDRY[3]

[1]University of Saskatchewan, Department of Geological Science, Saskatoon, Canada, mag346@mail.usask.ca (* presenting author) and jim.hendry@usask.ca

Introduction

Uranium ore tailings produced in northern Saskatchewan, Canada often contain elevated concentrations of **As, Se, Mo and Ni**, **(elements of concern, EOC).** These EOCs are immobilized within the tailings solid phase through complexation (chemical adsorption) or co-precipitation with ferric oxide (HFO) minerals such as ferrihydrite (FH).[1-2] Although the redox conditions in the tailings are oxic, even after 15 years of storage, concern exists as to impact of the development of anaerobic conditions at depth (E_h~ 500 mV) on the stability of these EOCs. Research suggests HFOs are unstable under moderately reducing conditions (E_h ~ +100 mV). As a result, they may undergo phase transformation and redox active species (such as Fe, As, and Se) may undergo reduction of their oxidation states. To understand the impact of an anoxic environment on the stability of the EOCs, a set of anaerobic reduction test were conducted on pure synthetic adsorbed systems and on more complex tailings samples.[2]

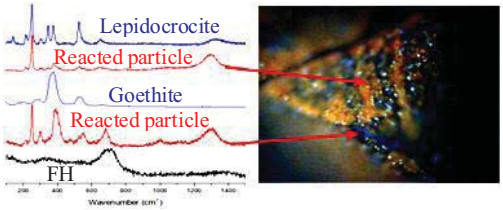

Figure 1: Micro-Raman and optical image of reduced X-FH particle

Results and Conclusion

We investigated solids with X/Fe molar ratios of 0, ~ 4, ~30 (X= 0, As and Mo) which are similar to those found in the DTMF products [1,2] and reacted these under two sets of conditions for all our products: high and low [Fe^{+2}] at pH 8 and 10, using lime as a base (as per the industrial process). In the case of the pure FH @ pH 8 and 10, phase transformation to lepidocrocite-goethite and complete uptake of the Fe^{+2} added were observed (Figure 1). For the AsO_4-FH samples, only samples at higher Fe/As ratios (~4) was phase transformation not observed (via Micro-Raman nor PXRD) at both pH's irrespective of the [Fe^{+2}]. Significant arsenic release (~ 10 ppm) was observed in the case of Fe/As 4 and pH 10. In case of the MoO_4-FH, phase transformation to goethite-lepidocrocite was observed at all Fe/Mo ratio's at pH 8 but not at pH 10. High Mo release (> 20ppm) was observed for the Fe/Mo ~4 solid at pH 8, and pH 10 for both Fe/Mo solid ratios. The difference in chemical properties such as phase transformation and element release of these molecules may be attributed to their X-O bond lengths (As-O= 1.68 Å vs. Mo-O= 1.76 Å), and chelating nature (inner vs. outer sphere) in the adsorbed state to FH.[1,3]

Enhanced metal release from acid mine drainage sediments due to the interaction with municipal waste water

The mining area of Aljustrel belongs to the well-known Iberian Pyrite Belt in Portugal. In spite of recent reclamation of the land where the old tailings were deposited, there is still a significant production of acid drainage waters that flow to the north in the Ribeira da Água Forte watershed. The stream waters are mixed with municipal waste water at 2 km from the source, for reasons that ultimately reside on the potential attenuation capacity of this high pH, low Eh, and organic-rich water. Although the visual impacts on the landscape seem to be attenuated, this apparently idyllic situation hides an unsuspected increase of metals in the flowing waters all along the stream length. This situation was detected because during large periods of the year in the dry season, the flow along the stream is mostly fed by the waste water with little or no input from the acid drainage waters. However, the stream hydrochemistry reveals that not only all the important trace metals remain equally concentrated in solution, but also that the stream waters are a bit more acidified as compared to the situation when mixing with the acid drainage waters from the old tailings occurs.

A detailed study of the stream sediments mineralogy by XRD and Mössbauer Spectroscopy shows that these sediments have important amounts of jarosite-group minerals and abundant small particle Fe-oxyhydroxides (SPO), mostly ferrihydrite. The sediments down to the mixing zone also have minor quantities of pyrite ± sphalerite. Beyond the mixing zone, sulfides disappear and SPO dominate, while jarosite has a minimum precisely at the mixing zone. Some hundreds of meters downstream schwertmannite was also detected. These findings suggest that the waste water input is actually promoting the reductive dissolution of jarosite and SPO from the stream bed sediments at the mixing area releasing the metals adsorbed onto these phases back into solution. Subsequent Fe hydroxide precipitation and the metastable nature of schwertmannite sustain an acid environment in spite of the feeding waters having a pH above 8. This maintains metals in solution, with the exception of As that is adsorbed on the newly formed Fe-hydroxides along the stream path. All other elements arrive at the discharge point of the stream 10 km away with the same concentration in solution as when they started at the mixing zone.

This work is a contribution from project METALTRAVEL – POCI/CTEGEX/61700/2004, funded by MCTES-FCT, Portugal.

Organic Matter in Sediments from the North American Arctic Margin

MIGUEL A. GOÑI[1*], ALISON O'CONNOR[2], ZOU ZOU KUZYK[3], CHARLES GOBEIL[4], ROBIE MACDONALD[5]

Abstract

To better understand the nature and distribution of the sedimentary organic matter in margin sediments off the North American Arctic, we analyzed thirty cores collected from all its major basins, including Baffin Bay/Davis Strait, the Canadian Archipelago, three regions of the Beaufort Sea (Mackenzie River Shelf, East Alaskan and West Alaskan Shelves), as well as the Chukchi and Bering Seas. Measurements included organic and inorganic carbon contents, mineral surface area, stable carbon and radiocarbon compositions of organic matter and a variety of CuO oxidation products derived from both terrigenous vascular plant and non-vascular plant sources. Our analyses showed major differences in the compositions of surface sediments along the North American Arctic margin. For example, while organic carbon contents were relatively uniform in all regions, ranging between 1 and 2 wt%, inorganic carbon contents were extremely elevated in the Canadian Archipelago sites (up to 8 wt%). Based on their depleted ^{14}C signatures, the elevated carbonate contents in these latter sediments reflect inputs from erosion of limestone bedrock in the adjacent terrain. Marked contrasts in the distribution of terrigenous-specific biomarkers indicated significant differences in the inputs of land-derived materials. For example, the highest carbon-normalized yields of lignin phenols were found in sites along the shelf portion of the Beaufort Sea, including off Barrow Canyon and Mackenzie Shelf. In contrast, sediments from Baffin Bay and the Archipelago were relatively devoid of these terrigenous markers. Compositional contrasts among biomarker classes indicated differences in provenance of land-derived organic matter among regions. Inputs from coastal erosion appear to be more important in the western parts of the Beaufort, Chukchi and Bering Seas, whereas export from the Mackenzie River dominate the eastern Beaufort sea.

Is the deuterium isotope composition of amber a reliable inland paleoclimatic indicator?

G. GONZALEZ[1,*] R. TAPPERT[2], A.P WOLFE[1], AND K. MUEHLENBACHS[1]

[1]University of Alberta, Edmonton, Canada, ggonzale@ualberta.ca (*presenting author)

[2]University of Innsbruck, Innsbruck, Austria.

Hydrous deuterium-exchange experiments have shown that a significant fraction of the original D/H composition of bulk kerogens, bitumens and expelled oils may participate in isotopic exchange reactions during burial diagenesis. However, it is unknown to what extent resins and their fossil counterpart amber, exchange hydrogen isotopes following their biosynthesis. This situation hinders the application of resin D/H measurements in paleoenvironmental reconstruction. As compared with other plant-derived compounds resins seem to preserve most of the chemical and isotopic features during their transformation to amber [1,2]. Yet, in fossil resinoids the number of hydrogen-containing functional groups seems to decrease, whereas the number of aromatized groups apparently increases with increasing age [3,5,6]. Accordingly, the possibility of a significant D-isotopic exchange with meteoric waters during burial cannot be ruled out. By using a series of immersion experiments in deuterated (D-enriched) waters over a period of several months at several temperatures, here we investigate whether significant D-isotopic exchange occurs during early thermal maturation and polymerization of conifer and angiosperm resins. At 90 ºC, equivalent to ~3 km of burial, modern conifer and angiosperm resins have an average post-metabolic D exchange of 4.63%, compared to only 1.08% for mature, polymerized ambers. At 55 ºC the degree of exchange is considerably lower: 1.9% for resins and 0.6% for ambers, Our results indicate that most D/H isotopic exchange occurs prior to polymerization reactions of resins, thereby confirming that D/H measurements from amber constitute a potentially sensitive proxy for environmental reconstructions of past climates, ecologies, and hydrological regimes.

Femtosecond laser ablation ICP-MS: high repetition rate diode-pumped ytterbium performance

J.J. GONZALEZ[1,3], H. LONGERICH[2], J.YOO[3] AND R.E. RUSSO[1]

[1]Lawrence Berkeley National Laboratory, Berkeley, USA, jjgonzalez@lbl.gov (* presenting author) rerusso@lbl.gov

[2]Memorial University, Newfoundland, CA henryl@mun.ca

[3]Applied Spectra, Inc, Fremont,CA USA, jyoo@appliedspectra.com

Laser Ablation ICP-MS

Without doubt, the femtosecond laser offers compelling advantages to direct solid sample laser ablation (LA) chemical analysis with detection of elements and isotopes using ICP-MS. The femtosecond laser reduces matrix effects due to a nominal heat-affected zone (no fractionation) and provides a nanometer particle aerosol that is ideal for transport, vaporization and ionization in the ICP. Several groups have shown the benefits of femtosecond LA-ICP-MS, but there remains conflicting reports of the 'optimun' wavelength, energy and pulse duration for geological sample analysis. Fundamental studies have shown in many cases that these parameters are significantly relaxed once the pulse duration is less than approximately 1ps. Most of the previous fs-ablation applications have been demonstrated using Ti:Sapphire lasers. We demonstrated excellent performance for several geological samples using a smaller footprint, lower cost, and more reliable diode-pumped ytterbium femtosecond laser, even using wavelengths at 1um. Precision, sensitivity and accuracy were established and will be reported. In addition, the high repetition rate of this laser was demonstrated for rapid bulk analysis of inhomogeneous granite samples.

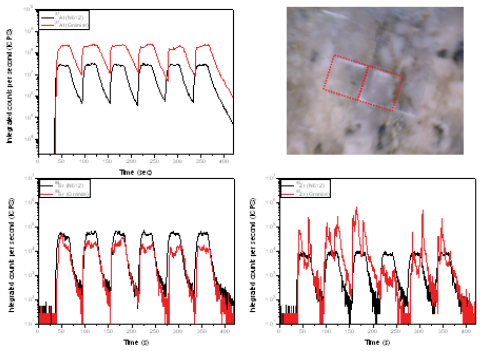

Figure 1: ICP-MS transient signal of selected isotopes produced by high repetition rate femtosecond laser ablation of NIST 612 and granite at 6um spot size, 40mm/sec and 20KHz. Scans show the effect of elemental inhomogeniety.

Conclusion

This talk will describe the current status of femtosecond laser abaltion ICP-MS with emphasis on the benefits of a reliable and stable diode pumped ytterbium solid state laser.

Novel synthesis of iron sulfide for carbon dioxide reduction

JOSIE GOODALL[1]*, HUSN-UBAYDA ISLAM[1], NATHAN HOLLINGSWORTH[1], ANNA ROFFEY[1], KATHERINE B. HOLT[1], GRAEME HOGARTH[1], GOPINATHAN SANKAR[1], JAWWAD A. DARR[1]

[1]University College London, London, UK *j.goodall@ucl.ac.uk

Overview

Despite the high thermodynamic stability of CO_2, biological systems are capable of both activating and converting it into a range of organic molecules, under moderate conditions. Successful conversion of CO_2 into useful chemical intermediates without the need for extreme reaction conditions would be of enormous benefit Iron-nickel sulfide membranes formed in the warm, alkaline springs on the Archaean ocean floor are increasingly considered to be the early catalysts involved the emergence of life. These anaerobic reactions are thought to have been catalyzed by small (Fe,Ni)S clusters similar to the surfaces of present day sulfide minerals.[1]

We have synthesised iron sulfide nanomaterials using a novel synthesis methods based on continuous hydrothermal synthesis, where flows of aqueous solutions of iron and sulfide ions are brought into contact with a flow of superheated water (at 450 ºC). This results in sudden, rapid crystallisation of nanoparticle metal sulfides. A flow reactor such as this offers the potential to affect the particle properties, such as composition, based on modelled predictions of active catalysts. The conditions and processes occurring during synthesis can be compared to those that might occur in hydrothermal vents.[2,3] The electrochemical properties of these materials and their stability and activity towards CO_2 and their selectivity to products can be evaluated.

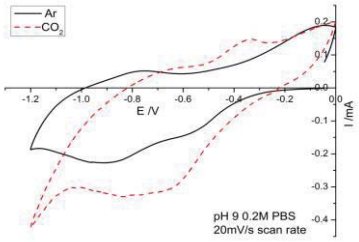

Figure 1: Comparison of the electrochemical behaviour of Ni-doped greigite under argon and CO_2.

Results

Based on comprehensive computational investigations, a number of iron and iron-nickel sulphide nanoparticles have been designed, synthesised, tested, characterised, and evaluated for the activation and chemical modification of CO_2 at low voltages (obtainable from solar energy). Succesful synthesis methods for greigite, mackinawite, pyrrhotite, pyrite and nickel sulfide as well as doped greigite nanostructures have been developed. Structures including nickel-doped greigite (above) show clear differences in electrochemical behaviour in the presence and absence of CO_2.

Taking control of subsurface behavior with Smart Gels – an oil & gas exploitation perspective

HARVEY GOODMAN[1*]

[1]Chevron Energy Technology Company, Chevron Fellow (hego@chevron.com)

The safe, environmentally friendly and cost efficient exploitation of oil and gas resources is becoming increasingly complex. For example, deepwater subsalt developments require fewer wells that must produce reliably over longer periods of time to justify the large capital expenditures necessary to develop. Enabling technologies being developed focus on a wide range of applications along the entire value chain used to discover, recover and transport high energy density resources to the consumer. This discussion will focus on smart materials, particularly smart gels applications that appear promising for subsurface behaviour illumination or imaging and CO2 sequestration applications. Smart gel actions that can be triggered to respond to specific subsurface conditions is an extremely attractive option for geomechanical model forecasts calibration. Calibration of theoretical models used to predict rock mechanical behaviour during drilling and through production can use smart gel trigger responses to excite the subsurface in an observable manner. This may lead to improved calibration of time-dependent model predictions that consider near-wellbore osmotic effects (pore pressure & swelling) and to ground truth far-field reservoir mechanical response to pressure depletion. With regard to applications in geological storage of CO2, an important risk to containment loss is through leakage pathways associated with injection wells. The well schematic shown in Figure 1 illustrates potential CO2 leakage pathways. Regaining containment by sealing these leakage pathways may be problematic, particularly for extremely small crack apertures. The design and application of smart gels to restore CO2 containment will be discussed.

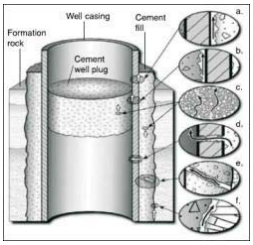

Figure 1: Possible leakage pathways in an abandoned well (modified after Gasda et al., 2004).

^{54}Cr and $\Delta^{17}O$ in carbonaceous chondrites and an old $^{53}Cr/^{53}Mn$ age of the Paris meteorite

CHRISTA GÖPEL[1]*, JEAN-LOUIS BIRCK[1,2], PIERRE CARTIGNY[1,3], NELLY ASSAYAG[1,4], AND BRIGITTE ZANDA[5]

[1]IPGP, Paris, France, gopel@ipgp.fr (* presenting author)
[2]birck@ipgp.fr, [3]cartigny@ipgp.fr, [4] assayag@ipgp.fr
[5]MNHN, Paris, France, zanda@mnhn.fr

Mn/Cr isotope systematics in meteorites presents an interesting tool because this isotope system holds double information: the ^{53}Cr-^{53}Mn couple allows us to obtain chronological information while the ^{54}Cr isotope systematics yields information on the mixing of nucleosynthetically distinct components. Although the variations of the ^{54}Cr abundances in meteorites are not yet fully understood, they are nevertheless so systematic that they can be used as a classification tool, very similar to the oxygen isotope systematics.
We present Mn/Cr and oxygen isotope data obtained on recently discovered and/or unclassified carbonaceous meteorites. The oxygen isotopic compositions were determined by laser fluorination on small fragments; the Cr isotopic compositions were measured on sequential dissolution steps of bulk rock powders of all meteorites and on separated mineral fractions of two of them. The mineral separates of Paris, forsterite, fayalite, fine-grained material around chondrules (FGR), fall on a line with a slope of $^{53}Mn/^{55}Mn = 6.183 \times 10^{-6}$ and $^{53}Cr_i = -0.165$. This slope can be translated into an age based on the LEW Cliff 86010 anchor [1] and corresponds to $4566.33 \pm 0.63 \times 10^6$ y. This old Mn/Cr age shows that the first chondrules formed rapidly (1-2 $\times 10^6$ y) after CAIs. The mineral isochron obtained on Tafassasset indicates a younger equilibration age: $4563.31 \pm 0.42 \times 10^6$ y.
The ^{54}Cr abundances measured in the bulk rocks of all samples studied as well as the isotopic pattern of the sequential leaching steps allow us to classify Tafassasset as CR, Niger I as CI, Paris as CM and NWA TBC as CV chondrites. Although the existence of a correlation between ^{54}Cr and oxygen in carbonaceous chondrites has recently been questioned [2], our new $\Delta^{17}O$ data for Niger I ($\Delta^{17}O$ = -0.361 ±1.189), NWA TBC (- 4.052 ± 0.550) as well as the ^{54}Cr abundances of Tafassasset (^{54}Cr= 1.42± 0.076), Paris (^{54}Cr= 0.925 ±0.098), Niger I (^{54}Cr= 1.64±0.11) and NWA TBC ^{54}Cr= 1.08±0.19) seem to match such a correlation.

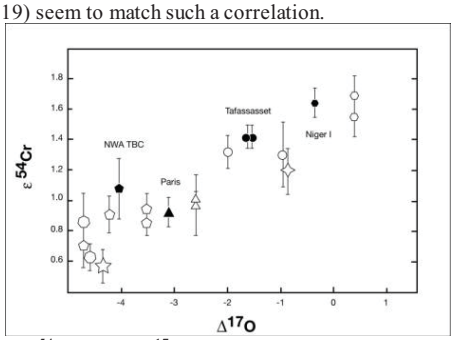

Figure 1: $\varepsilon^{54}Cr$ versus $\Delta^{17}O$ in carbonaceous chondrites, data from new meteorites are shown as solid symbols. Published data of CC from [3-5]

Isotopic analysis of sulfide captured on photographic film: Laboratory and field experiments

PAUL GORJAN[1*], DAVID A. FIKE[1], AND WILLIAM P. GILHOOLY III[2]

[1]Washington University in St Louis, St Louis MO, USA, pgorjan@levee.wustl.edu (* presenting author), dfike@wustl.edu

[2]Indiana University-Purdue University Indianapolis, Indianapolis, USA, wgilhool@iupui.edu

Sulfide is formed in sediment pore waters or in the water column of stagnant water bodies by the action of anaerobic sulfate-reducing bacteria. Sampling of free sulfide in natural environments has typically been done using syringes (for water column) or cores (for pore water). Yet the resolution of these approaches is often too coarse to capture steep environmental (e.g., redox) or ecological gradients in microbially dominated sediments.

We seek a means to capture a continuous record of ambient sulfide for subsequent stable isotope ($\delta^{34}S$) analysis. Previous work highlighted the potential of sulfide capture on metallic silver disks [e.g., 1-3]. However, this is not suitable for frequent deployments, particularly covering areas greater than a few cm^2. Here we build upon previous work for capturing atmospheric sulfide [e.g., 4,5], via reaction with the silver compound embedded in photographic film to form silver sulfide, which can then be quantified. This technique has the potential to capture a continuous $\delta^{34}S$ record across a wide range of environments and has the advantages of being inexpensive, readily available, rapidly deployable, and can be used *en masse* for sampling [4]. Here we test the reliability of photographic film to accurately capture the $\delta^{34}S$ signature of aqueous sulfide in laboratory experiments as well as in a natural setting.

In laboratory experiments, strips of photographic film were immersed in dissolved sulfide solutions with pH spanning 7–11 in closed systems and in contact with the atmosphere. No isotopic offset was detected for films immersed in high pH solutions. However, at pH ~7 films were consistently depleted by 1–2‰ relative to fluids, which we attribute to fractionation between sulfide species within the solution.

The method was also tested at a field site. Mahoney Lake in British Columbia, Canada, has sulfide present in the water column below ~7 m depth. Photographic film was lowered into the water alongside syringes for sulfide collection and a comparison made between the isotopic composition of sulfide from the film and the syringes. As with the laboratory experiments, the film sulfide was depleted by 1–2‰ compared to the aqueous sulfide under circumneutral pH.

Complexation of Neptunium(V) with *Bacillus subtilis* endospores and their exudates

DREW GORMAN-LEWIS[1*], MARK P. JENSEN[2], ZOË R. HARROLD[1] AND MIKAELA R. HERTEL[1]

[1]University of Washington, Seattle, USA, dgormanl@u.washington.edu (* presenting author)

[2]Argonne National Laboratory, USA

Biological media may affect the movement of neptunyl ions, a highly toxic and potentially mobile radionuclide, in the environment. Most previous investigations of neptunyl-microbial interactions have focused on interactions with vegetative bacterial cells. However, endospores are known to comprise up to ca. 50% of the total bacterial populations in some environments and reserachers have identified endospore counts in soils as high as ca. 10^5 CFU/g of soil. Despite endospores being important biological media in the environment, neptunyl-endospore interactions have been ignored. Thus, we investigated neptunyl ion interactions with *Bacillus subtilis* endospore surfaces and their exudates.

B. subtilis endospore exudates are dominated by dipicolinic acid, which is a ligand that strongly binds neptunyl ions. *B. subtilis* endospores contain a large reservoir of dipicolinic acid in their cortex that can be released during germination or changes in permeability of the endospore coat, the latter being the most likely form of release in this work. Spectrophotometric investigations of the chemical form of neptunyl ion in endospore exudate solutions were consistant with the formation of neptunyl-dipicolinate complexes. Due to the strength of the 1:1 neptunyl-dipicolinate complex, neptunyl speciation in these experimental systems was heavily influenced by exudate complexation and controlled the extent surface adsorption. Neptunyl ions weakly adsorbed onto the endospore surface and sorption decreased with increasing pH, which corresponds to increasing aqueous complexation by dipicolinate.

Using spectrophotometric measurements of neptunyl-dipicolinate complexes and neptunyl-endospore adsorption data, we determined thermodynamic stability constants for both species. With stability constants determined in this work, we compared controls on neptunyl partitioning in simulated systems with *B. subtilis* vegetative and sporulated cells, (at dipicolinc acid concentrations corresponding to the extent of sporulation), and generic natural organic matter. Neptunyl complexation by dipicolinic acid exerted the greatest biological control in the simulated systems. This work highlights the importance of considering radionuclide complexation by microbial exudates when trying to understand the fate and transport of radionuclides in the environment.

Endolithic (bio)weathering and rock varnish in East Antarctica as early-Earth analogs of "protosoils"

SERGEY GORYACHKIN[1*], ALEX CHERKINSKY[2], NIKITA MERGELOV[1] AND ILIA SHORKUNOV[1]

[1]Institute of Geography, Russian Academy of Sciences, Moscow, Russia, goryachkin@igras.ru (* presenting author)

[2]Center for Applied Isotope Studies, University of Georgia-Athens, Athens, USA, acherkin@uga.edu

Introduction

Rock varnish and endolithic organisms being quite informative as early-Earth analogs are very well studied apart however their interaction and possible cogenesis have never been particularly explored, as well as nobody has studied them as soils. Endolithic organisms of Antarctic Dry Valleys inhabit structural cavities in the superficial rock interior [1]. The other common feature of Antarctica is the red-brownish colour of solid rocks (rock varnish).

Results and Conclusion

Our explorations in coastal oases of East Antarctic at field and microscopic scales showed that such system as "endolithic organisms-granitoid rock-weathering products" has all features to be denominated as "protosoil": (1) rock layer exposed to external abiotic factors; (2) this layer is inhabited by living organisms synthesizing and decomposing organic matter (OM); (3) induced by biotic and abiotic factors the initial lithomatrix is transformed *in situ*, the transformation products (e.g. fine earth) are retained and/or taken away, the vertical heterogeneity (microprofile) is formed. Organo-mineral horizons of endolithic soil contain 0,2-3,3% C and 0,02-0,47% N. ^{14}C mean residence time of OM reaches 480±25 y BP, $\delta^{13}C$= -23,7- -21,0 ‰. Major pedogenic products are numerous Fe-C- Si-Al- S-Cl-Ca-Mg-containing bio-coatings which cover cavities in the rock. Main binding material are amorphous Si and Al with incorporated detritus. SEM morphology and composition of coatings correspond to those observed in varnish on rock (Fig. 1).

Thus, certain types of rock varnish could be the products of endolithic (bio)weathering exposed after exfoliation and transformed by external factors. This hypothesis can't explain all rock varnishes (e.g. formed by accretion). However, this "endoliths-varnish" system may be recognized as an early-Earth "protosoil".

Temporal variation in $^{187}Os/^{188}Os$ of the Arabian Seawater

VINEET GOSWAMI[1*], SUNIL K. SINGH[2]

[1]Physical Research Laboratory, Ahmedabad, India. vineetg@prl.res.in (* presenting author)

[2]Physical Research Laboratory, Ahmedabad, India. sunil@prl.res.in

Residence time of Os is 8-40 ka in the ocean [1], long enough to homogenise its isotopic signature in the global ocean but short enough to track the variations in its supply to ocean on glacial – interglacial time scale. Recent studies have shown variation in Os isotopic composition of seawater over glacial – interglacial time scale [2-5]. These variations have been interpreted in terms of variation in intensity of continental weathering.

To obtain a reliable and high reosolution record of marine $^{187}Os/^{188}Os$ form the Arabian Sea, sediments from a core in the south-eastern Arabian Sea (SS-3101G; 6.0°N, 74.0°E) have been analyzed. Samples have been leached by mild acidic peroxide solution to obtain the seawater Os isotope composition. The results display significant variation in $^{187}Os/^{188}Os$ of marine Os record from the Arabian Sea during last 29 ka. The $^{187}Os/^{188}Os$ of seawater in the most recent sample has a value of 1.04 ± 0.01, close to the Os isotopic composition of present day seawater (1.06 ± 0.01) [6]. The Os isotopic composition of the Arabian seawater vary in phase with that of the global ocean since last lat 29 ka except during the Last Glacial Maxima (LGM). During LGM, $^{187}Os/^{188}Os$ deviates from the trend set by the global ocean and shows an excursion towards higher $^{187}Os/^{188}Os$. Os concentrations of the leachable fraction of sediments from the Arabian Sea are higher during the LGM. Further, the Re contents of the LGM sediments are also higher.

Higher concentrations of Re and Os in the sediments deposited during the LGM indicate more suboxic/anoxic conditions at the sediment water interface during that time. Lower oxygen content in the bottom water of the Arabian Sea could have been caused by the reduced transport of polar waters (North Atlantic Deep water, NADW) into the Arabian Sea. Deviation of Os isotope composition of Arabian Seawater from the global oceanic trend and higher concentration of Re and Os during LGM, thus, indicate the reduced supply of NADW to the Arabian Sea during LGM, resulting in partial isolation of the Arabian Sea from rest of the oceans during the LGM [7-9].

Engineered nanomaterials in rivers – exposure scenarios for Switzerland at high spatial and temporal resolution

F. GOTTSCHALK[1,2*], CHR. ORT[3], R.W. SCHOLZ[2] AND B. NOWACK[1]

[1] Empa – Swiss Federal Laboratories for Materials Science and Technology, Technology and Society Laboratory, fadri.gottschalk@empa.ch (* presenting author), nowack@empa.ch

[2]ETH Zurich, Institute for Environmental Decisions, Natural and Social Science Interface, roland.scholz@env.ethz.ch

[3]Eawag – Swiss Federal Institute of Aquatic Science and Technology, Christoph.Ort@eawag.ch

Introduction and methods

Two models, one based on probabilistic material flow analysis [1] and one based on graph theory [2], were combined to calculate predicted environmental concentrations (PECs) of engineered nanomaterials (ENMs) in rivers at local resolution. PECs for nano-TiO_2, nano-ZnO and nano-Ag were modeled for river sections downstream from 543 sewage treatment plants (STPs) at base flow conditions. Flow measurements over a 20-year period (1988–2007) at 20 selected locations were used to assess temporal variation. Due to the absence or ambiguity of available data on ENM dissolution behavior or agglomeration/sedimentation rates two "extreme" transport scenarios were considered: (i) a reactive scenario *with rapid (complete)* ENM *transformation* or sedimentation in rivers between two STPs and a conservative scenario *without any* ENM removal from the liquid phase.

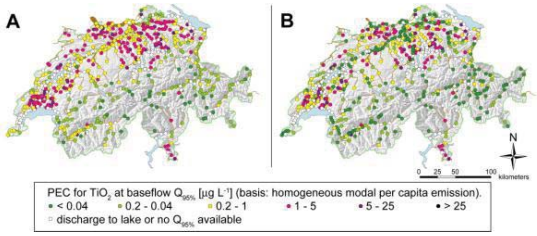

Figure 1: PECs of nano-Ag in Swiss rivers at base flow conditions (A: conservative scenario, B: reactive scenario).

Results

The highest concentrations were found in the midlands or near urban centers. Rural, alpine and pre-alpine values were negligibly small (Fig. 1). Temporal variation of PECs was evaluated by considering a whole range of "typical cases": small to large rivers (highly variable to more attenuated flow rates) and predominantly alpine to urban catchments (low to high ENM input). The alpine Rhine showed the smallest concentrations: the nano-Ag PECs ranged from 0.01 ng L^{-1} to 0.6 ng L^{-1} (conservative scenario). Some of the highest concentrations were observed within a lowland river section: 0.3 ng L^{-1} to 60 ng L^{-1} nano-Ag (conservative scenario).

Ultrapotassic lava flows from Colli Albani Volcanic District (Central Italy) give insights into the crystallization of magmatic calcite in effusive rocks

FERNANDO GOZZI[1*], MARIO GAETA[1,2], CARMELA FREDA[2], SILVIO MOLLO[2], TOMMASO DI ROCCO[3], FABRIZIO MARRA[2], LUIGI DALLAI[4], ANDREAS PACK[3]

[3]Georg August Universität, Geowissenschaftliches Zentrum, Göttingen, Germany.
[4]CNR-Istituto di Geoscienze e Georisorse, Pisa, Italy.

Calcite crystals are relatively common in alkalic hypoabyssalite and kimberlite rocks, but rarely documented in effusive rocks (e.g. alkaline lava flows). Magmatic calcite in effusive rocks has been usually related to mantle-origine carbonate; only in very few cases, it has been explained throughout magma-sediments interaction.

The ultrapotassic Colli Albani Volcanic District (Central Italy) represents one of the most peculiar volcanic districts on the Earth because of its liquid line of descent characterized by differentiated, low silica (SiO_2≤45wt%), K-foiditic magmas. Field, geochemical, and experimental studies have demonstrated that such a differentiation trend, starting from trachybasaltic parental magma, is mainly due to magma-carbonate sediments interaction. One of the most intriguing question concerning Colli Albani petrology is the occurrence of calcite crystals in the groundmass of some lava flows. In general, Colli Albani lava flows are made up of leucite and clinopyroxene phenocrysts and the groundmass contains leucite, clinopyroxene, and Ti-magnetite. More evolved products may also contain calcite, usually associated with nepheline. A detailed microtextural study of these calcite-bearing lava flows has shown that calcite occurs as follows: i) interstitially, associated with clinopyroxene, nepheline and phlogopite; ii) in ocelli, associated with fluorite and tangentially arranged clinopyroxene; iii) in coronitic reaction zone around K-feldspar xenocrysts. These microtextural features clearly indicate that calcite crystallized under magmatic conditions. Moreover, the high $\delta^{18}O$ (25-29‰ SMOW) and low $\delta^{13}C$ (down to -19‰ PDB) values of calcite crystals prove the sedimentary origin of the carbonate involved in the process. Finally, the occurrence of limestone fragments in the lava flows accounts for a syn-eruptive assimilation of the carbonate sediments. The high activity of fluorine in the Colli Albani magmas, as demonstrated by the occurrence of F-rich mineral phases (i.e, amphibole and mica), associated with fast crystallization due to the low magma viscosity, can have played a central role on the subsistence of sedimentary carbonate melt (then calcite crystals) at atmospheric pressure. This study may help unravelling the formation processes of the so-called "pseudocarbonatites", i.e. carbonated rocks related to the anatexis of crustal limestone.

Dissolved organic matter concentration and character influence Hg-S bioavailability to Hg-methylating bacteria

ANDREW M. GRAHAM[1*], ALLYSON L. BULLOCK[1], GEORGE R. AIKEN[2], AND CYNTHIA C. GILMOUR[1]

[1]Smithsonian Environmental Research Center, Edgewater MD, USA, grahaman@si.edu (*presenting author)
[2]U.S. Geological Survey, Boulder, CO, USA

Mercury methylation occurs primarily in mildly sulfidic environments where nanoparticulate forms of Hg-S are increasingly recognized to be of significance [1,2]. In this study, we sought to elucidate the role of dissolved organic matter (DOM) in altering the bioavailability of Hg-S to a model Hg-methylating bacterium, *Desulfovibrio desulfuricans* ND132. Methylmercury (MeHg) production by strain ND132 was evaluated in short-term washed cell assays in Hg-S-DOM solutions containing DOM isolates of varied origin, size, and composition, as well as a wide range of [Hg]/[DOM] and [Hg]/[sulfide] concentration ratios.

Under mildly sulfidic conditions (1-10 μM total dissolved sulfide), MeHg production was found to increase linearly with increasing DOM concentration, while relative bioavailability (i.e., fractional Hg methylation) increased logarithmically with increasing [DOM]/[Hg] ratio. Equilibrium speciation calculations indicated that Hg binding to DOM-thiols did not outcompete Hg binding to sulfide, and that solutions were supersaturated with respect to β-HgS(s) (metacinnabar) under most experimental conditions. We hypothesize that DOM enhanced MeHg production by stabilizing small, poorly crystalline HgS particles against growth/aggregation. Supporting this hypothesis, we found no DOM-dependent enhancement in Hg methylation in the presence of a strong Hg-binding ligand (L-cysteine) at concentrations sufficient to outcompete sulfide for inorganic Hg. Further, we found that while all DOM isolates tested (n = 12) enhanced MeHg production to some degree (2- to 25-fold enhancement at 20 mg C/L and 0.5 nM added Hg), the enhancement in Hg methylation correlated with the DOM isolates' specific UV absorbance (SUVA), a measure of DOM size and aromaticity. This finding is significant in that DOM size and aromaticity have been demonstrated to be key characteristics controlling HgS precipitation and dissolution [3], suggesting a link between dynamics of HgS precipitation/dissolution, Hg uptake, and Hg methylation.

Overall, our results point to the limits of existing equilibrium-speciation based models for Hg uptake and methylation. In addition to Hg and sulfide concentrations, DOM concentration and character are potentially important variables for predicting *in-situ* Hg-methylation rates in natural systems.

Apollo 15 zircons reveal age of young impact

MARION L. GRANGE[1*], ALEXANDER A. NEMCHIN[1], ROBERT T. PIDGEON[1] AND CHARLES MEYER[2]

[1]Curtin University, Perth, Australia, m.grange@curtin.edu.au
[2]Johnson Space Center, Houston, USA.
(* presenting author)

We have investigated microstructures of zircon and apatite grains, their textural context and U-Pb ages, in Apollo 15 sample 15405, aiming to extend the existing database consisting of Apollo 14 and 17 breccia samples. Sample 15405 was chipped from a boulder at Station 6A, south of the landing site and close to the Apennine Front. It is a clast-bearing impact melt breccia, with a crystalline matrix, similar in chemistry to KREEP basalt, and containing KREEP basalt and quart-monzodiorite (QMD) clasts. It contains zircon and apatite grains both within the matrix and in QMD clasts.

Zircon grains in the matrix are abraded or broken fragments. Zircons in both matrix and clasts are anhedral, showing oscillatory and sector zoning in CL. Previous work [1] on zircon included in QMD clasts indicated a disturbed U-Pb system in the grains with an upper concordia intercept at 4294±26 Ma and a lower intercept at 1320 +240/-280 Ma (2σ). New data show comparable patterns, with no age distinction between zircon from the matrix and from clasts: both types show concordant and discordant ages, although oscillatory zoned zircon are systematically concordant. The combination of concordant analyses gives the age of 4335±7 Ma (2σ). When combining these data with discordant ages from zircon and apatite, a lower intercept is obtained at 1570±51 Ma (2σ). In addition, a single spot in one zircon shows a concordant age at 2053±14 Ma (1σ).

These young U-Pb ages have never been found before in lunar zircons that are usually >3.9 Ga. It indicates that the relatively robust U-Pb system in zircon has been severely disturbed at ~1570 Ma (and maybe also at ~2.05 Ga). Such late disturbance is also recorded in Ar-Ar ages at ~1.3 Ga [2] and ~2.1 Ga [3]. These authors [3] interpreted these young ages as disturbance following close-by impacts that they tentatively identified as Aristillus and Autolycus, respectively.

If these young U-Pb ages of zircon can be associated with a particular impact event, this would be the first time a clear link can be established between a specific impact event and a zircon age. This would have major implications for constraining variations in the flux of impactors through the history of the inner Solar System, as so far only relative ages of craters exist. Previous studies [3] showed that even poorly defined ages of specific crater, i.e. much less precise that what can be obtained using zircon, can dramatically increase our understanding of the impact flux of the Moon, and by extension of the Earth. Such opportunities have to be fully explored making breccia 15405 one of the key samples in the lunar collection.

The importance of hickory trees (*Carya*) in biogeochemical cycling of meteoric ^{10}Be

DARRYL E. GRANGER* AND GRACE CONYERS

Department of Earth and Atmospheric Sciences, Purdue University, West Lafayette, IN USA, dgranger@purdue.edu (* presenting author), gconyers@gmail.com

Meteoric ^{10}Be is widely used to monitor weathering and erosion of soils, with little regard to biogeochemical cycling. We found that hickory trees (Carya spp.) strongly bioaccumulate beryllium. Because oak-hickory forests are a dominant biome over much of the eastern United States, hickory trees can play an inordinately large role in the cycling of meteoric ^{10}Be in these areas.

To explore the role of trees in biological cycling of ^{10}Be, we analyzed composite samples of wood and leaves from four dominant tree species (red hickory, Carya ovalis; black oak, Quercus velutina; red maple, Acer rubrum; and tulip poplar, Liriodendron tulipfera) as well as soil at the Martel experimental forest in northern Indiana, USA. We analyzed samples from 1 ha of unmanaged forest growing on loess and loamy till of Late Wisconsinan age.

We found that hickory contains the highest beryllium concentrations by a factor of 50-100, with an average of 0.39 ppm (dry mass) in the wood, subequal to the average exchangeable [Be] in the soil of 0.43 ppm. Abscised hickory leaves have a higher [Be] of 2.0 ppm. The isotopic ratio ^{10}Be/^{9}Be in all four tree species was similar, ranging from 6-8 x 10^{-9}. Using standard allometric equations relating tree biomass to trunk diameter, and assuming that belowground biomass has the same [Be] as aboveground, we calculate that hickory trees at our site contain an average of ~0.5% of the total ^{10}Be under their crown and that 5-15% of this Be is cycled annually by leaf abscission. It is not clear at this point what fraction of Be in litterfall is recycled into the plant, returned to the soil, or carried to groundwater as organic complexes.

Although the fraction of ^{10}Be in standing biomass is small, annual cycling in litterfall can be significant when integrated over thousands of years. Using our values for [^{10}Be] in litterfall, we can estimate the probability that a given atom of ^{10}Be in a forest soil will have passed through a hickory tree. Hickories occupy an average of ~10% of the oak-hickory forest area. Assuming that trees are randomly distributed and that litterfall Be is returned to the soil, and maintaining a constant ^{10}Be budget for generality, we calculate that nearly half of all ^{10}Be in the forest soil will have passed through a hickory tree over the past 10 ky. It is clear that hickories can transport a sizable fraction of the total ^{10}Be in their nutrient cycle, and that they may be responsible for landscape-scale Be mobility.

Biogeochemical cycling of ^{10}Be has not previously been fully appreciated. It is known that many plants and fungi contain Be at the 0.1-0.5 ppm level (ash mass), approximately 10 times lower than in hickory, and that the larch tree (Larix) also accumulates Be. There has been no systematic survey, however, to examine ^{10}Be in the ecosystem. Much more work is needed to understand ^{10}Be mobility in the biosphere, including the influence of ecosystem shifts, land management, harvesting, and burning, both natural and anthropogenic. It is possible that ^{10}Be signals previously attributed to soil erosion may instead be due to biological disturbance.

Weathering at the Mineral-Fungus-Bacteria Interface Analyzed with Scanning Electron Microscopy and Helium Ion Microscopy

Introduction and Methods

Bacteria and fungi are documented agents of chemical weathering and nutrient uptake by higher plants. However, the role of biofilm in these processes is poorly understood. This study examines components of a laboratory column growth experiment to study the mineral-fungus-bacteria interface, morphology of mineral surfaces, and associated microbes and biofilm when calcium and potassium sources are varied. We hypothesized that 1) under limiting Ca and K conditions, thick biofilm cover develops to protect the mineral-fungus-bacteria interface and facilitate direct cation uptake from the minerals; 2) as Ca and K are made increasingly available in the input solutions, biofilm becomes thinner, patchy and less developed.

Red Pine (*Pinus resinosa* Ait.) was grown in leach tubes filled with quartz sand and 0.5 wt% biotite and 1 wt% anorthite. Half of the trees were inoculated with *Suillus tomentosus* and a variety of soil bacteria and the other half were left without inoculation. Columns without biology served as controls. The columns were supplied with Ca and K in irrigation water at 0, 10, 30 and 100% of what a healthy tree would need for growth. A subset of columns were destructively sampled after one month and three months growth. Biotite and anorthite were analyzed from the rhizosphere of each tree and also from the bulk material with helium ion microscopy (HeIM) and scanning electron microscopy (SEM) equiped with energy dispersive x-ray spectroscopy (EDS).

Results and Discussion

Microscopy images show that after one month, bacterial colonization dominated the rhizosphere with few areas of fungal development. By the 3rd month, abundant fungal hyphal cover of rhizospheric minerals developed in the 0 and 10% Ca and K treatments and the 30 and 100% Ca and K treatments remained less colonized. The bulk material of the tree treatments and the controls remained nearly unaffected by microbes. Fungal hyphae appear to "search" for weaknesses of the crystal structure such as particle and step edges, existing fractures and perhaps inpurities or inclusions. Bacteria are associated with fungal hyphae in some places, but do not form large biofilm colonies. Biofilm and polysaccharide cover remained patchy through the 3 month growth period in all treatments, but a slight decrease of cover was detected with increasing concentrations of Ca and K in the irrigation solutions.

In conclusion, our study shows that biofilm is directly affected by Ca and K concentrations in input solutions, but later time points of our experiments (6 and 9 months), most likely with more developed biofilm, will be analyzed to support our first hypothesis.

Boron isotope based CO_2 record during retreat of the Antarctic ice sheet

ROSANNA GREENOP[1*], GAVIN L. FOSTER[1], PAUL A. WILSON[1]

[1]Ocean and Earth Sciences, National Oceanography Centre Southampton, University of Southampton, Waterfront Campus, Southampton, SO14 3ZH, United Kingdom r.greenop@noc.soton.ac.uk (*presenting author)

Large ice sheets have existed on Antarctica since the Eocene-Oligocene transition (~34 Ma) when atmospheric CO_2 dropped below around 750 ppm. Results of ice sheet modelling experiments suggest that once the land based East Antarctic ice sheets had grown, a powerful hysteresis effect should have acted to make them inherently stable necessitating high CO_2 levels >> 750 ppm to initiate deglaciation [1]. However, the deep sea oxygen isotope record [2] and results of proximal ice drilling [3] suggest that there has been large fluctuation in Antarctic ice sheet volume, while existing CO_2 records appear to have remained relatively low and constant [2].

Here, we explore this hysteresis effect using boron isotopes, measured by MC-ICPMS, to produce high-resolution CO_2 records during the warming into the Mid-Miocene Climatic Optimum, a time interval associated with significant retreat of the Antarctic Ice Sheet [3]. A high-resolution boron isotope record has been produced for the time period between 15.5 and 17 Ma at ODP Site 761 (16°44.23′S, 115°32.10′E 2179 m). Our results show relative changes in atmospheric CO_2 across this time interval. By combining this new record with records of proxy ice volume change we shed new light on our understanding of CO_2 driven retreats of the Antarctic ice sheet.

In order to study ^{1}H and D distributions in individual apatite grains $\{Ca_5(PO_4)_3(F,Cl,OH)\}$ in a range of lunar rocks collected during the Apollo program, we have been using a new ion microprobe technique that combines quantitative spot analyses with semi-quantitative 2-D ion imaging. We find the Moon has abundant water and a distinct range of D/H compared to known water sources in the solar system [1]. Since our publication, we have measured D/H and OH in lunar apatite in five more samples. New samples include mare basalts 10047 and 12064 that both have high δD, but moderate water contents (<2000 ppmw OH) in comparison to other mare basalts that we have measured. New analyses of mare basalt 12039 have been performed, a rock from which a significant portion of our pubished data was derived. These new analyses of 12039 suggest less variability in D/H than reported for this sample.

We continue to see that the mare basalts have significant hydroxyl in their apatite grains (with the exception of olivine basalt 12040). Estimates for the lunar-mantle water content from apatite grains are fraught with assumptions. However, with some assumptions, we can estimate the H_2O content of the lunar mantle that produced 12039. For 3-5% partial melting, and assuming no assimilation of volatile-bearing material by the magma, a mean partition coefficient of 0.4 for OH between apatite and melt (e.g. [2]), and that apatite is the only OH-mineral crystallizing from the magma, and no degassing of H_2 or H_2O, and, finally, that our highest water content apatite represents 99% crystallization of the magma, we estimate 5-8 ppm H_2O for the 12039 source region.

Isotopic evidence for the early use of ceramics in cooking meats and processing milk from sheep and goats

MICHAEL W. GREGG[1*], GREG F. SLATER[2]

14b. Reciprocal interactions between archaeology and archaeometry focusing on characterization of ancient human settlements and their environmental impacts

This paper presents molecular and isotopic evidence for prehistoric subsistence practices associated with the earliest use of clay and manufacturing of pottery vessels in a narrow geographic corridor linking the Middle East with Central Asia. Through use of our recently-developed protocol for extraction, isolation and transesterification of free fatty acids from archaeological pottery[1], $C_{16:0}$ and $C_{18:0}$ saturated fatty acids with ratios consistent with degraded animal fats[2] were obtained from fired-clay and pottery fragments from Hotu and Belt Caves in northern Iran. These rock shelters, situated on the late Pleistocene shoreline of the Caspian sea in the foothills of the Alborz mountains, were excavated by University of Pennsylvania anthropologist Carleton Coon in the fall of 1949 and the spring of 1951[3,4]. The mid-Mesolithic to late Neolithic period human occupations from which these materials were recovered date between 4850 and 13250 calBC[5,6].

Compound-specific isotopic analyses ($^{13}C/^{12}C$) of $C_{16:0}$ and $C_{18:0}$ fatty acids surviving in 16 of 37 fired-clay and pottery fragments (43%) revealed ratios of $\partial^{13}C$ values consistent with those of modern ruminant milk fats and carcass fats of sheep, goats and pigs[2,1]. These results demonstrate that clay was used in cooking meats during the late Pleistocene and pottery vessels were used in processing milk from sheep and goats at the onset of the Holocene — the earliest direct evidence of these two subsistence practices reported in this region to date. These findings raise many questions concerning core and peripheral areas of independent economic innovation in western Eurasia, and draw attention to the compelling need for additional research into the role of ceramic technologies as a catalyst for a sedentary way of life in Central Asia following the last Ice Age.

[4]University Paris 6 - CNRS

Through bioturbation, macrobenthos is known to indirectly control the fate of sedimented organic matter including its mineralisation through early diagenetic processes. The diversity of macrobenthos and more specifically coastal macrobenthos is now at threat to the rise of a large variety of human-induced disturbances. The consequences of a decline of macrobenthos diversity on sedimented organic matter mineralization are still largely unknown. Up to now, they have been mostly studied through an experimental approach consisting in the *in vitro* assessment of mineralisation fluxes at the water-sediment interface in the presence of an increasing complexity of macrobenthic assemblages [1]. This approach has most often resulted in the determination of slight unpredictable effects. It suffers from major drawback including the fact: (1) that macrobenthos assemblages are reconstructed at random whereas species extinction does not, and (2) the importance of diversity relative to other potential controlling factors is not assessed.

We will present another possible approach consisting in assessing the effect of diversity by carrying out comparative *in situ* studies. In order to unravel the effects of possible confounding factors, it should be coupled with a hierarchical approach, which consists in considering that the intensity of mineralization results from the superposition of the effects of different types of ranked factors: first abiotic factors, second the quantity of organic matter, third the quality of organic matter, and only fourth macrobenthos diversity. This approach allows for the assessment of the relative importance of all main potential controlling factors given that co-correlation between them is properly handled. It requires studying a large variety of ecological/biogeochemical situations, which is currently achieved within the framework of the French National program BIOMIN.

This on-going project consists in an interdisciplinary study including the assessment of: (1) abiotic parameters, (2) sedimented organic matter quantitative (e.g., C and N) and qualitative (Chl *a* and EHAA) characteristics, (3) bioturbation (bioirrigation and sediment reworking), and (4) mineralization fluxes (oxygen and nutrients). It is carried out in five main ecosystems located along the French Metropolitan coast, namely: (1) the Rhône River prodelta, (2) the extremity of the dilution area of the Rhône River, (3) The Arcachon Bay, (4) the Garonne River prodelta, and (5) the Bay of Biscaye.

We will first report on preliminary results obtained within the Rhône river prodelta. Based on these results, we will then use the hierarchical approach described above to assess whether or not taking into account macrobenthos diversity enhances the description of mineralization fluxes by abiotic parameters and organic matter characteristics.

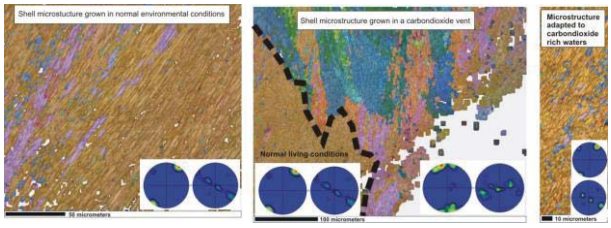
The sensitivity of *Mytilus* shell microstructure and geochemistry to environmental change

ERIKA GRIESSHABER[1]*; SABINE HAHN[2], ADRIAN IMMENHAUSER[2] AND WOLFGANG SCHMAHL[1]

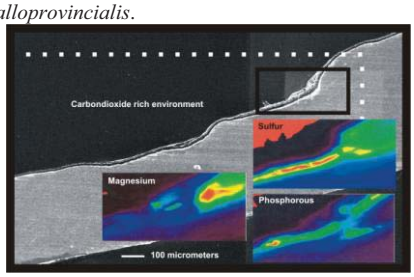
[1]Department of Earth and Environmental Sciences, LMU Munich, Germany, E.Griesshaber@lrz.uni-muenchen.de

[2]Institut für Geologie, Mineralogie, Geophysik, Ruhr-Universität Bochum, Germany,sabine.hahn@rub.de

Preservation of biological hard tissues offers unique opportunities for reconstructing environments of formation. Prerequisites for a precise reconstruction are the profound understanding of the studied biological material as well as their ability to record environment derived signatures. Even though bivalves are perfect archives for past environmental change they have not yet been used to interpret ocean acidification events. In a multianalytical approach combining microstructure imaging, crystallographic texture analysis and trace element geochemistry we investigated the microstructural and geochemical responses of *Mytilus galloprovincialis* shells to seawater acidification. Live specimens of *M. galloprovincialis* were transplanted from Ischia harbour (Mediterranean Sea) to nearby CO2 vents and exposed to mean seawater pH of 8.07 (harbor) and 7.25 (vent). The shells recorded the shock of transplantation and environmental change in both, their microstructure, texture (Figure 1), trace element (Figure 2) and carbon and oxygen isotope record [1]. We explore in this paper the potential of three different proxies within the same carbonate archive and test the potential of *Mytilus* to preserve in its shells acidified seawater conditions.



Figures 1. The shock of transplantation from normal to acid environmental conditions recorded in the microstructure and texture of *Mytilus galloprovincialis*.



Figures 2. The transplantation from normal to an acid environment is manifested in the shells ultrastructure and in its major and minor element chemical variation.

Coal-to-gas: Uncertainty in CH_4 emissions and climate impacts

W. MICHAEL GRIFFIN[1*] AND STEFAN SCHWIETZKE[2]

[1]Carnegie Mellon University, Tepper School of Business, Engineering and Public Policy, wmichaelgriffin@cmu.edu (* presenting author)

Section Heading

Increasing the use of natural gas (NG) for power generation and other industrial purposes is perceived as an part of a portfolio to decarbonize the domestic and global economy. While many studies indicate greenhouse gas (GHG) emissions reductions from NG production and use relative to coal [1], the potential climate benefits remain largely uncertain and depend on three main factors. First, CH_4 emissions from NG production, distribution and use are uncertain, and some estimates eliminate the overall GHG reductions [2]. Second, the combined climate response due to direct and indirect radiative forcing from GHG and aerosol emissions remains to be quantified [3]. Third, the rate of a potential coal-to-gas transition can influence future temperature change trajectories [4], and has not been analyzed in detail.

Our analysis addresses these issues by combining data and models from life cycle assessment (LCA), an emissions accounting tool, and climate science. We determine a reduced range of possible life cycle CH_4 emissions through comparison with atmospheric observations and modeling results from the literature. Methods to generate these top-down estimates include a combination of (a) measuring CH_4 concentrations from a global observation network, (b) employing atmospheric emissions transport models, and (c) measuring CH_4 isotope ratios to distinguish emissions sources [5]. We further establish coal-to-gas transition scenarios based on constraints for resource availability and industry development. A probabilistic climate model is used to translate the emissions distributions and scenarios into temperature change trajectories. The model accounts for uncertainty in the magnitude of aerosol forcing and climate feedbacks, which represent low probability and high impact events [6].

Results and Conclusion

Preliminary results show that CH_4 emissions estimates can be significantly constrained. For example, over a 10-year period the upper bound life cycle CH_4 emissions overestimate observed absolute emissions by 75-100%. In terms of climate impacts, the degree to which lower CO_2 and aerosol emissions from reduced coal combustion compensate for higher CH_4 emissions due to higher NG varies depending on the transition scenario. Work in progress investigates the probability of each scenario to cross the policy relevant 2 degree celsius temperature threshold.

Context and Results

A U-Pb/Hf-isotope study of >16,000 zircons from sources worldwide has demonstrated that at least 70% of Earth's continental crust probably formed in Archean time [1], and much probably is >3 Ga old. The model-age (T_{RD} and T_{MA}) distributions of ca 500 low-Re sulfides in mantle-derived peridotite xenoliths, mainly from the Kaapvaal, Siberian and Slave cratons, peak between 2.5-3.0 or 3.0-3.5 Ga, depending on locality. In detail, at each locality the oldest T_{MA} model ages from the mantle sulfides correlate well with the oldest U-Pb ages and Hf model ages from crustal zircons. Younger T_{MA} peaks commonly coincide with later major crustal events.

The sulfides in mantle xenoliths are secondary phases, and Os model ages probably are biased toward young ages. Most of the studied sulfides are from garnet-bearing peridotites, and garnet is generally a secondary phase in these rocks [2]. In Siberian xenoliths, model ages of sulfides included in garnet are younger on average than those of sulfides included in olivine. However, detailed searches of the most depleted peridotites available have thus far revealed very few sulfides with model ages >3.5 Ga, just as the oldest widespread crustal ages are around 3.5 Ga.

Conclusions

These data suggest that the oldest crust and the oldest, highly depleted SCLM are broadly coeval, and are interpreted as forming during massive mantle overturns that produced the residual Archean SCLM, providing buoyant "life rafts" that ever since have supported and preserved the continental crust. The 3.5 Ga overturn event changed Earth's fundamental tectonic behaviour, and truly marks the end of the Hadean period

Investigating controls on calcium isotope ratios in marine carbonates and barite across the Paleocene-Eocene Thermal Maximum

ELIZABETH M. GRIFFITH[1*], MATTHEW S. FANTLE[2], THOMAS D. BULLEN[3], ANTON EISENHAUER[4], AND ADINA PAYTAN[5]

[1]Kent State University, Kent, USA, egriffi9@kent.edu (* presenting author)

[2]Pennsylvania State University, University Park, USA, mfantle@psu.edu

[3]U.S.Geological Survay, Menlo Park, USA, tdbullen@usgs.gov

[4]IFM-GEOMAR, Kiel, Germany, aeisenhauer@geomar.de

[5]University of California, Santa Cruz, USA, apaytan@ucsc.edu

The stable calcium isotopic composition of seawater can be controlled over million-year time scales by the relative fluxes of Ca into and out of the ocean, given knowledge of the isotopic compositions of these fluxes. Ocean acidification, such as occurred at the Paleocene-Eocene Thermal Maximum (PETM), should perturb the riverine input of Ca relative to Ca output as pelagic $CaCO_3$. We therefore expect coincident variability in the Ca (and C) cycles that should be evident in the Ca isotope record. Yet environmental and post-depositional factors can affect the isotopic composition of a recording phase resulting in values inconsistent with changes in seawater Ca isotopic composition. This study measures Ca isotopes in marine barite and bulk carbonates over the PETM in order to evaluate their use as recorders of seawater $\delta^{44}Ca$.

This study reports high temporal resolution (~25 ka) Ca isotopic compositions ($\delta^{44}Ca$, relative to Bulk Earth) of bulk marine carbonates and coeval marine pelagic barite from ODP Leg 199 Site 1221C (Equatorial Pacific) and bulk carbonates from ODP Leg 198, Site 1212B (Shatsky Rise). The study also reports $CaCO_3$ content and bulk carbonate $\delta^{13}C$ and $\delta^{18}O$ for 1221C and 1212B. The marine barite Ca isotope record decreases by 0.3‰ after the benthic extinction event (BEE), increases to a maximum (-0.7‰) as $CaCO_3$ accumulation rates peak, and returns to values near modern day (-1.3‰) <100 ka after the BEE. Interestingly, bulk carbonate $\delta^{44}Ca$ values are distinct from the barite record. At Site 1221C, carbonate $\delta^{44}Ca$ increases just after the barite $\delta^{44}Ca$ drop and stays high (~0.4‰) until the barite record returns to near modern $\delta^{44}Ca$ values. Sediments at 1221C decrease to near zero $CaCO_3$ accumulation at the BEE, strongly suggesting that dissolution occurred. By comparison, the 1212B core has high $CaCO_3$ content (80-98%) over this interval and exhibits trends that are similar to the 1221C marine barite record but vary in absolute magnitude.

One hypothesis to explain the observed differences is that post-depositional diagenetic reactions (dissolution/recrystallilzation) in the sedimentary column influence the measured $\delta^{44}Ca$. Alternately, it is possible that variations in local Ca cycling can explain the differences in the carbonate and barite records. We will explore both hypothesis using numerical models and various data.

A high-resolution paleoclimate reconstruction using C and N isotopes in a subarctic environment, northern Canada

FRITZ GRIFFITH[1*], IAN CLARK[1], TIM PATTERSON[2], ANDREW MACUMBER[2], JENNIFER GALLOWAY[3], AND HENDRIK FALCK[4]

[1]University of Ottawa, Dept. of Earth Sciences, Ottawa, Ontario, Canada, fgrif103@uottawa.ca (* presenting author)
[2]Carleton University, Dept. of Earth Sciences, Ottawa, Ontario, Canada
[3]Geological Survey of Canada, Calgary, Alberta, Canada
[4]Northwest Territories Geoscience Office, Yellowknife, Northwest Territories

The Tibbitt-to-Contwoyto Winter Road (TCWR) is the sole overland route servicing diamond mines north of the city of Yellowknife, Northwest Territories (NWT), Canada. Because the majority of the TCWR traverses frozen lakes, late freezing or early thawing of these lakes can drastically shorten the transportation season, imparting significant economic consequences on mining operations. Such was the case in 2006, when a warm and stormy winter season associated with an El Niño Southern Oscillation (ENSO) event resulted in a significant and costly reduction of shipments to the mines. As the use of the TCWR is projected to increase in the coming years, planners and policy makers require a sound scientific understanding of past regional climate variability upon which to base their development strategies. Previous research has been valuable in gaining a broad understanding of regional long-term climate change; however, no research has provided a climate record with a resolution high enough to identify medium- to short-term climate phenomena that might be affecting this region (e.g. sub-decadal ENSO cycles and the decadal-scale Pacific Decadal Oscillation [PDO]).

This study is an integral component of a larger-scale study designed to develop a comprehensive database of high-resolution paleoclimate data for the NWT, using a variety of proxies. As part of the larger study, freeze cores were taken in 2010 from 10 lakes along the TCWR and sliced at 1-mm intervals using a custom-designed freeze core microtome. We report here the results of preliminary bulk ^{13}C and ^{15}N isotope analyses, taken at 1-cm intervals throughout the Danny's Lake and Horseshoe Lake cores. Higher-resolution analysis is underway for sections of the Danny's Lake core in order to identify short-term climate cycles. Additionally, C and N isotopic compositions are currently being analysed for surface sediment samples of over 90 lakes scattered along a latitudinal gradient throughout the NWT. These data will be used to create a paleoclimatic transfer function, which will correlate spatial variations in isotope values to climate parameters, and provide a means of using temporal variations in these isotopes down-core to quantitatively reconstruct past climate change.

Preliminary results from the Danny's Lake core show clear trends in isotopic compositions for both C and N isotopes and suggest distinct stages of lake evolution. Previous to 6700 BP, there are large long-term fluctuations in isotope values, which may be related to significant variations in vegetation or lake water levels. At 6700 BP, a sudden change in trends, as well as a sharp colour change in the sediment, suggest a significant and abrupt shift in lake dynamics, the source of which is currently under investigation. A positive correlation between the C/N ratio, %C, and %N from 6700-4000 BP suggests an increase in terrestrial organic matter input to the lake. This increase stops at 4000 BP and is stable to the present. Comparison of these preliminary results to the paleoclimatic transfer function will provide greater insight into the causes of these trends.

Influence of mineral surfaces on Re speciation in sulfidic porewaters

LAURA M. GROSKREUTZ[1*] AND TRENT P. VORLICEK[1]

[1]Minnesota State University, Mankato, Minnesota, USA, laura.groskreutz@mnsu.edu (*presenting author) trenton.vorlicek@mnsu.edu

Introduction

The thioperrhenate anions may be important species in the chemical pathway to Re deposition within sulfidic waters. Thioperrhenate formation reactions may be written:

$$Re^{VII}O_4^-{}_{(aq)} + nH_2S_{(aq)} \rightleftharpoons Re^{VII}O_{4-n}S_n^-{}_{(aq)} + nH_2O_{(l)}\ (n = 1\text{-}4)$$

Because of their immense areas and hydrated properties, oxide surfaces are known to influence various environmentally relevant reactions within porewaters of soils and sediments [1,2]. Mineral catalysts have been shown to greatly enhance the rate of thiomolybdate reactions [1]. To test the conjecture that thioperrhenate reactions are also catalyzed by oxide surfaces, solutions were prepared to contain 0 to 10 g/L δ-Al_2O_3, 10 µM ReO_4^- and10 mM ΣS^{2-} at pH = 7.0. ReO_4^- remaining in the filtered solutions after 0.2 and 22 days was quantified using ion chromatography (IC) with suppressed conductivity detection.

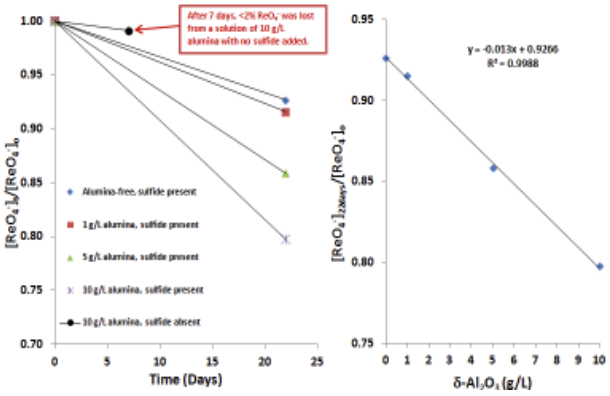

Figure 1: Left: loss of ReO_4^- from test solutions over time. Right: loss of ReO_4^- after 22 days as a function of δ-Al_2O_3 mass loading.

Conclusion

The left panel of the figure shows an increasing rate of ReO_4^- loss as the mass loading of δ-Al_2O_3 increases. Closed circles indicate <2% of initial ReO_4^- is lost from analogous sulfide-free suspensions; observed losses in the sulfidic suspensions cannot be due to adsorption of ReO_4^-. The right panel shows the loss of ReO_4^- after 22 days exhibits linearity with increasing mass loading. These data demonstrate that δ-Al_2O_3 enhances the rate of a sulfidation reaction(s) involving ReO_4^-. Further inquiry is required for definitive identification of reaction product(s). These results may help to explain observations that Re removal only occurs below the sediment-water interface in temporally anoxic basins, even when the overlying water column is also sulfidic [3].

Mechanisms of subglacial groundwater recharge as derived from noble gas, ^{14}C, and stable isotopic data

TIM GRUNDL[1*], NATHAN MAGNUSSON[1], MATTHIAS BRENNWALD[2], ROLF KIPFER[2]

[1*] University of Wisconsin-Milwaukee, Geosciences Department, Milwaukee, USA
[2]EAWAG, Swiss Federal Institute of Aquatic Science and Technology, Duebendorf, Switzerland

Major ion, noble gas, stable isotope and ^{14}C data collected from a transect along groundwater flow path within a confined Paleozoic aquifer in northeastern Wisconsin, USA are used to deduce the effect of the Laurentide Ice Sheet (LIS) on the underlying aquifer. Major ion trends, ^{14}C ages and $\delta^{18}O$ derived temperatures that decrease to -5.6 ºC during the last glacial maximum (~10 kyr. B.P. to ~26 kyr. B.P.) indicate that recharge continued when ice covered the area. A $\delta^{18}O$ derived temperature record that extends well below freezing, a contrasting noble gas temperature record that remains constant at ~3º C (Figure 1), high excess air (ΔNe) values

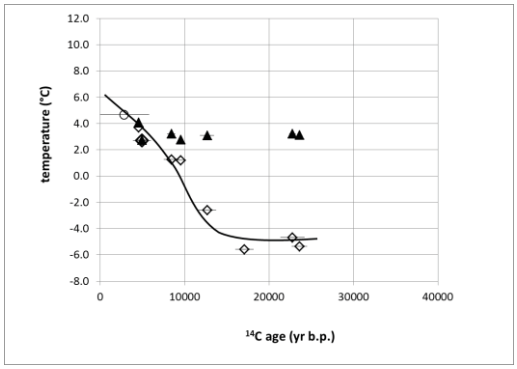

Figure 1: Oxygen isotope temperature (open diamonds) and noble gas temperatures (solid triangles) versus corrected ^{14}C ages.

and strong noble gas fractionation patterns indicate that supraglacial melt was the dominant constituent of aquifer recharge. Recharge occurred within the ice sheet as a part of a very dynamic englacial hydrologic system that experienced recharge heads of as much as 7.8m. Comparisons to a similar transect taken 150 km to the south [1] show different recharge mechanisms occurring near the terminus of the ice sheet. To the author's knowledge this is the first time that noble gas and isotope tracers have been used to deduce the mechanism of aquifer recharge beneath continental ice sheets.

Enrichment of Li in fluids exsolved from the Harney Peak leucogranite Black Hills, South Dakota

MARK L. GRZOVIC[1*] AND PETER I. NABELEK[1]

[1]Department of Geological Sciences, University of Missouri-Columbia, Columbia, MO, USA, mlg6wc@mail.missouri.edu (* presenting author)

Fluid inclusions provide a way to directly sample the composition of magmatic fluids and are therefore a key to investigating the role of fluids in differentiation of magmas and element mobility within plutonic systems. Laser ablation (LA) ICP-MS analysis and microthermometry were used to determine quantitatively the chemical compositions of individual fluid inclusions in the Harney Peak granite-pegmatite (HPG) system in South Dakota. HPG has a simple mineralogy, it has had no interaction with meteoric fluids and it has not been metamorphosed [1]. In the HPG system, magmatic fluids were key to development of pegmatitic segregations and a broad field of Li-bearing pegmatites. Moreover, Wilke et al. [2] attributed an enrichment of Li in the metamorphic aureole of the HPG to expulsion of Li-bearing fluids from the HPG. The objective of this study was to determine the composition of the putative magmatic fluids in order to evaluate their potential role in the differentiation of the HPG and development of the pegmatite field and metasomatic aureoles.

All analyzed fluid inclusions were hosted in quartz. Types of inclusions are: type 1 (H_2O-CO_2+salts), type 2 (H_2O+salts), type 3 (CO_2-rich) [3]. Concentrations of Li, B, Na, K, Rb and Cs were measured by LA-ICP-MS. Raw data were reduced using the AMS data reduction software [4].

Results indicate elevated concentrations of alkali elements in the fluid inclusions. The inclusions are primarily composed of Na (up to 25.7 wt.%), K (up to 0.8 wt.%) and Li (up to 0.9 wt.%), but also contain minor concentrations of Rb (≤0.01 wt.%) and Cs (up to 0.05 wt.%). Initial analysis also suggests a significantly higher Li concentrations is secondary type 2 inclusions compared to primary type 1 inclusions. Secondary type 2 inclusions on average have concentrations of 0.3 wt.% Li whereas primary inclusions contain less than 0.1 wt.%. This suggests that these elements were concentrated in the magmatic fluid when it seperated from the HPG magma, and that Li was further concentrated in the aqueous fluid when the magmatic fluid unmixed into carbonic and aqueous fractions.

Li is important in pegmatite formation as at elevated concentrations it can reduce the viscosity of a magma and inhibit crystal nucleation, leading to the crystalization of few large crystals [5]. The results suggest that Li in magmatic fluid was important in the formation of the pegmatite field and the metasomatism of the aureole.

KAOLINITE PRECIPITATION RATES AT PH 4 AND 25 °C.

S. GUDBRANDSSON [1], V. MAVROMATIS[2], Q. GAUTIER[3], N. BOVET [4], J. SCHOTT[5] AND E.H. OELKERS[6]

[1] GET, CNRS/UMR 5563-Université Paul Sabatier, Toulouse, France, snorgud@hi.is (*),[2] GET, CNRS/UMR 5563-Université Paul Sabatier, Toulouse, France, mavromat@get.obs-mip.fr, [3] GET, CNRS/UMR 5563-Université Paul Sabatier, Toulouse, France, gautier@get.obs-mip.fr, [4] Nano-Science Center, Department of Chemistry, University of Copehagen, Denmark. bovet@nano.ku.dk,[5] GET, CNRS/UMR 5563-Université Paul Sabatier, Toulouse, France,schott@get.obs-mip.fr, [6] GET, CNRS/UMR 5563-Université Paul Sabatier, Toulouse, France, oelkers@get.obs-mip.fr

This study focuses on the precipitation rates of kaolinite ($Al_2Si_2O_5(OH)_4$), a common low temperature secondary clay mineral forming during silicate rocks weathering. To date a number of studies have reported kaolinite dissolution rates (1, 2, 3, 4) but far fewer precipitation rates have been reported (1, 2, and 4). Rates were measured at pH 4 and 25 °C as a function of saturation state using low defect Georgia kaolinite, KGa-1b, as seeds in constant volume mixed flow reactors. Precipitation was induced by injecting into the reactor at similar rates two separate aqueous solutions, one Al-rich and one Si-rich. All fluids were fixed to ionic strength of 10 mM using NaCl. Reactive fluids were sampled daily, keeping the volume in the reactor constant. Sampled fluids were filtered and analyzed for Si and Al concentration. Solids recovered after all experiments exhibit identical X-ray diffraction patterns compared to those of the initial seed. Similar results were observed for the Al/Si surface ratio of these solids as measured by XPS. These observations demonstrate that the only mineral phase precipitating in our experiments was kaolinite. Furthermore, precipitation rates obtained from aqueous Si concentrations are closely consistent with those obtained from aqueous Al concentrations. Measured rates exhibit a systematic variation, increasing linearly with the square root of the kaolinite saturation index (see Fig.). This behaviour, consistent with TST-derived rate laws, indicates that kaolinite growth is controlled by the simple incorporation of Al and SiO_2 at the numerous growth sites (likely crystal edge sites) present at kaolinite surface.

1.1 Billion-years-old biomarkers from a microbial mat

NUR GUENELI[1*], ERIC LEGENDRE[2], AND JOCHEN J. BROCKS[1]

Biomarkers and the Proterozoic

Molecular fossils, or biomarkers, are altered biogenic compounds that can be preserved in the geological record for hundreds of millions of years and assigned to specific precursor molecules. Therefore, biomarker analysis makes it possible to assess major groups of organisms that contributed organic matter to ancient microbial communities. The mid-Proterozoic interval, ~1.8 Ga to 0.8 Ga ago, comprises major steps in the evolution of life and Earth chemistry. However, in a re-appraisal of published biomarkers from this period, we only found indigenous bitumens in 9 geological basins, and only 3 fall into the age bracket 1.4 Ga to 0.9 Ga; the 1.2 Ga Hongshuizhuang Fm. N China [1], the 1.1 Ga Taoudeni Basin, NW Africa [2] and the 1.0 Ga Nonesuch Fm., NE USA [3]. Here, we present a detailed study of biomarkers from microbial mats in the Taoudeni Basin.

Mat biomarkers of the 1.1 Ga Taoudeni Basin, NW Africa

The shales of the Taoudeni Basin belong to an organic-rich mat facies [2]. We found TOC levels as high as 16%, and Rock Eval parameters reveal low thermal maturity. *n*-Alkanes range from C_{12} to C_{37} with a maximum at C_{17}. Pristane and phytane are present but we did not detect any higher acyclic isoprenoids. Hopanes are abundant, including 3β-methylhopanes, although concentrations of 2α-methylhopanes were very low. Even though the mats contain simple fossils of eukaryotic orgin, diagnostic eukaryotic steranes were not detected. However, we found triaromatic steroids of possible methanotrophic bacterial origin. Most significantly, we detected aryl isoprenoids with distinct substitution patterns. These biomarkers together describe a shallow-water microbial mat community that was presumably inhabited by oxygenic cyanobacteria, anoxygenic phototrophic purple (Chromatiaceae) and green (Chlorobiaceae) sulphur bacteria, as well as methanotrophic bacteria. The biomarker assemblage is very similar to biomarkers from the 1.64 Ga Barney Creek Formation (BCF) in northern Australia [4], which has been described as an euxenic deep water environment. However, this new data suggests that it may instead represent a shallow water habitat harbouring microbial mats.

Our results represent the oldest direct observation of the complexity of Precambrian microbial mat ecosystems.

Chemical-hydrodynamic control of arsenic mobility at a river confluence

PAULA GUERRA[1], CHRISTIAN GONZALEZ[1], CRISTIAN ESCAURIAZA[1], CARLOS BONILLA[1], GONZALO PIZARRO[1], PABLO PASTEN[1*]

[1]Pontificia Universidad Catolica de Chile, Santiago, Chile, ppasten@ing.puc.cl (* presenting author)

River confluences are natural reactors where key process controlling the fate of contaminants at different scales occur. A better understanding of the interactions between biogeochemical reactions and the hydrodynamics of a river confluence may lead to innovative strategies for contaminant risk evaluation and management.

The Lluta river is a precious water resource for Arica y Parinacota in northern Chile, an extremely arid region. Although the construction of a dam is being planned to increase water availability, the likely accumulation of arsenic-rich iron oxyhydroxides in the dam sediments has prompted careful analysis from environmental authorities and the local scientific community. The main source of As-rich fine particles is the confluence between two rivers in the Chilean Altiplano, the Caracarani and the Azufre river, thus making it a perfect natural laboratory to study interactions between biogeochemical reactions and hydrodynamics.

We performed field and laboratory studies to characterize the chemistry and hydrodynamics at this confluence. After mixing of the Caracarani (pH=8; Fe, As<0.1 mg/L, low turbidity, Q~150L/s) and the Azufre river (pH=2, Fe=80 mg/L, As=2 mg/L, low turbidity, Q=50 L/s), a highly variable spatial distribution of pH and turbidity was found within the first 300m downstream of the confluence. Characteristic light-brown fine particulate material was found in stagnant areas with varying As concentrations up to 600 mg As/kg sediment for low flows. We reproduced the mixing of these waters at different velocities using jar-test type of experiments. Although the production of fine oxyhydroxides was also observed, the concentration of arsenic in the flocculated material (particles >0,45 um) was remarkably lower (<50 mgAs/kg of sediment) compared to the natural flocs. Furthermore, we found that the mixing velocity is a critical parameter determining the As sequestration potential by te oxyhydroxides.

Acoustic Doppler velocimetry at the confluence showed spatially variable turbulence intensities at the streamwise and across-stream directions, producing heterogenous distribution of particulate material on the river bed. Fresh flocs are thus exposed to varying chemical environments and hydrodynamic turbulent stresses determining arsenic sorption, floc formation, and floc strength. At larger time and spatial scales, flow characteristics during flood and drought seasons are likely to determine the formation/mobilization of arsenic repositories within the watershed.

Abstract

Metamorphic core complexes are ubiquitous features in orogenic belts around the world and offer exceptional opportunities to investigate the rheological and thermal characteristics of the middle crust during orogenesis. The Clearwater metamorphic core complex in northern Idaho, U.S.A. exposes some of the deepest rocks in the Cordilleran orogen and records a complicated polymetamorphic history starting in the Paleoproterozoic, with the youngest high-grade metamorphism resulting from late Cretaceous Sevier crustal thickening.[1, 2, 3] Categorization of the Clearwater complex as a core complex has recently been confirmed based on structural data, thermobarometric data, and $^{40}Ar/^{39}Ar$ cooling ages, all of which suggest rapid Eocene exhumation of regionally metamorphosed mid- and lower-crustal rocks within the complex.[1, 3] Despite these data, the structural and thermal evolution of the Clearwater complex during Eocene exhumation remains cryptic.

The Clearwater complex is comprised of two lithologically and structurally distinct zones: an internal zone comprised of basement schist, gneiss, and anorthosite, and an external zone with both Archean to Paleoproterozoic basement and metapelitic rocks of the overlying Mesoproterozoic Belt Supergroup.[1, 4] These zones are bound by conjugate sets of E- and W-verging normal faults. The geological significance of these faults is unclear. This paper integrates new $^{40}Ar/^{39}Ar$ muscovite and biotite cooling ages along an E-W transect across the Clearwater complex with respect to major extensional structures, 1:24,000-scale mapping, microstructural analysis, and metamorphic phase equilibria modelling in order to constrain the structural and thermal evolution of the Clearwater complex from maximum crustal thickness to Eocene gravitational collapse of the Sevier orogenic belt.

SCAVENGING OF ^{230}TH AND ^{231}PA AT THE BERMUDA RISE

ABEL GUIHOU[1*], J. KIRK COCHRAN[1], DAVID BLACK[1]

[1] School of Marine and Atmospheric Sciences, Stony Brook University, Stony Brook, NY 11794 USA, abel.guihou@stonybrook.edu (* presenting author)

Abstract

The Bermuda Rise is a site of great paleoceanographic interest due to its high sediment accumulation rates, due in part to intense lateral advection. The particle-reactive U-series nuclides ^{230}Th and ^{231}Pa have been used at the Bermuda Rise and elsewhere as tracers of ocean circulation (e.g. AMOC), but their use is complicated by the influence of particle composition on the scavenging of these radionuclides. The recently initiated Bermuda Rise Flux Project (BaRFlux) offers an opportunity to resolve some of the processes controlling the delivery of ^{230}Th and ^{231}Pa to the seafloor. BaRFlux aims to better constrain the sedimentation process at the Bermuda Rise through sampling filterable particles in the water column as well as sinking particles caught in sediment traps. We have deployed a mooring consisting of 10 sediment traps, with two traps each at water depths of 300, 1000, 1500, 2500 and 4200 meters. Each depth has a trap collecting particles as a function of time and a trap separating particles in situ according to their settling velocity. The sediment trap mooring is turned around ever 3 months. Seawater samples also have been taken to characterize the distributions of ^{230}Th and ^{231}Pa in the water column. This contribution will present preliminary results on the effects of particle flux, particle sinking velocity and lateral advection on the scavenging of ^{230}Th and ^{231}Pa from the water column to the sediment at this site.

Understanding gas dynamics in unsaturated fractured granite using SF_6, CO_2, Rn and other noble gases.

S. GUILLON[1,2*], E. PILI[1,2], J.-C. SABROUX[3], P. AGRINIER[2]

The Roselend Natural Laboratory

In the Roselend Natural Laboratory (French Alps), a tunnel provides access to the heart of unsaturated fractured crystalline rocks at 55 m depth below ground surface (Figure 1). This underground research facility allows studying gas transfer between a 60 m^3 chamber isolated at the dead-end of the tunnel and vertical and horizontal boreholes at the surface. Transport properties were determined at various scales using these boreholes and chamber.

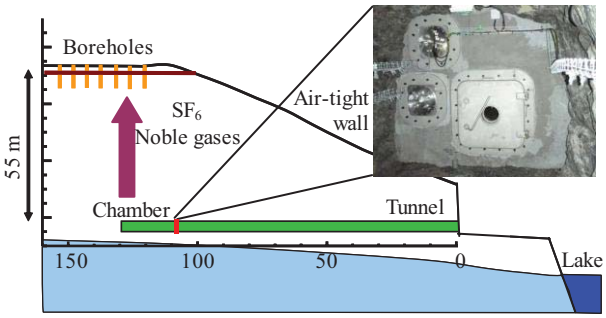

Figure 1: Setting of the Roselend Natural Laboratory, near the artificial Roselend lake, with the isolated chamber and boreholes.

Experimental and numerical results

We carried out a field-scale tracing experiment using SF_6 with the aim to serve for a forthcoming experiment using helium-3 and other noble gases. SF_6 was injected in the isolated chamber at 150 mbar above atmospheric pressure during 2 hours. SF_6 breakthrough was detected after only 10 hours at the ppb level in several surface boreholes, consistent with advective transfer in major fractures. SF_6 concentration in the surface progressively increased up to 30 ppm, and started to decrease 4 months after injection, indicating slow migration in the porous matrix.

^{222}Rn and CO_2 (concentration and $\delta^{13}C$) are monitored on the long term in the tunnel and at the surface. These gases are naturally produced by the rock. Air without tracer repeatedly injected from the chamber is able to flush large amounts of these gases out of the porosity.

These experiments are used to better understand gas dynamics and residence time in this dual porosity medium, in response to natural solicitations (meteorological, biological, geochemical, mechanical) and particularly barometric pressure fluctuations and variable water saturation. Numerical modeling is presented to account for the driving processes deduced from observations.

TTG Lu-Hf isotope evidence for a deep mantle-continental crust connection

M. GUITREAU[1,2]*, J. BLICHERT-TOFT[1,2], H. MARTIN[3], S.J. MOJZSIS[2,4] AND F. ALBARÈDE[1,2]

[1] Ecole Normale Supérieure de Lyon, 69007 Lyon, France (*presenting author: martin.guitreau@ens-lyon.fr)

[4] University of Colorado, Boulder, CO 80309, USA

The principle that growth of continents depletes the upper mantle from its most fertile fraction goes back several decades [1,2]. A widely held tenet is that continental crust grows either by melting of oceanic crust [3,4] or by fluxing the mantle wedge above subduction zones [5]. An alternative view holds that continents form through magmatic processing at subduction zones, not of regular oceanic crust, but of oceanic plateaus [6,7]; this would account for the apparent episodic character of crustal growth [8]. The present work reports MC-ICP-MS Lu-Hf isotope data for a large collection of Archean granitoids belonging to typical TTG (Tonalite-Trondhjemite-Granodiorite) suites. Both the whole-rock and zircons were analyzed, and the results are discussed in the broader context of the extensive literature database on Hf isotopes in zircons. Our results demonstrate that the Lu/Hf ratio of the mantle source of TTGs has not significantly changed over the last 4 Gyr. Continents therefore most likely grew from nearly primordial unfractionated material extracted from the deep mantle via rising plumes that left a depleted melt residue in the upper mantle. The deep mantle could retain its primitive relative element abundances over time because sinking plates are stripped barren of their oceanic and continental crustal components at subduction zones; this process results in only small proportions (<15-25%) of present-day continental mass getting recycled to great depths. Zircon populations extracted from the analyzed TTGs have Hf isotopic compositions very consistent with those of their host whole-rocks, whereas the U-Pb system in the same grains is often disturbed. This discrepancy creates spurious positive correlations with age when variable initial ε_{Hf} values are determined. The problem is endemic to the Archean detrital zircon record and consistent with experimental results bearing on the relative retentivity of Hf vs. U and Pb in zircon [9]. We argue that this behavior accounts for the generally negative ε_{Hf} values reported for Archean zircons and which are at odds with the present TTG data set. If Hadean Jack Hills zircons are considered in light of our results, the mantle source of continents appears to have remained unchanged for the last 4.3 Gyr.

Phase Equilibria constraints on the origin of the Peridot Mesa basanite

Amber Gullikson[1], Gordon Moore[2*], Kurt Roggensack[1]

[1] Arizona State University, School of Earth and Space Exploration, Amber.gullikson@asu.edu, Kurt. Roggensack@asu.edu
[2] University of Michigan, Department of Earth and Environmental Sciences, Gordon.moore@asu.edu*

Peridot Mesa is well-known for its gem quality peridot (Wrucke et al. 2004) and xenoliths of spinel-bearing peridotite (Frey and Prinz, 1978). Little is known of the lava that brought these mantle xenoliths to the surface however. The purpose of this study was to gain a better understanding of the origins of alkali basalts, and in particular the pre-eruptive conditions of the Peridot Mesa basanite. Phase equilibria experiments were performed on the Peridot Mesa basanite, over a range of various pressures, temperatures, and volatile content.

The phenocryst assemblage of the Peridot Mesa basanite is clinopyroxene, olivine, plagioclase, and spinel. An important feature of this lava is the presence of two phenocrystic olivine compositions. The first population is Mg-rich (Fo 73-80), and averages in size from 20-100 microns, and does not appear to have been in equilibrium at the time of eruption. The observation of prominent diffusion rims, re-equilibrating to a higher Fe content around the outer portion of the crystal supports this conclusion. The second olivine group has a lower Mg content, ranging between Fo 65-69. This population of olivine is 4-10 microns in size, with a less common, reversed zoning, making the rim slightly more Mg-rich (Fo 70). The presence of two compositionally different olivine phenocrysts can possibly be explained by a magma mixing event that occurred just before eruption, although these features are not seen in any of the other phenocryst phases.

In order to replicate the natural phase assemblage and determine magma conditions prior to eruption, a series of phase equilibria experiments were performed using a 1-atm Deltech furnace and a non-end loaded piston cylinder. The starting material for all runs was made by melting the natural sample at 1 atm and an oxygen fugacity of NNO, and quenching to a glass to ensure homogeneity. For the high P runs, glass chips were sealed in an AuPd capsule and run under anhydrous, CO_2-rich, or H_2O under-saturated conditions, ranging between 1050°C-1250°C and 0.1 MPa up to 2 GPa of pressure. The majority of H_2O under-saturated experiments contained 2wt% H_2O or less, with a few runs conducted at 5 wt% added H_2O.

Despite numerous experiments performed at a wide range of conditions, the mineral assemblage of this lava has yet to be reproduced experimentally. Plagioclase, a ubiquitous mineral in the Peridot Mesa lava, has failed to crystallize in any experiment. Significant temperature, pressure, and volatile constraints have been placed on the basanite by the presence of hydrous minerals, and the stability of olivine and clinopyroxene. Samples run under pressures greater than 500 MPa, and temperatures cooler than 1150°C crystallized phlogopite and amphibole minerals readily, neither of which are found in the lava. Also, olivine phenocrysts only occurred at temperatures 1100°C or cooler, and the amount of water present in the system is restricted by the appearance of hydrous minerals and/or the lack of olivine and clinopyroxene.

Phase equilibria experiments on the Peridot Mesa basanite have provided insight into the poorly understood history of this alkali basalt. The fact that hydrous minerals are present at 500 MPa or greater in pressure, even in anhydrous runs, leads to the conclusion that the phenocrysts formed under low pressure and low-H_2O content conditions. The stability of olivine also requires crystallization temperatures at or below 1100°C. The observation of two olivine populations in the natural sample, and the fact that plagioclase could not be reproduced in the lab, supports the possibility of magma mixing and a complex origin and eruption history for this lava.

A new strategy for the production of homogeneous standards for microbeam techniques

DETLEF GÜNTHER[1]*, DANIEL TABERSKY[1], NORMAN A. LUECHINGER[2] AND SAMUEL C. HALIM[2]

[1]ETH Zurich, Department of Chemistry and Applied Biosciences, Laboratory of Inorganic Chemistry
(*correspondence: guenther@inorg.chem.ethz.ch)
[2]Nanograde, Wolfgang-Pauli-Str., P/O 239, 8093 Zurich, Switzerland

The glass series of NIST 61x have been the major standard materials particularly useful for quantification for laser ablation – inductively coupled plasma mass spectrometry (LA-ICP-MS) [1]. However, heterogeneities have been reported in some sample charges [2]. Furthermore, geologically important elements such as Ti, Fe, and Mg are very low in concentration; platinum group elements (PGE) are either absent in these materials or present in very low concentrations. Therefore, alternative methods for the production of standard materials were investigated with the aim to extend quantifiable elements in the NIST glass series, in particular the PGEs, and to provide materials which overcome the reported heterogeneities.
A novel approach now provides standard materials with heterogeneities in the size range of 20-50 nm. This approach further provides PGE concentrations in the range of 500 mg/kg; multiple analyses of these novel standard materials confirm a RSD for PGEs in the order of 1-3 %.

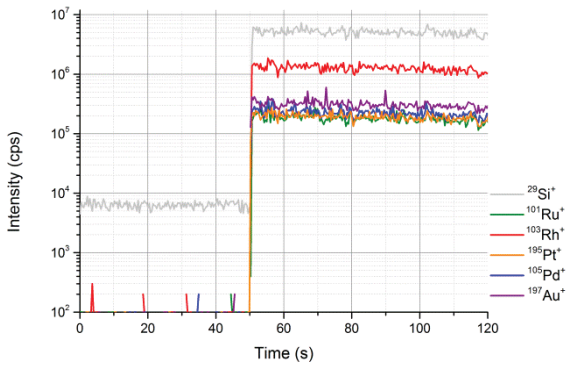

Figure: Transient LA-ICP-MS of the PGE-doped silicate.

The glass series NIST 61x and the newly synthesized materials provide identical ablation characteristics. The setup of production, preliminary results and first figures of merit will be discussed.

^{13}C-^{18}O bonds in dissovled inorganic carbon: Toward a better understanding of clumped isotope thermometer in biogenic carbonates

WEIFU GUO[1*], SANG-TAE KIM[2], JIE YUAN[3], JAMES FARQUHAR[4], BENJAMIN H. PASSEY[5]

[1]Woods Hole Oceanographic Institution, Woods Hole, MA, USA wfguo@whoi.edu (* presenting author)

[4]University of Maryland, College Park, MD, USA
[5]Johns Hopkins University, Baltimore, MD, USA

Application of the 'clumped isotope' thermometer in biogenic carbonates yields invaluable information regarding paleotemperatures [1]. Most biogenic carbonates analyzed so far appear to be free of clumped isotope vital effects [1], except for some surface corals [2,3]. This constrasts against ubiquitous oxygen isotope vital effects in biogenic carbonates, and potentially consitutes another advantage of clumped isotope thermometer. To better understand the incorportation of clumped isotope signals in biogenic carbonates, we present new experimental and theoretical constraints on equilibrium and kinetic clumped isotope fractionations among different dissovled inorganic carbon (DIC) species.

Sodium (bi)carbonte solutions of different pH were prepared and equilibrated at 25°C and 50°C, and the DIC species in each solution were then quantitatively precipitated as barium carbonate (yields >95%). Based on clumped isotope analyses of these precipitates, we determined, relative to statistical distribution, the abundance anomalies of ^{13}C-^{18}O bonds in CO_3^{2-}(aq) are 0.392±0.016‰ and 0.354±0.020‰(2σ) respectively at 25°C and 50°C (assuming the clumped isotope fractionation during phosphoric acid digestion of barium carbonate is 0.015‰ smaller than calcite [4]). These values are 0.041±0.014‰ and 0.009±0.029‰(2σ) lower than those in HCO_3^-(aq) equilibrated at the same temperatures, consistent with our lastest theoretical estimation of the equilibrium clumped isotope fractionations among different DIC species. This could potentially explain the general absence of clumped isotope vital effects in most biogenic carbonates [5,6]. We note, however, the oxygen isotope fractionation between disssolved HCO_3^- and CO_3^{2-} we determnined from our experiments are 0.3-0.4‰ smaller than those reported in previous studies [7,8].

We also estimated the kinetic fractionations of clumped isotope species associated with CO_2 hydration and hydroxylation reactions based on first principles transition state theory, and will discuss their implications for clumped isotope thermometry in biogenic carbonates.

With between 2,000 and 12,000 Gt of carbon released over ≤10 ka (see [1] and references therein), the Paleocene-Eocene Thermal Maximum (PETM) is regarded as the best analogue for understanding the long-term effects of present-day fossil carbon combustion (e.g. [2]). Deep ocean acidity displayed a strong response to this carbon cycle perturbation, witnessed in the substantial temporary shoaling of the Carbonate Compensation Depth (by >2 km) [3] but, as yet, no constraints exist for the response of surface water *p*H through this event. If the initial injection of carbon occurred sufficiently rapidly (relative to the mixing time of the oceans) it should have resulted in a significant drop in surface water *p*H that subsequently recovered to near pre-event values. Such a perturbation of surface water *p*H is potentially traceable by means of the boron isotopic composition (expressed in $\delta^{11}B$) of marine carbonates.

In this presentation we will investigate the upper ocean's *p*H response through the PETM with new $\delta^{11}B$ records from two species of planktic foraminifera from the North Atlantic (DSDP Site 401). We present complementary boron isotope and B/Ca records for the mixed layer (using *Morozovella subbotinae*) and the thermocline (using *Subbotina patagonica*), both sampled from the same sedimentary depths at high resolution spanning the entire event. Planktic foraminifera at Site 401 are very well preserved, implying minimal diagenetic alteration of their primary $\delta^{11}B$ and B/Ca signatures.

Through calculations assuming various seawater $\delta^{11}B$ and alkalinity configurations, we aim to provide new constraints on the evolution of surface water *p*H and atmospheric pCO_2 across the PETM to better constrain the amount of carbon released and, hence, its likely source.

The Gulf of Mexico Pb isotope response to elevated deglacial freshwater fluxes

MARCUS GUTJAHR[1*] AND ANNA NELE MECKLER[2]

[1]National Oceanography Centre, Ocean and Earth Sciences, Southampton, UK, m.gutjahr@soton.ac.uk (* presenting author),

[2]Swiss Federal Institute of Technology Zurich (ETHZ), Geological Institute, Zurich, Switzerland nele.meckler@erdw.ethz.ch

The disintegration of the North American Laurentide ice sheet during progressive warming throughout the last deglaciation provides an excellent opportunity to study changes in continental surface conditions and its effect on the dissolved runoff signal. The climate in interior North America shifted from glacial conditions dominated by intense (sub-)glacial physical and significantly reduced chemical weathering rates to wetter and warmer conditions in the transition to the Holocene. Various mineral phases in freshly exposed rock substrate weather relatively quickly, resulting in increased dissolved runoff fluxes for many major and trace elements during deglacial warming (cf. [1]). For tracing ice sheet retreat, elements displaying incongruent chemical weathering behaviour are particularly useful as long as these elements have short residence time in seawater such as dissolved Pb ($\tau \sim 20$-30 years).

At the NW Atlantic Laurentian Fan and deeper Blake Ridge, two Pb isotopic data sets suggest a significant increase in riverine input from proximal North American sources eastward during and after the Younger Dryas [2, 3]. The magnitude of change between these two sites suggests a proximal-distal relationship with the source of this radiogenic Pb signal most likely being located within the Gulf of St Lawrence. Together with Laurentide ice sheet margin retreat patterns presented from interior North America, oxygen isotope records derived from the Gulf of Mexico [4] and one multi-proxy data set from the outer St. Lawrence estuary [5], these Pb isotope records suggest that the signal recorded in the NW Atlantic very likely traced a major runoff reorganisation in interior North America during the mid-Younger Dryas.

Apart from [5], the identification of increased deglacial freshwater input into NW Atlantic sites by means of surface water $\delta^{18}O$ has proven difficult if not impossible [6]. Conversely, the supposedly preceding mid-deglacial Laurentide-derived freshwater runoff into the Gulf of Mexico was clearly recorded in surface-dwelling foraminifera in the open Gulf of Mexico [4, 7]. In order to complement the existing NW Atlantic Pb isotope records, we therefore present a new authigenic Fe-Mn oxyhydroxide derived Pb isotope record from core MD02-2550 within the Orca Basin in the Northern Gulf of Mexico. This core has a well-dated deglacial section and contains oxygen isotopic and organic matter content-based evidence for enhanced freshwater runoff during this key interval [7], allowing direct comparison with the new Pb isotope records.

Fluid-rock interaction in the Strange Lake peralkaline granitic pluton, Canada: Implications for REE/HFSE mobility

A.P. GYSI* AND A.E. WILLIAMS-JONES

Dept. of Earth and Planetary Sciences, McGill University, Montreal, Quebec H3A 2A7, Canada, alexander.gysi@mail.mcgill.ca (* presenting author)

Alkaline and peralkaline intrusions, such as at Strange Lake [1] and Thor Lake [2] in Canada, are unusually enriched in rare earth elements (REE) and in the high-field strength elements (HFSE) yttrium (Y), zirconium (Zr) and niobium (Nb). Understanding the geochemistry of this type of intrusions is urgently required because of the need to develop resources of the REE/HFSE to meet increasing societal demands for new technologies employing these elements.

Previous studies have demonstrated the importance of hydrothermal remobilization in concentrating the HFSE and REE in alkaline and peralkaline intrusions [1,2,3]. These intrusions are typically enriched in fluorine, which other studies have shown substantially affects the geochemical behavior of HFSE/REE in fluids and melts. In the present study, we focus on the alteration observed in subsolvus granites and pegmatites located in the northwestern part of the Strange Lake pluton. This zone is strongly enriched in HFSE/REE and is characterized by intense fluid-rock interaction due to the infiltration of F-rich fluids. Field relations indicate multiple infiltration events with the formation of veins and breccias, and pervasive alteration of the granites. The infiltration was largely confined to a NE-SW trending zone enriched in pegmatites, which we suspect formed a porous path for focused fluid flow. Mineral textures provide strong evidence for hydrothermal fluid-rock interaction involving the co-precipitation of secondary HFSE/REE minerals with hydrothermal fluorite. Preleminary results indicate that zirconosilicates were the primary source for the rare metals, and suggest that upon dissolution of these minerals, the rare metals complexed with F^- present in the fluid and were remobilized. Previous studies have also shown the importance of other complexes including Cl^- and CO_2^{-3} in mobilizing HFSE/REE [1]. We have investigated the capability of such fluids to leach rare metals from the primary rock and control the remobilization and concentration of the HFSE and REE.

The availability of Ca is one of the major factors controlling fluoride activity (aF^-) and mobility of HFSE/REE in peralkaline granites. Two of the keys to successful exploration for HFSE/REE in F-rich igneous systems, such as Strange Lake, are understanding the mechanisms of fluid-rock interaction from the magmatic-hydrothermal transition to the final stages of fluid-rock interaction, and correctly evaluating the associated alteration assemblages.

Investigating bioalteration products on seafloor basalts, Fe sulfides and Fe oxyhydroxides using scanning transmission X-ray microscopy (STXM) and absorption spectroscopy

AMANDA G. HADDAD[1*], COLLEEN L. HOFFMAN[1], FRIEDER KLEIN[2], SARAH A. BENNETT[1,3] ROMAN A. BARCO[1] AND KATRINA J. EDWARDS[1]

[1]University of Southern California, Los Angeles, USA, agturner@usc.edu (* presenting author)
[2]Woods Hole Oceanographic Institution, Woods Hole, USA, fklein@whoi.edu
[3]NASA Jet Propulsion Laboratory, Pasadena, USA, sarah.a.bennett@jpl.nasa.gov

Section Heading

Seafloor hydrothermal vent chimneys and the basaltic ocean crust are chemically reduced at the time of their formation but quicky undergo alteration following exposure to the oxygenated seawater. Alteration reactions (namely Fe and S oxidation and hydration) begin immediately at the rock-seawater interface yet when occuring abiotically, these reactions are kinetically inhibited, occuring very slowly if at all. It is suggested that microbes influence, if not control, these low-temperature alteration reactions at the rock-seawater interface in order to fix an estimated ~1x10^{19}g C per year [1]. In doing so, they influence global cycling of C, Fe, Mn, S and many other biogeochemically salient elements [2].

Understanding seafloor microbe-mineral interactions requires that we characterize how the minerals are changing as a result of being colonized by microbes. To investigate bioalteration products of seafloor microbe-mineral interactions, polished panels of common seafloor substrates (basalts, Fe sulfides, Fe oxyhydroxides) were allowed to react with in situ bottom water on the flanks of the Lo'ihi Seamount, Hawai'i for up to three years. After reaction, these panels developed thin (micron-scale) veneers of secondary alteration products and have been shown to harbor microbes found on seafloor basalts and hydrothermal sulfides (Haddad, unpub. data). We examined the products for morphology via scanning transmission X-ray microscopy (STXM) and changes in chemistry and mineralogy via C K-, Fe K- and O K-edge near edge X-ray absorbtion fine structure (NEXAFS). The alteration products on the reacted panels are amorphous Fe(III) and short-range Fe(III) mineralloids similar to those found on seafloor basalts. We present the range in chemistry and particle morphologies observed and discuss the variability with mineralogy.

Abstract

Iron is one of the most common redox species in soils and sedimentary rocks. Amongst iron-bearing phases, phyllosilicates might play key roles in various bio-geochemical processes involving redox reactions, where structural Fe (Festr) acts as a renewable source/trap of electron. A large set of data from kinetics, spectroscopic or electrochemical studies on dioctahedral smectites demonstrate that reduction of Festr impacts many clay properties such as colour, layer charge, swelling pressure, and colloidal properties that are linked to layer structural changes. Experiments also suggest that this mechanism is partly reversible, depending on type and properties of the primary oxidized clay and on extent of iron reduction level. The complexity of the involved mechanisms makes the prediction of Festr redox properties challenging. For instance, only empirical models are currently available to quantify structural changes as a function of reduction level. However, a predictive and mechanistic model of these changes is a prerequisite to develop a thermodynamic model for Festr redox properties. In this contribution, we propose a mechanistic statistical model to explain 2:1 layer excess negative charge changes induced by chemical reduction (dithionite) of structural Fe(III) to Fe(II). This model completes this published by Drits and Manceau [1] and was calibrated on data from our own and from the literature.

Weathering of marine sediments in a natural high-CO_2 environment: A geochemical investigation of the hydrothermal seeps of Yonaguni Knoll, Okinawa Trough

MATTHIAS HAECKEL[1]*, VOLKER LIEBETRAU[1], DIRK DE BEER[2], STEFFEN KUTTEROLF[1]

[1]GEOMAR Helmholtz Centre for Ocean Research Kiel, Kiel, Germany, mhaeckel@geomar.de (* presenting author), vliebetrau@geomar.de, skutterolf@geomar.de

[2]Max Planck Institute for Marine Microbiology, Bremen, Germany, dbeer@mpi-bremen.de

Carbon dioxide capture and storage (CCS) has been recognized as one practical option for mitigating anthropogenic CO_2 emissions and several demonstration projects aim at storage units below the seafloor. However, the likelihood for potential CO_2 leakage and its impacts on the marine environment are still unclear and have to be assessed.

One approach is the study of natural analogues, i.e. natural CO_2 seeps, mainly of volcanogenic origin. Here, we present geochemical data from the sediment-covered hydrothermal seeps of Yonaguni Knoll in the southern Okinawa Trough, NE off Taiwan.

Two seep sites were investigated in detail: (a) Abyss Vent, where hot, supercritical CO_2 is percolating through the sediment, and (b) Swallow Chimney, where liquid CO_2 and CO_2 hydrate form in the surface sediments. Geochemical and isotopic analyses of the porewater and solid phase indicate intense weathering of the sediments: carbonates are completely dissolved in the surface sediments, but also reactive silicate minerals, such as K-feldspars, plagioclases and pyroxenes, are leached by the low-pH fluids. Consequently, the CO_2-saturated porewaters are relatively enriched in K, Ca, Mg, and also contain high alkalinity values of 30-60 meq/l typically buffering the pH at 4.6-4.8.

While at Abyss Vent CO_2 and fluids are emitted into the water column at high advection velocities, in contrast, at Swallow Chimney the condensed liquid CO_2 and/or gas hydrates seem to have reduced the permeability trapping the CO_2 effectively below the seafloor in a depth of 30-100 cm. Here, intensive reactions with the sediments are observed. Applying a transport-reaction model to both data sets, natural weathering rates for high CO_2 conditions are determined. Strontium isotopic composition of the porewater, bulk sediment, chimney and volcanogenic material helps to constrain the mass balance of the weathered compounds.

Exploring the effects of bedrock nutrient density on life and topography in the Sierra Nevada Batholith, California

W. JESSE HAHM[1*], SAYAKA ARAKI[1], BARBARA S. JESSUP[1], CLAIRE E. LUKENS[1], ANNE E. KELLY[2], AND CLIFFORD S. RIEBE[1]

[1]University of Wyoming, Laramie, USA, whahm@uwyo.edu (*presenting author)

[2]University of California, Irvine, USA

As primary producers, plants form the basis of ecosystems. Plants themselves, however, depend on underlying substrates for mineral nutrients, which are ultimately derived from weathering of local bedrock and influxes of allocthonous dust [1]. Substrates that lack essential nutrients may preclude colonization of plant life. Where plants are absent, soil production and retention are hindered, leading to exposure of bedrock, which in turn inhibits erosion relative to surrounding soil-mantled, vegetated terrain [2]. This raises the possibility of a feedback wherein exposed bedrock hillslopes emerge in relief as stable features due to low intrinsic nutrient density. We explore the potential for such a feedback in the Sierra Nevada Batholith, California, which provides a natural laboratory for studying how gradients in intrinsic nutrient density correspond with gradients in vegetation. We restrict our analysis of controls on vegetation to minimally disturbed, unglaciated terrain, thus eliminating potentially confounding effects of intensive land use and glacial scour. We measured bedrock bulk geochemistry for slopes spanning a wide range in above-ground biomass, thus quantifying variations in intrinsic nutrient density. We leverage these point measurements of geochemistry with existing geochemical databases and geologic maps. Using spatial analysis we compare our geochemical data with measurements of above-ground biomass, net primary productivity, and remotely sensed vegetation density. Across our study area, nutrient density, as revealed by concentrations of phosphorus and magnesium in bedrock, varies by more than an order of magnitude. Biomass likewise varies widely, ranging in extremes from densely vegetated giant sequoia (*Sequoiadendron giganteum*) groves to sparsely distributed stands of stunted conifers within otherwise bare-bedrock landscapes. We find that bedrock with low intrinsic nutrient density is often associated with low biomass per unit area at sites where local climate is similar to that of forests with high biomass and productivity. This implies that bedrock nutrient density may serve as a first-order control on vegetation distributions across some portions of our study area. Our measurements of cosmogenic nuclides from exposed bedrock surfaces indicate that they are eroding slower than surrounding soil-mantled terrain, confirming that linkages between intrinsic nutrient density and vegetation could regulate relief at hillslope to mountain scales.

Computer simulations of iron-nickel sulphides in water

SAIMA HAIDER*, DEVIS DI TOMMASO, RICARDO GRAU-CRESPO, ALBERTO ROLDAN, NORA H. DE LEEUW

University College London, Department of Chemistry, UK
*saima.haider.09@ucl.ac.uk (presenting author),
n.h.deleeuw@ucl.ac.uk

The structural analogy between FeS/(Fe,Ni)S minerals and the (Fe,Ni)S clusters present in biological enzymes has led to suggestions that these minerals could have acted as catalysts for the origin of life. It has been suggested that life arose from a redox and pH front on the Hadean ocean floor [1], whereby the meeting between the hydrothermal front generated in the oceanic crust with the acidic oceanic fluid led to a spontaneous precipitation of FeS and NiS 'membranes/bubbles' which acted as reaction centres for carbon-carbon bond forming reactions. Here we present a computational study aimed at investigating the structure, dynamics and stability of Fe_xS_y (x, y $\leq$ 4) clusters in water. We shall also discuss violarite ($FeNi_2S_4$) surface structures and stabilities, and their affinity towards water

First, we will present first principles molecular dynamics simulations of the nucleation of iron sulphide clusters from aqueous solution, where our calculations of the Fe and S ions and the primary building unit FeS in water reveal that the effect of sulphur on the hydration structure of iron is to significantly reduce its first coordination shell compared with isolated Fe^{2+} and Fe^{3+} ions in water. However, simulations of Fe_xS_y particles (x, y $\geq$ 2) show that these clusters are unstable in water under the ambient conditions in our simulations, where we discuss any competing reactions such as the formation of iron hydroxides.

Because Ni is an important impurity in iron sulphides and potentally plays a vital role in the catalytic reactions, we will also present our calculations of the uptake and distribution of Ni ions in greigite-structured materials, employing a joint thermodynamical and statistical mechanical approach.

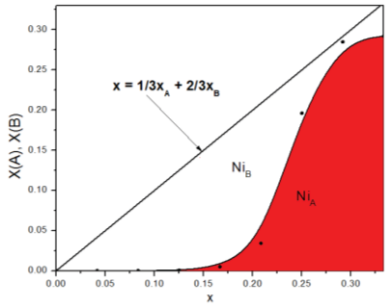

Figure 1: Distribution of Ni over tetrahedral (A) and octahedral (B) greigite sites, as a function of the total Ni concentration (x) at 600 K.

Finally, we have calculated the surface structures and stabilities of violarite - the fully-orded $FeNiS_2$ mineral – and investigated their interaction with the aqueous environment and propensity towards dissolution.

Molecular dynamics simulations of Y in silicate melts and implications for element partitioning

V. HAIGIS[1*] AND S. JAHN[1]

[1]GFZ German Research Centre for Geosciences, Telegrafenberg, 14473 Potsdam, Germany, haigis@gfz-potsdam.de (* presenting author)

Element partitioning depends strongly on the composition and structure of the involved phases. Whereas the influence of mineral phases is well described by the lattice strain model [1], the dependence of partition coefficients on melt chemistry is still poorly understood. However, there is ample evidence that the distribution of, e.g., rare earth elements between mineral and melt or between two immiscible melts varies considerably with melt polymerization [2]. Hence, if one uses trace element contents of igneous rock samples to constrain *P-T-t* paths of the material, the dependence of geochemical affinities on melt composition has to be understood.

We performed molecular dynamics simulations to investigate the coordination environment of Y (as an exemplary trace element) in silicate melts of different compositions in the model system $CaO-Al_2O_3-SiO_2$ [3]. This structural information was then linked to the partitioning behavior of Y. A wide range of melt polymerization was sampled by varying the relative abundance of network-modifying CaO. The results show that the local atomic structure around Y depends systematically on melt composition: when melt polymerization decreases (i.e. CaO content increases), the coordination of Y by oxygen decreases, as well as the average Y-O bond length. These changes are reflected by an increased oxygen order around Y and were confirmed by extended x-ray absorption fine structure (EXAFS) spectroscopy on glasses of the same composition as in the simulations. Moreover, we found a tendency of Y to form clusters with Ca and conclude that the presence of network modifiers facilitates the incorporation of Y into melts. This observation is in agreement with the observed trend of rare earth elements to partition preferentially into more depolymerized melts.

In a more quantitative approach, we modelled exchange reactions of trace elements and major elements between different phases. The computational method of thermodynamic integration allows the calculation of equilibrium constants and free energies of these reactions, which are directly related to fractionation processes. The thermodynamic results confirm the more qualitative explanation of partitioning behavior in terms of melt structure.

We emphasize that the method, applied here to Y in silicate melts, is very general and can be used, in principle, to predict element partitioning between arbitrary phases quantitatively. It thus complements the lattice strain model (which focuses on the role of mineral phases) by taking into account the influence of melt or fluid structure on element partitioning.

Carbon- isotope stratigraphy; a correlation tool for Cenomanian–Turonian carbonates in Southern Iran

*Elham Hajikazemi[1], Ihsan Al-Aasm[2,4], And Mario Coniglio[3]

[1]Department of Geology, Iranian Offshore Oil Company, Tehran, Iran, ekazemi@iooc.co.ir (*presenting author)
[2]Department of Earth and Environmental Sciences, University of Windsor, Ontario, Canada, alaasm@uwindsor.ca
[3]Department of Earth and Environmental Sciences, University of Waterloo, Ontario, Canada, coniglio@uwaterloo.ca
[4]The Petroleum Institute, Abu Dhabi, UAE

Introduction:

The Cenomanian-Turonian Sarvak Formation forms one of the main hydrocarbon reservoirs in southern Iran and the Persian Gulf. Surface and subsurface sections from this heterogeneous carbonate reservoir were examined to define the chemical conditions of the Mid- Cretaceous basin. The obtained data were compared to previously published data of the Tethyan region for stratigraphic correlation. This was carried out using detailed petrography, stable carbon, and oxygen and strontium isotope analysis.

Results:

The $\delta^{13}C$ values (range from -6.4‰ to 4.1‰, VPDB) for Sarvak carbonate matrix fall well within the Mid-Cretaceous marine values. Superimposing of these data on the Cenomanian-Turonian $\delta^{13}C$ curve shows a good global correlation, including similar $\delta^{13}C$ excursions. These positive excursions in $\delta^{13}C$ values reflect the Cenomanian-Turonian Oceanic Anoxic Event (OAE). The occurrence of thinly laminated Ahmadi shales and Khatiyah bituminous shaly limestone (members of the Sarvak Formation) confirms the anoxic condition and corresponding OAE of Mid-Cretaceous basin in the studied area. These shales could be considered as a potential source for the Upper Sarvak Formation and also the other important reservoirs of the younger ages.

There is a positive shift in $\delta^{13}C$ values within the strata with values of between +3.3 and +4.1 ‰ which corresponds to the well-defined Mid-Cenomanian Event (MCE). This positive excursion is detected both in surface and subsurface sections.

Negative values (e.g. -6.4‰) were obtained from samples collected along the paleoexposure surfaces on top of the Sarvak Formation which reflect the effect of meteoric diagenesis on these carbonates.

The $^{87}Sr/^{86}Sr$ ratios from surface and subsurface samples plotted on the Cenomanian-Turonian portion of the secular seawater curve of Burke et al. (1982) [1] show that the majority of the obtained values fallow the Cenomanian portion of the curve and confirm the validity of present carbon-isotope data.

Conclusions:

Carbon- isotope stratigraphy could be used as a regional and global correlation tool in Cenomanian-Turonian carbonates even in heterogeneous Formations (i.e. Sarvak Formation).

The results of this study added new data to the isotopic composition records and confirmed the occurrence of OAE in the eastern margin of the Neo-Tethys Ocean.

Understanding the influence of sulfur cycle processes on the evolving oxidation state of the oceans and atmosphere, on the chemical composition of seawater and on the respiration of sedimentary organic matter requires knowledge about the removal of sulfur from the oceans as pyrite and as sulfate evaporites. Most approaches have attempted to constrain the magnitude and isotopic composition of influxes to the ocean and have used measurements of isotopic ratios in sedimentary pyrite and sulfates to constrain the relative magnitude and isotopic composition of the outfluxes in the context of isotope mass balance models [1-4]. These studies suggest an average Phanerozoic fractional pyrite burial rate (f_{pyr}) of approximately 0.4 [1-4], with the notion that variation in f_{pyr} values reflects changes in the rates of sulfate reduction.

Taking an inverse approach, we attempted to constrain the burial flux of sulfate evaporites and then test various sulfur cycle models for consistency with independent physical understanding of the sulfur cycle. Our data were derived from a comprehensive stratigraphic database [5], with unprecedented spatial and lithological resolution in North America and the Caribbean (NAC). Using constraints on deposit age, we converted evaporite volumes into burial rates. On long timescales, the burial rates correlate with the area of continental shelf at latitudes of net evaporation (±10–50°), whereas short-timescale variability in sulfate deposition corresponds to variability in the rate of sea level change. We used these relationships to scale the NAC data globally and to generate a synthetic record of global Phanerozoic sulfate burial rates. The average Phanerozoic sulfate evaporite burial rate is $\sim 3.3\times10^{11}$ mol yr^{-1}. Sulfur entering the ocean in excess of this amount must exit as pyrite and given estimates of riverine sulfate influxes to the ocean ($1.5–3.5\times10^{12}$ mol yr^{-1} [3,6]), the implication is that f_{pyr} has had a value of ~0.7–0.9 over Phanerozoic time.

The results describe a marine sulfur cycle where the majority of net outputs and inputs are burial and oxidative weathering of sedimentary pyrite, respectively. While perturbations to the pyrite burial rate have likely occurred over short timescales, models of constant or slowly varying pyrite burial yield results that are consistent both internally and with existing observations of seawater sulfate concentration and $\delta^{34}S$. Over the time intervals resolved by the data, the long-term value we estimate for f_{pyr} is generally high, and large downward excursions in its value are associated with high rates of sulfate evaporite burial, rather than times of less pyrite burial. High values of f_{pyr} also imply a larger than previously thought role for the sulfur cycle in stabilizing atmospheric oxygen levels.

[4]University of Iceland, Reykjavík, Iceland

Nitrogen isotopes in Ocean Island Basalt (OIB) glasses show positive values, up to +6 ‰, which has led to ideas on ancient nitrogen recycling from the surface to the deep mantle [1]. If indeed the source of the N is the deep mantle then there should be correspondence between the highest primordial noble gas signatures (i.e. highest $^{3}He/^{4}He$ ratios) and the positive $\delta^{15}N$ signatures. However, the current database of $\delta^{15}N$ from high $^{3}He/^{4}He$ OIB is limited. Given the excellent exposure of fresh and glassy material, Iceland remains one of the few hotspot localities where this hypothesis can be tested in detail.

We report new high-precision nitrogen isotope data for 34 geochemically well-characterized subglacial basaltic glasses using newly developed methods at Scripps [2]. The glasses, which cover all the currently- active volcanic zones of Iceland, span a wide range in helium isotope (8-26 R_A) but show rather limited $^{40}Ar/^{36}Ar$ ratios (298-1330) [3]. N-isotopes in samples with sufficient, i.e., detectable, N_2 (> 2 $\mu cm^3STP/g$) range from -2.9 ‰ to +6.2 ‰. To avoid samples potentially affected by degassing-induced isotopic fractionation and/or air interaction, we have filtered the $\delta^{15}N$ dataset using $^{4}He/^{40}Ar^*$ ratios to identify (and remove) highly degassed samples (n= 8). In contrast to He-isotopes, there appears to be no spatial control on the filtered $\delta^{15}N$ dataset; however, we note the dominance of positive values in the Eastern Rift Zone.

We investigate simple binary He-N_2 isotope mixing and show that these data can be explained with K mixing values ($K=(N/He)_{MORB}/(N/He)_{PLUME}$) between 1 and 50 indicating that the high $^{3}He/^{4}He$ signature may in fact be coupled with a high $\delta^{15}N$ endmember [4] that has either i) lost He before mixing with the MORB endmember, similar to the two-step model of He depletion followed by open-system degassing developed by [3], and/or ii) excess N_2. We speculate that the high $\delta^{15}N$ endmember needed to explain these mixing relationships strongly suggest recycled N-components in the Icelandic mantle.

The accessory mineral record of metamorphism and protracted melt crystallization in a metamorphic core complex

BENJAMIN W. HALLETT[1*] AND FRANK S. SPEAR[1]

[1]Rensselaer Polytechnic Institute, Troy, New York, USA, halleb3@rpi.edu (* presenting author), spearf@rpi.edu

Partial melting during high grade metamorphism is an important mechanism of crustal differentiation. In the northern East Humboldt Range metamorphic core complex of Nevada, USA, Late Cretaceous high grade metamorphsim and leucogranite intrusion was followed by decompression, resulting a steep P–T path segment across fluid absent dehydration melting melting reactions in aluminous pelites.

U/Th-Pb and trace element SHRIMP analyses of zircon and monazite from metapelites indicate a complex metamorphic and partial melting history that includes protracted zircon crystallization and 3–4 chemically distinct phases of monazite growth in each sample. Monazites from within the Winchell Lake nappe (WLN) show moderate Y cores, low Y/higher Th mantles, and high Y rims, giving Th-Pb ages of ~84 Ma, 72–63 Ma, and 30–40 Ma respectively. Monazites from lower structural levels (beneath the WLN) commonly show irregularly-shaped low U cores that give Jurassic–Early Cretaceous Th-Pb ages. These cores may constitute the only evidence for an earlier Mesozoic metamorphic event in the East Humboldt Range. Chemical zoning patterns are generally similar to WLN monazite, but Cretaceous monazite core growth began >10 m.y. earlier. Higher U cores/mantles from these monazites fall in two age groups, near 96 Ma with low Y, and near 84 Ma with more moderate Y. High Y monazite from a sillimanite-bearing leucosome gives a weighted mean age of 83 ± 2 Ma, interpreted to represent leucosome crystallization beneath the WLN. Thin, higher Y monazite rims beneath the WLN give ages near 71 Ma and 35 Ma.

Zircons from migmaties within the WLN give concordant U-Pb ages spanning from 78–61 Ma, interpreted to represent protracted crystallization of in situ anatectic melt. Zircon grown during melt crystallization, in both leucosome and melanosome domains, shows a moderate depletion in heavy rare earth elements (HREE). This is consistent with growth during melt crystallization and resorption of observed HREE-depleted garnet on the decompression and cooling path. Garnet zoning patterns suggest fairly rapid cooling from peak temperature conditions (~750°C, 7 kbar), evidenced by relatively narrow diffusion profiles for resorbed garnet that back-reacted with melt. A lack of significant residual alkali feldspar and muscovite indicates that a large portion of the anatectic melt was lost from the system.

Zircon U-Pb and Ti data from the WLN are consistent with an extended presence of small amounts of melt at near-solidus conditions (~680°C, 5 kbar) for nearly 15 million years, suggesting that cooling nearly ceased at these conditions and melt-enhanced ductile flow did not occur at this time in the East Humboldt Range. As a result, retrograde net transfer reactions involving melt or a residual fluid phase are limited (1) kinetically, by grain boundary and volume diffusion, and (2) by the evolution of the reactive bulk compositon due to segregation and crystallization of anatectic melt.

The origins of Earth's volatiles

ALEX N. HALLIDAY[1*]

[1]Department of Earth Sciences, University of Oxford, Oxford, U.K., alexh@earth.ox.ac.uk (* presenting author)

The decay of ^{40}K to ^{40}Ar allows calculation of Earth's current ^{36}Ar budget. For example, if K/U_{BSE} =13,800 [1] and average mantle $^{40}Ar/^{36}Ar$ = 10,000-30,000 (based on OIB, MORB and well gas data [2,3]), then only 1 to 3% of Earth's ^{36}Ar is in the mantle ((4-11)×10^{37} atoms). This holds regardless of whether the mantle is residual to degassing or largely unrelated to the present atmosphere. It has been argued that much of the mantle's Ar and other volatiles are recycled by subduction in which case primordial degassing was presumably closer to 99%. However, significant Ar recycling is hard to reconcile with the apparent K-Ar age of the mantle of 4.0 Ga.

The upper mantle ^{3}He concentration [4] and atmosphere-corrected noble gas patterns in MORB and OIB sources [2] facilitate calculation of noble gas concentrations in the seismic lower mantle using the above total mantle ^{36}Ar budget. These are 5 to 10 times higher than in the upper mantle. If much of the Ar, Kr and Xe is recycled the mass balance of primordial Ne should be different. In fact $^{20}Ne/^{36}Ar$ in OIB and MORB sources are similar [2]. This upper / lower mantle mass balance is based on the degree of degassing, which in turn is based on the K/U_{BSE} which assumes chondritic refractory elements (hence U and Th) in the BSE. If instead impact erosion has stripped Earth's incompatible elements [5], depletion of U and Th by ~40% would yield an upper / lower mantle that is roughly balanced in concentrations for K, U, ^{36}Ar and ^{20}Ne.

Earth's atmospheric $^{20}Ne/^{36}Ar$ is close to that of Venus, Mars, and CI and enstatite chondrites, contrasting with 4 orders of magnitude variation in other solar system reservoirs. This and other evidence suggests that the terrestrial planets acquired most of their volatiles from chondrite like materials and not from fractionated solar nebular gases, consistent with the Kr isotopic composition of the mantle [6]. The $^{20}Ne/^{22}Ne$, $^{36}Ar/^{38}Ar$ and $^{20}Ne/^{36}Ar$ ratios of the atmosphere are consistent with a minor solar component, consistent with that in the mantle [2-4]. If carbonaceous or enstatite chondrites are the ultimate starting materials for Earth's volatiles there has been up to 2 orders of magnitude depletion in ^{1}H, ^{12}C, ^{14}N and ^{130}Xe relative to ^{3}He, ^{20}Ne, ^{36}Ar and ^{84}Kr. A similar pattern is shown by the atmospheres of Venus and Mars. Like Xe, but unlike other noble gases, C and N form low temperature species [7] with an EUV first ionization potential less than that of H. Therefore, depletion in these elements could be related to ionization with EUV in the inner solar system and / or core formation. The present C/N of Earth and the atmospheres of Mars and Venus are close to chondritic providing evidence that these budgets were established by later chondritic veneers. However, a major fraction of Earth's water (~70% but dependent on assumptions about the mantle inventory) would appear to predate this late acquisition, as argued by Drake [8].

Nickel removal mechanisms from neutral contaminated drainage by sulfate-reducing passive biofilters

AÏSSA HAMANI-ZALAGOU[1*], BRUNO BUSSIERE[1], CARMEN MIHAELA NECULITA[1] AND GERALD J ZAGURY[2]

[1]Université du Québec en Abitibi-Témiscamingue, 445 boul. de l'Université, J9X 5E4, Rouyn Noranda, Canada, Aissa-zalagou-M.Hamani@uqat.ca*

[2]Ecole Polytechnique de Montréal, 2900 boulevard Édouard Montpetit, H3T 1J4, Montréal, Canada, gerald.zagury@polymtl.ca

Contaminated neutral drainage (CND) is generally characterized by low sulfate concentrations, but with metals concentrations exceeding the norms. The treatment of CND by sulfate reducing passive biofilter (SRPB) is an attractive option for the mining industry. The main challenge for its long-term effectiveness lies in the choice and the proportion of the components in the reactive mixture. In this study, two reactive mixtures were tested in duplicate for the treatment of synthetic CND (pH of 6.5 and 7.8) contaminated with nickel (2.26 mg/L Ni) by SRPB. The first mixture was composed of leaf compost, poultry manure, sawdust, and wood chips, whereas in the second, the compost was replaced by peat. The results of the batch tests showed Ni removal efficiencies higher than 90% in all mixtures. However, the mechanisms of Ni removal seemed different in the two mixtures and also over time for the same mixture. The higher rate of sulfate removal in the first mixture indicates that it would promote sulfate reduction, while Ni removal in the second mixture would be essentially related to sorption mechanisms. Overall, the SRPB filled with both mixtures can be effective for the treatment of DNC in order to reduce Ni concentrations to values below the regulatory criteria.

Top-down growth of travertine veins revealed from U-Th dating at Little Grand Wash (Utah)

B. HAMELIN[1*], P. DESCHAMPS[1], J-P. GRATIER[2], E. FRERY[2,3], N. ELLOUZ-ZIMMERMAN[3], A. RØYNE[4], F. RENARD[2,4], D. DYSTHE[4]

[4]Physics of Geological Processes, University of Oslo, 0316 Oslo, Norway

Thermogenic travertine mounds may be examined as an outcrop analog for natural CO_2 long-term storage. As they form at the mouth of springs where CO_2 degassing drives carbonate precipitation from waters flowing from depth along active faults, they record the complex history of leakage/sealing of natural deep CO2 reservoirs.

The morphology of these mounds is often characterized by widespread and intriguing decimetric veins of white calcium carbonate, that lay parallel or oblique to the usual stratigraphic travertine. These veins may extend horizontally over several tens of meters, and may represent up to 50% of the total volume of the travertine mound.

We present here U-Th ages obtained from one such vein from the Little Grand Wash area (Utah), near the Crystal Geyser. ^{230}Th/U ages were determined by thermo ionization mass spectrometry. Very high U concentrations (7.2 – 9.2 ppm) combined with high (^{234}U/^{238}U) ratios and low detrital ^{232}Th concentrations result in U-Th age uncertainties of ± 9-14 yr for a mean age of the vein of 6 Kyr. Taking advantage of this high accuracy and resolution, we show that the vein grew unexpectedly from top to bottom over about a thousand years. The chemical composition of the geothermal fluid remained stable during this period, as indicated by very small variations of the $(^{234}U/^{238}U)_0$ activity ratio between 4.19 and 4.26 ± 0.005.

We propose that this counter-intuitive downward growth can be driven by the force of crystallization, implying that this mechanism is able to uplift the rock above the vein. We also show that the growth rate of the vein is fully compatible with the over-saturation state and with the expected percolation rate of the fluids. The inferred mechanism may possibly be generalized to the formation of horizontal veins in other geological settings. This study also shows that one must be very careful when interpreting travertine data, for example geochemical evolution, from samples removed from drill hole since the ages of the successive layers are not necessarily continuous from top to bottom or in stratigraphic order.

Atypical depleted mantle components at Mohns Ridge and along the Mid-Atlantic Ridge near the Azores

Lu-Hf and Sm-Nd isotopic systems have proven useful to track ancient mantle depletion signals in basalts. For both isotopic systems, during mantle melting events, parent-daughter ratios are higher in the residue than in the melt. Since these two isotopic systems have similar geochemical behavior during magmatic processes, a time-integrated evolution is expected to produce a strong correlation. However, in the particular case of mid-oceanic ridges samples, it has long been documented that Hf and Nd isotope compositions can be decoupled [1]. We present Hf, Nd, Pb and Sr isotope and trace element data for basalts from the Lucky Strike segment of the Mid-Atlantic Ridge together with published data from Mohns ridge area [2]. In a Hf-Nd isotope diagram, these two data sets define a similar correlation with a slope significantly steeper than the mantle array (Fig. 1). Two different hypotheses are discussed to explain this atypical Hf-Nd correlation: (i) a kinetic process during the current melting event [2] and (ii) an anomalous mantle source created by an ancient melting event with residual garnet [3]. Based on our sampling of the Lucky Strike segment, we show that the unusual Hf isotope signature can be the result of re-melting a refractory component in the mantle rather than the effect of disequilibrium melting. This observation provides new constraints on the structure of the Mid-Atlantic ridge upper mantle around the Azores and along Mohns ridge.

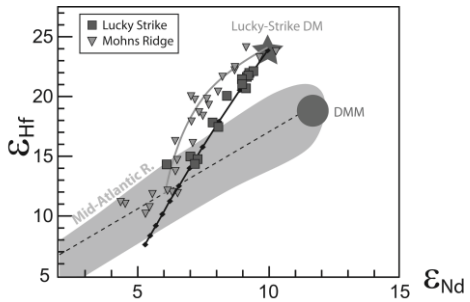

Figure 1: Atypical Hf-Nd isotopes values in Lucky Strike and Mohns ridge depleted mantle.

Avanavero Large Igneous Province: a short-lived and widespread Paleoproterozoic mafic event in the Guiana Shield, Amazonian Craton: U-Pb geochronological, geochemical and paleomagnetic evidence

[4]Universidade de Sao Paulo, Geofísica, Sao Paulo, Brazil, frankb@iag.usp.br, dagrella@iag.usp.br

The Avanavero Large Igneous Province (LIP) constitutes the most important Paleoproterozoic mafic magmatic event in the Guiana Shield, northern Amazonian craton. It comprises voluminous tholeiitic dykes and sills, the latter intrusive into regional sedimentary cover sequences such as Roraima Supergroup and Urupi Formation. Geochemical evidence suggests variable influence and modification by continental lithosphere, similar in many respects to chemically equivalent Karoo and Columbia River continental flood basalts of the Phanerozoic.

We present new U-Pb (ID-TIMS) baddeleyite ages of 1795 ± 2 Ma and 1793 ± 1 Ma from the Pedra Preta and Quarenta Ilhas gabbroic sills occurring in the Pakaraima and Urupi Blocks, respectively, at the north and south extremes of the Guiana Shield, north of the Phanerozoic Amazon basin. Combined with a single earlier ID-TIMS U-Pb age of 1794 ± 4 Ma for a mafic dyke [1], these ages confirm a broad suspicion from earlier isotopic studies (Rb-Sr, K-Ar, U-Pb SHRIMP) for the existence of a major ca. 1.78-1.80 Ga Avanavero magmatic event spanning eastern Venezuela-Guyana-Suriname-northern Brazil. The new results, however, potentially collapse the duration of intrusive activity to only a few Myr. Moreover, coeval gabbroic magmatism (Crepori sill) in the Central Brazil Shield suggests the Avanavero LIP originally extended across Brazil, south of the Amazon basin, towards the opposite side of Amazonia.

A synoptic summary is provided regarding the interpreted geometry of this expansive magmatic province, and we explore possible links between the dominant suite of sills and potential feeder dyke swarms. Available reliable paleomagnetic data favour a Laurentia/Baltica/Amazonia link at 1.78 Ga, and this large landmass may have represented the core of a hypothesized Columbia (Nuna) supercontinent during Paleo- and Mesoproterozoic times.

Kinetics and thermodynamics of calcite nucleation on self-assembled monolayers

LAURA M. HAMM[1*], NIZHOU HAN[1], ANTHONY F. GIUFFRE[1], JAMES J. DE YOREO[2] AND PATRICIA M. DOVE[1]

[1]Virginia Polytechnic Institiute and State University, Blacksburg, Virginia, USA, (correspondence: maehamm6@vt.edu)
[2]Lawrence Berkeley National Laboratory, Berkeley, California, USA

Sites of biogenic calcification are comprised of a complex macromolecular assemblage that is implicated in regulating the onset of mineralization. Previous studies have qualitatively investigated the influence of functional group chemistry on calcium carbonate ($CaCO_3$) formation using self-assembled monolayers (SAMs) as proxies for the macromolecules associated with biominerals. While these efforts have demonstrated that chemical functionality influences calcium carbonate phase, morphology, and nucleating face, they cannot provide insights into the kinetics of nucleation or the energy barrier associated with mineralization.

This study tests the hypothesis that specific chemical functional groups regulate the kinetics and thermodynamics of $CaCO_3$ formation by using SAMs with different termini (-COOH, -PO_4, and -SH) as substrates for calcite nucleation. We measured nucleation rates on each substrate at a variety of chemical driving forces both above and below the reported solubility of amorphous calcium carbonate (ACC), although ACC formation was not observed in these systems. Using classical nucleation theory to interpret the kinetic data, we calculated calcite-substrate interfacial energies and estimated substrate-specific effects on the thermodynamic barrier to nucleation. Calcite – substrate interaction forces were quantified with independent dynamic force microscopy measurements. A second part of the study investigated the effect of magnesium on calcite nucleation rates and barriers for selected substrates.

The kinetic measurements show a strong dependence of calcite nucleation rate on functional group chemistry. Interfacial free energies for 16-C alkanethiols terminated by –COOH and –SH were reduced to 82 and 91 mJ/m^2, respectively, from approximately 110 mJ/m^2 reported for calcite in solution. The kinetic behaviour is accurately described with classical models of nucleation, and calcite-substrate interaction force is positively correlated with the reduction in interfacial free energy. Rate measurements from solutions containing progressive amounts of magnesium demonstrate reductions in calcite nucleation rate without affecting the thermodynamic barrier to nucleation.

The role of sulfides on high field-strength element budget during enstatite chondrite melting

Introduction

High field-strength elements (HFSE) are usually considered to be incompatible lithophile elements during planetary magmatic processes. However, troilite analyses in enstatite chondrites and achondrites (aubrites) show high Ti concentrations, which are not found in ordinary chondrites [1]. In order to quantify this behavior and to check whether is applies to the other HFSE, we have conducted melting experiments relevant to enstatite chondrites under controlled (and low, down to IW-5) oxygen fugacity. Experiments were performed at 1 atmosphere using evacuated silica tubes, and 5 GPa, using multianvil apparatus. Starting material was doped and experimental products were analyzed using microbeam techniques (electron probe, laser ablation ICP-MS).

Results

For oxygen fugacity (fO_2) about IW-2, sulfide / silicate melt partition coefficients for all HFSE are below 1. As fO_2 is lowered below IW-4, Ti is preferentially incorporated in Fe-rich sulfide. The same applies to V, Nb, and Ta. V and Nb have about the same D (sulfide / silicate melt), while Ta is about one order of magnitude lower. These observations are similar to previous observations on metal / silicate partitioning [2]. However, in the case where metal is present we find that V and Ta have about the same D (metal / silicate melt), about one order of magnitude lower than that of Nb. This result differs from [2]. For the cited elements, pressure does not seem to affect partitioning in the investigated range. In the case of Zr and Hf we find that low fO_2 favors their incorporation into the sulfide phase, while no notable change is found for the metal. Moreover, our results suggest that Zr may be compatible in the sulfide phase at low fO_2 (D sulfide / silicate melt > 1), while D for Hf approaches unity. Pressure appears to increase Zr and Hf solubility in the sulfide phase.

Discussion

The chalcophile character of Zr (and maybe for Hf at more reduced conditions) is a new feature, which may be related to observed Ti behavior in enstatite chondrites and achondrites [1]. If we consider that the Earth's differentiation started at reducing conditions (close to those of enstatite chondrites), Zr and Hf may have been trapped by sulfide melts and stored in a sulfur dominated reservoir. This reservoir may then have been assimilated into the core or, alternatively, it may have remained a separate reservoir in the silicate mantle.

Recent studies have used Ca isotope fractionation to directly trace Ca transport along different biogeochemical pathway in various terrestrial ecosystems [1-3]. In an extension of these studies we present Ca isotope and Mg/Ca compositions of rain water, groundwater, bedrock (carbonates), soil and plant samples measured by TIMS using a ^{43}Ca-^{48}Ca double spike to gain information about the biogeochemical processes in a typical karst forest (Guizhou province, Southwest China).

The $\delta^{44/40}Ca$ of rainwater and groundwater are very similar, both of them are enriched in the ^{44}Ca when compared to bedrock, indicating that groundwater is supplied mainly by rain and that there is no significant Ca isotopic fractionation during the dissolution of Ca originating from the carbonate bedrock. Our results confirm previous findings that Ca isotopes will be fractionated down the line from bedrock (0.36 ‰) to forest soil (0.04 ‰) and to leaves (-0.26‰). Organic rich soils are enriched in ^{40}Ca relative to organic depleted soils, following the sequence farm land > burnt grass land > forest land > shrub land > grass land. In contrast, Mg/Ca ratios increase from in the same sequence indicating a distinct loss of Ca due metabolisation in plants. The recycling of plant material and soils as well as the variation in $\delta^{44/40}Ca$ and Mg/Ca in plant-soil ecosystem can be well described by an open-system Rayleigh fractionation model, indicating the preferential enrichment of ^{40}Ca and Ca in plants.

Seasonal and interannual change in mercury sequestration at Dome Fuji, Antarctica

YEONGCHEOL HAN[1*], YOUNGSOOK HUH[1], SUNGMIN HONG[2], SOON DO HUR[3], HIDEAKI MOTOYAMA[4]

The total mercury concentration (Hg_T) was determined with high precision in snow pit samples collected every 2.5 cm down to 2 m, covering ~27 years (1983-2010), at Dome Fuji in East Antarctica. This high-resolution data provide new information on seasonal and interannual change in mercury sequestration rate and factors affecting it.

The Hg_T ranged between 0.20 (±0.02, 2σ) and 5.20 (±0.05) pg g^{-1} with variations at seasonal and interannual time scales. The mean mercury sequestration rate was estimated to be 3.1 ± 0.1 pg cm^{-2} yr^{-1}, slightly higher than the previous estimate at Dome Fuji [1]. By comparison with sulfate concentration, $\delta^{18}O$-δD and deuterium excess profiles, the seasonality was characterized by summertime maxima in Hg_T, even though the peaks were not always exactly in phase. The enhanced mercury sequestration may be related to the active photochemical dynamics of mercury in summer [2]. We ascribe the interannual change to the variation in the atmospheric circulation over Antarctica that regulates the meridional transport of aerosols containing oxidant precursors, continental dust, moisture and heat, each of which is thought to play a role in the mercury dynamics on the Antarctic Plateau [3].

Results

Pb and Hf isotope ratios from 139 basalt glasses sampled at < 10 km intervals along 2000 km of the Southeast Indian Ridge (SEIR) between 86°E and 110°E show bimodal distributions. The bimodality in both Pb and Hf isotope ratios confirms the presence of ancient compositional streaks in the Indian Ocean upper mantle [1]. The density of streaks is well described by a Poisson distribution having a characteristic thickness of ~25 km.

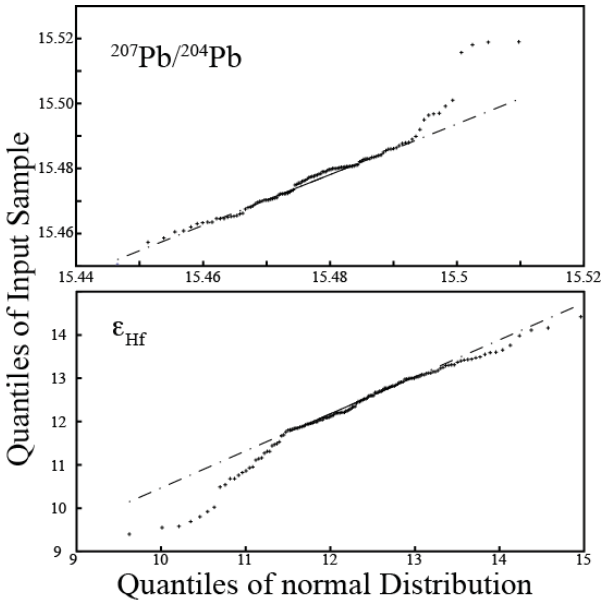

Figure 1: QQ plots for Pb and Hf isotopes for 139 SEIR glasses [this work; 1, 2] show that these MORB melts reflect a mantle source in which the isotope compositions are bimodal rather than a single gaussian population.

Implications

Pb isotopes in SEIR basalts all carry a DUPAL [3] isotope signature. Two possible origins for the bimodality and DUPAL signature are: (1) ancient melting that involved garnet fractionation, with subsequent pollution of the upper mantle by continental material during Gondwana breakup; (2) inherited heterogeneity from the early Earth.

Synthesis of Mn minerals at ambient temperature and pressure

MATTHIAS HÄNDEL[1*], THLIO RENNERT[1,2], AND KAI U. TOTSCHE[1]

[1] Friedrich-Schiller-Universität Jena, Institut für Geowissenschaften, Burgweg 11, D-07749 Jena, Germany, matthias.haendel@uni-jena.de (* presenting author), kai.totsche@uni-jena.de

Manganese minerals are widespread in soils, sediments, water and ores. Particularly, Mn oxides play important roles in many soil chemical processes, are effective sorbents for metal ions and can oxidize organic and inorganic contaminants. Manganese oxides mostly occur together with other minerals and are therefore difficult to separate. To study fundamental processes on reactivity and kinetics pure phases are needed.

The objective of this work was to synthesize Mn minerals at ambient conditions and without the use of strong acids and bases. We designed 4 different experimental approaches based on $KMnO_4$ reduction. The reaction time varied between 1 and 550 days and the influence of the organic modificators acetate, citrate and lactate was checked. The reaction products were characterized mineralogically (XRD, FTIR), morphologically (SEM, BET) and chemically (SEM-EDX, ICP-OES, IC).

After a period of 1 day a poorly crystalline precursor birnessite [$K_4Mn_{14}O_{27}$•$9H_2O$] was the sole mineral phase that was formed in all reaction batches. Depending on the educts and on the modificator, several transformations of birnessite were observed over time. In 3 of 4 experiments without modificator, birnessite remained stable but increased in crystallinity and decreased in surface area with time. In one approach birnessite was stable in the first 90 days followed by slow dehydration and transformation to cryptomelane [KMn_8O_{16}].

The modificator acetate showed no effects on both crystallization behavior and mineral transformation. Birnessite that was formed in the presence of either citrate and sulfate, or citrate and chloride partly transformed to rhodochrosite [$MnCO_3$]. Chloride especially promoted this carbonization, which ended after 185 days in an equilibrium state. The final precipitate contained 80% rhodochrosite and 20% birnessite. Citrate had no effects on the reaction in the other 2 approaches and birnessite remained stable. Also lactate promotes the formation of rhodochrosite in the presence of sulfate or chloride. In contrast to citrate, lactate transformed the residual birnessite to manganite [γ-MnOOH]. In the other 2 approaches lactate induced a complete transformation of the precursor birnessite to feitknechtite [β-MnOOH] between 7 and 30 days after starting. The lactate- induced transformation of birnessite to manganite or feitknechtite could be related to the strong reducing property of lactate.

Our pathways to synthesize Mn minerals are feasible on a large scale, can produce crystallites in different sizes and with a well-defined surface area. The products can serve as model minerals in studies on kinetics and reaction behaviors of Mn minerals, and may also have a potential for remediation of contaminated sites.

Magmatic degassing in contrasting volcanic systems of the Vanuatu arc: constraints from uranium-series isotopes

HEATHER HANDLEY[1*], SIMON TURNER[1], MARK REAGAN[2], GUILLAUME GIRARD[2], AND SHANE CRONIN[3]

[1]Department of Earth and Planetary Sciences, Macquarie University, Sydney, Australia, heather.handley@mq.edu.au (* presenting author), simon.turner@mq.edu.au

[2]Department of Geoscience, University of Iowa, Iowa City, IA, United States, mark-reagan@uiowa.edu, guillaume-girard@uiowa.edu

[3]Institute of Natural Resources, Massey University, Palmerston North, New Zealand, s.j.cronin@massey.ac.nz

Recent and present volcanism in the Vanuatu arc (South West Pacific Ocean) occurs at a variety of volcano types that exhibit a wide range of eruptive behaviour: from post-caldera lava-lake activity and lava flows at shield volcanoes (Ambrym), moderately explosive sub-plinian events and associated pyroclastic-flows and lava flows at stratovolcanoes (Lopevi), to persistent strombolian and vulcanian-style eruptions at scoria cones (Yasur). This precludes a generic model of magmatic and eruptive behaviour for the Vantuatu arc volcanoes and necessitates a detailed study of each system.

Uranium-series disequilibria in volcanic rocks offer unique insights into pre-eruptive magmatic systems over process-relevant timescales e.g., ^{238}U-^{230}Th (380 Ka), ^{230}Th-^{226}Ra (8 Ka) and ^{226}Ra-^{210}Pb (100 a). The short half-life of ^{210}Pb ($t_{1/2}$ = 22.6 years) and the volatile nature of the intermediate isotope, ^{222}Rn, (intermediate between the ^{226}Ra parent and ^{210}Pb daughter) provide valuable information on magma transport, evolution and degassing over a timescale more pertinent to the processes leading up to volcanic eruptions.

We present new Uranium-series isotope data (U-Th-Ra-^{210}Pb) for young (< 100 years old) volcanic samples from Ambrym, Lopevi and Yasur volcanoes to investigate the timescales of magmatic evolution and degassing in the contrasting volcanic systems. ^{210}Pb deficits ($(^{210}Pb/^{226}Ra)_0 < 1$) in Ambrym and Yasur volcanic rocks suggest effective open-system magmatic degassing of ^{222}Rn, consistent with the persistent lava-lakes/exposed magma and significant gas emissions observed at both volcanoes. Lopevi, on the other hand, displays excess ^{210}Pb ($(^{210}Pb/^{226}Ra)_0 > 1$) in the most mafic samples suggesting that ^{222}Rn gas accumulation and fluxing preceding and/or during eruption (on a decadal timescale) may be responsible for the more explosive-style of eruption witnessed at this volcano. Significant accumulation of recently crystallised plagioclase phenocrysts can also create ^{210}Pb excesses in volcanic rocks, however, this process is not supported by the petrographic and geochemical data. In summary ^{210}Pb-^{226}Ra disequilibria in Vanuatu volcanic rocks reveal a strong link between pre-eruptive magma degassing systematics and the resultant style of volcanic activity.

Mechanism of microbial hydroxyapatite manufacture and its application to radionuclide remediation

STEPHANIE HANDLEY-SIDHU[1]*, JOANNA C. RENSHAW[1], BJORN STOLPE[1], JAMIE R. LEAD[1], RICHARD A.D. PATTRICK[2], JOHN M. CHARNOCK[2], STEPHEN J. BAKER[1], MARK O. CUTHBERT[1], LYNNE E. MACASKIE[1]

[1] The University of Birmingham, Edgbaston, B15 2TT, UK (*correspondence: s.handley-sidhu@bham.ac.uk)

[2] The University of Manchester, Oxford Road, M13 9PL, U.K.

Introduction

Hydroxyapatite (HAP) shows potential for the remediation of metal contaminated waters [1, 2]. *Serratia sp.* contains high levels of an atypical phosphatase enzyme located in the bacterial periplasmic space and attached to extracellular polymeric substance; this enzyme cleaves glycerol-2-phosphate, liberating inorganic phosphate and providing the nucleation site for the growth of biological hydroxyapatite (Bio-HAP) crystals [1, 3]. Evidence suggests that the growth of Bio-HAP is controlled within spatial localisation of the biological space on and in close proximity to cells [1, 3]. Crystalline HAP [$Ca_{10}(PO_4)_6(OH_2)$] is described as ten calcium cations aligned in 2 non equivalent sites denoted as Ca(1) and Ca(2). The Ca(1) site contains four cations each surrounded by nine oxygen atoms, whereas, the Ca(2) site contains six cations each surrounded by 7 oxygen atoms [4].

Experimental

Various techniques (Atomic force microscopy, scanning and transmission electron microscopy, BET surface area, X-ray diffraction) were used to characterise the properties and structure of HAP. To investigate how HAP properties influence metal uptake, portions of biomineral were heated at different temperatures ranging from 200-700 °C before the sorption of key radionuclides (Eu^{3+} as an analogue for trivalent actinides, U^{6+}, Sr^{2+} and Co^{2+}). The amount of absorbed species was determined by inductively coupled plasma mass spectroscopy and synchrotron X-ray absorption spectroscopy (XAS) was used to determine the local environment.

Results and Conclusions

Controlled biomineral growth produces amorphous HAP, with a large surface area and more reactive surface. Untreated HAP viewed under TEM and AFM appeared as chain/needle structures of < 50nm length. As the HAP was heated from 200-700 °C the organics content and HAP surface area decreased and the mineral became more crystalline. Heat treating to 700 °C caused the HAP to anneal and larger spheres >100 nm in length formed. The potential of microbial HAP to remediate radionuclides and the stability of bound metals will be presented.

The redox state in mantle-derived garnet peridotite can be determined using the ratio of $Fe^{3+}/\sum Fe$ in garnet, which can be measured using Fe K-edge X-ray Absorption Near Edge Structure (XANES) [1] spectroscopy. This is a synchrotron based method which allows for *in-situ* measurement with high spatial resoloution. Redox state is expressed as oxygen fugacity (fO_2) and is an important control on carbon speciation in the mantle, particularly defining the boundary between carbonate stability relative to diamond or graphite.

A suite of garnet harzburgite and lherzolite xenoliths from the Wesselton kimberlite pipe, South Africa was analysed using electron probe microanalysis, LA-ICP-MS and Fe K-edge XANES spectroscopy with the aim of investigating the relationship between metasomatic enrichment and changes in redox conditions in the cratonic mantle beneath the Wesselton kimberlite pipes.

The suite shows evidence of multiple metasomatic events, including zonation in some garnet grains in which Ca, Fe and Ti enriched rims have overgrown highly refractory cores. Two distinct garnet REE patterns occur within the suite, 'sinusoidal' patterns typical of harzburgitic garnet in the cores, with 'normal' patterns typical of lherzolitic garnet on the rims. We quantitatively mapped the Fe^{3+} distribution in these grains using XANES and calculated average rim and core fO_2 values using the oxybarometer of Gudmundson and Wood [2]. The results indicate $\Delta \log fO_2$ of -1.37 (relative to FMQ) on the rim and -3.79 in the core at 1060 °C and 50 kbar. These values both fall in the diamond stability field in P-T-fO_2 space, however the rim fO_2 value is close to carbonate stability. Our results are in broad agreement with those of McCammon *et al.* [3] on similar samples.

We interpret this data in terms of quenching of the xenoliths caused by eruption of the kimberlite, during a strongly oxidising metasomatic event.

Geochemistry of the Bolkardağı Bauxite Province, Karaman-Turkey

NURULLAH HANİLÇİ

İstanbul University, Department of Geological Engineering
nurullah@istanbul.edu.tr

Abstract

Bolkardağı bauxite province is located in the Tauride Belt, southern Turkey (Fig.1). This province hosts a large number of bauxite deposits (e.g. Karataş, Bolkardede T., Arpaçukuru, Kızıldağ, Öşün Yaylası, Göztaşı, Kavaközü, Baharpınarı, Kemikli T.,) which occurred within the Bolkardağı Unit (BU), Namrun Tectonic Unit (NTU) and Aladağ Unit (AU), and these tectono-stratigraphic units are imbricated [1]. Both the lateritic and karstic-type bauxite deposits developed in the province. While the phyllites-schists are the footwall of the lateritic-type deposits, the recrystallised limestones are the footwall for the karstic-type. The Middle Jurassic recrystallised limestones overlies the bauxite deposits in the province. The deposits consist mainly of diasporite and hematite with minor boehmite, kaolinite and anatas minerals.

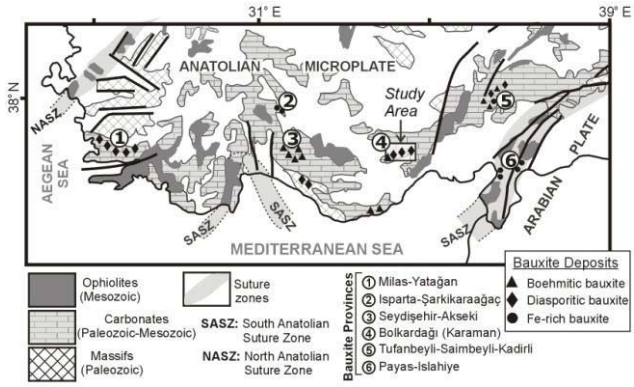

Figure 1: The bauxite provinces of the Turkey

The deposits contains 40.13 to 76.2 wt. % Al_2O_3 (aver. 53.3 %), 0.7 to 29.8 wt. % Fe_2O_3 (aver. 18.8 %), 0.6 to 24.9 wt. % SiO_2 (aver. 12 %), 11 % average LOI, 1.92 to 4.1 wt. %TiO_2 (aver. 2.7 %).

Al, Fe and Ti are mainly enriched elements during the bauxitization processes. The Al_2O_3 content increases from 28.6 % in average parent rock to 53.3% in average bauxite. Similar increases occur from 1.4 % to 2.7 % for TiO_2 content, from 7.6 % to 18.8 % for Fe content. The alkali (Na, K, Rb), alkali earth (Mg, Ca, Sr, Ba) elements, and silica content of the bauxites are lower than the parent rocks and saprolite, indicating extreme leaching during the bauxitization. The Ti, Zr, Hf, Nb, and Ta are the strongly immobile elements during the bauxitization processes, and the Fe, Ti, Sn, V, Pb, Ni and Cr are the gained elements in bauxitic zones in the Bolkardağı province.

From the stratigraphic evidence and geochemical data it is concluded that the Lower and Upper Triassic fillates-schists could have been the precursor rock for the bauxite deposits in Bolkardağı province. The bauxitization processes occurred pre-Middle Jurassic time, and the deposits included boehmite. The boehmitic bauxite was transformed to diasporitic bauxite due to post Cretaceous overtrusting and imbrication.

Introduction

Particular chemicals like pesticides which use, in agriculture, became inescapable are engendering an environmental pollution and more particularly that of the waters as well of surfaces as ground-water sheets.

It is urgent, for preservation of public health, to reduce at most our exposure to these substances and to operate everything to reduce and control these pollutants.

So, the presence of pesticides in drinkable waters is severely regulated and the producing companies of water, to conform to the established standards, are obliged to include in their networks of water treatment, processes to eliminate them.

The adsorption on the synthetized metal organic complexes may be a technique to disinfect waters polluted by pesticides and other chemicals.

In this context, some coordination compouds of manganese, copper, zinc and cobalt were tested in the adsorption of mitrobuzin present in contaminated water. The retained organis molecules are natural products (flavonoids and purines)

Results and Conclusion

The preliminary results seems encouraging and we report them here. They are compared to those obtained with a classic adsorbing agent, namely powdered activated carbon F400

The origin of platinum-group element enrichments in alkalic porphyry systems: evidence from melt inclusions

JACOB J. HANLEY[1]

[1]Department of Geology, Saint Mary's University, Halifax, Nova Scotia, Canada, jacob.hanley@smu.ca (* presenting author)

Introduction

To elucidate some uncertainties concerning PGE enrichment in alkalic porphyry systems, we have performed a comprehensive study of the mineralogy, bulk rock geochemistry and melt inclusion chemistry of two porphyry systems in British Columbia, Canada.

Results and Discussion

Discrete PGE minerals in these systems are represented by Hg-rich Pd-Pt-As-Sb species (naldrettite-stibiopalladinite-sperrylite) and Pd-Te-Hg species (kotulskite-temagamite). However, these mineral phases are unambiguously late-stage, having formed during either remobilization of the PGE during a stage of carbonate-chlorite alteration, or during an epithermal stage whereby low salinity vapour transported Pd, along with Au, Sb, As, and S and deposited these in quartz carbonate-pyrite veins that cross-cut the porphyry-stage veining.

An indication of the nature of primary enrichment in PGE is supported by LA-ICPMS analyses of primary silicate melt inclusions within leucite-olivine-clinopyroxene-phyric, high-Mg basalt flows that are coeval with the porphyry rocks. The inclusions preserve Pd/Pt ratios, determined by LA-ICPMS, that are very similar to Pd/Pt ratios in bulk ore samples, suggesting that the basalts and porphyry rocks are genetically related (e.g., mixing of mafic and felsic endmembers to produce a hybrid PGE-rich porphyry magma, or contamination of a mafic magma by crustal material during ascent).

Only limited decoupling of Pd from Pt occurred during melt fractionation or mixing, melt ascent, fluid exsolution, and ore precipitation. PGE precipitation in the porphyry stage occurred in pyrite (as a dissolved trace constituent) and was coincident to Co and Ni enrichment in the pyrite, an association that is observed in found in IOCG deposits and Outukompu-type (mantle-peridotite associated) Cu-Co-Ni deposits.

A global Os isotope signal in a narrow seaway – the Late Jurassic from the Barents Sea to S. England

[1] Geological Survey of Norway, 7491 Trondheim, Norway, judith.hannah@colostate.edu (*presenting author)
[2] AIRIE Program, Colorado State University, Fort Collins, CO, USA
[3] Physics of Geological Processes, University of Oslo, Norway

Late Jurassic organic-rich shales are the dominant source rock for expansive hydrocarbon reserves in the corridor extending from the North Atlantic through the North and Norwegian Seas to the Barents Sea. An enormous accumulation of organic matter is contained in shales deposited over ca. 15 m.y. from the Late Jurassic (Oxfordian) through the earliest Cretaceous (Berriasian). At this time, the region was a drowned continental shelf; a narrow seaway cluttered with small landmasses tenuously linked the Arctic and Tethyan marine systems. Re-Os geochronology is now available from four sites along this seaway, from NE to SW: Nordkapp Basin in the Barents Sea, Troms III on the northern Norwegian Shelf, Staffin Bay on the Isle of Skye (western Scotland) [1], and the Kimmeridge sea cliffs at Dorset (southern England) [2]. Shales from the four sites differ significantly in depositional environment and proximity to shoreline, and in related variations in trace metal chemistry. Despite this complexity, seawater $^{187}Os/^{188}Os$ captured in the shales is remarkably consistent for a given depositional age.

At the two northern locales, Nordkapp Basin and Troms III, Hekkingen Formation shales are divided into a basal Alge Member and overlying Krill Member. At Troms III, the distinction is clear: relative to the rich Alge source rock, the Krill has lower total organic carbon (TOC) and lower gamma radiation. At Nordkapp Basin, this distinction is blurred. TOC is high throughout the Hekkingen section and trace metal concentrations are significantly higher than at Troms III, even when normalized to TOC. Also, biostratigraphy indicates that the units are time-transgressive; Krill deposition ended earlier at Nordkapp Basin than at Troms III.

Our new Re-Os data show a consistent increase in the initial $^{187}Os/^{188}Os$ ratio through the Late Jurassic. Alge shales at Troms III and Nordkapp Basin, with isochron ages of ~152 and ~158 Ma, have relatively low initial $^{187}Os/^{188}Os$ ratios of about 0.51 and 0.45, respectively. Upsection, Krill shales with isochron ages <150 Ma, have ratios >0.6. The correspondence continues to the south, where Staffin Bay shales near the Oxfordian-Kimeridgian boundary yield an age of 154.1 ± 2.1 Ma with initial $^{187}Os/^{188}Os = 0.53 \pm 0.02$ [1]. The Kimmeridge Clay shales yield an age of 155 ± 4.3 Ma but with higher initial $^{187}Os/^{188}Os = 0.59 \pm 0.07$ [2]. Although the imprecise Kimmeridge isochron age is similar to that of the Staffin Bay and Alge shales, the biostratigraphy (*wheatleyensis* Subzone) indicates an early Tithonian age, more likely correlative with the Krill shales.

The rising initial $^{187}Os/^{188}Os$ shale ratios through the Late Jurassic closely mimic the $^{87}Sr/^{86}Sr$ seawater curve. Our study shows that seawater Os is well mixed, even in narrow, confined seaways with relatively shallow water and nearby shorelines. Seawater $^{187}Os/^{188}Os$ is faithfully recorded in organic-rich shales.

[3]Smithsonian Institution, Washington, DC, USA, santellic@si.edu
[4]Stanford Synchrotron Radiation Lightsource, Menlo Park, CA, USA, samwebb@slac.stanford.edu

Manganese (Mn) oxides are among the strongest sorbents and oxidants within the environment, controlling the fate and transport of numerous elements and the degradation of recalcitrant carbon. Both bacteria and fungi mediate the oxidation of Mn(II) to Mn(III/IV) oxides but the genetic and biochemical mechanisms responsible remain poorly understood. Furthermore, the physiological basis for microbial Mn(II) oxidation remains an enigma.

We have recently reported that a common marine bacterium (*Roseobacter* sp. AzwK-3b) oxidizes Mn(II) via reaction with extracellular superoxide (O_2^-) produced during exponential growth [1]. Here we expand this superoxide-mediated Mn(II) oxidation pathway to fungi, introducing a surprising homology between prokaryotic and eukaryotic metal redox processes. For instance, *Stilbella aciculosa*, a common soil Ascomycete filamentous fungus, precipitates Mn oxides at the base of asexual reproductive structures. This distribution is a consequence of localized production of superoxide by the well-known NADPH oxidase enzymes, leading to abiotic oxidation of Mn(II) by superoxide. Disruption of NADPH oxidase activity using the common oxidoreductase inhibitor DPI leads to diminished cell differentiation and subsequent Mn(II) oxidation inhibition.

We also show here that similar to fungi extracellular superoxide production is widespread throughout the bacterial domain. Yet, superoxide production does not, in fact, confer the ability to produce Mn oxides. This is a consequence of a backreaction between the products (Mn(III) and hydrogen peroxide) formed upon Mn(II) and superoxide reaction, leading to the regeneration of Mn(II). Indeed, we show that superoxide-mediated Mn oxide formation is reliant upon the removal of the hydrogen peroxide product. Thus, the formation of Mn oxides by the *Roseobacter* and *Stilbella* spp. requires both the production of superoxide and consumption of hydrogen peroxide. We believe that this need for hydrogen peroxide consumption hints to the role of heme peroxidases (recently implicated Mn oxidases) in bacterial Mn oxidation.

Taking into consideration that superoxide is a strong and versatile redox reactant serving as both an oxidant (e.g., Mn) and reductant (e.g., Fe, Cu, Hg) of metals, biological superoxide production may have profound influences on metal biogeochemistry beyond Mn.

Structural constraints on Mn(II) oxidation by biogenic Mn oxides

COLLEEN M. HANSEL[1*], DERIC R. LEARMAN[2], ANDY S. MADDEN[3], SCOTT D. WANKEL[1] AND SAM M. WEBB[4]

[1]Harvard University, Cambridge, MA, USA, hansel@seas.harvard.edu (*presenting author)
[2]Central Michigan University, Mount Pleasant, MI, USA, deric.learman@cmich.edu
[3]University of Oklahoma, Norman, OK, USA, amadden@ou.edu
[4]Stanford Synchrotron Radiation Lightsource, Menlo Park, CA, USA, samwebb@slac.stanford.edu

Manganse (Mn) oxides are vital components of environmental systems, controlling the fate and transport of contaminants, bioavailability of nutrients, degradation of recalcitrant carbon, and respiratory capacity of microbial populations. The oxidation of Mn(II) to Mn(III/IV) oxides has been primarily attributed to biological processes, due in part to the faster rates of bacterial Mn(II) oxidation compared to observed mineral-induced and other abiotic rates.

Here we reveal the reactivity of biogenic Mn oxides formed by a common marine bacterium (*Roseobacter* sp. AzwK-3b), which has been previously shown to oxidize Mn(II) via the production of extracllular superoxide [1]. The reactivity of the biogenic Mn oxides was explored by harvesting and characterizing Mn oxides formed within *Roseobacter* AzwK-3b filtrate at various time points followed by reaction with Mn(II) under an array of aqueous conditions [2]. Oxidation of Mn(II) by extracellular superoxide within *Roseobacter* filtrate results in the formation of colloidal (~20-40 nm in diameter) Mn oxides. These oxides are most similar to δ-MnO_2 – a highly disordered birnessite phase with turbostratic stacking and hexagonal symmetry. These colloidal Mn oxides are extremely reactive and induce further Mn(II) oxidation and Mn oxide formation. Interestingly, the oxidation of Mn(II) mediated by the colloidal Mn oxides includes a number of reaction pathways, involving the formation of organic and oxygen radicals at the oxide surface.

The reactivity of these Mn oxide minerals, however, is short-lived due to the rapid evolution of the initial hexagonal birnessite phase to a non-reactive triclinic birnessite phase. Thus, this structural evolution imposes the need for continuous production of new colloidal hexagonal particles for Mn(II) oxidation to be sustained, illustrating an intimate dependency of enzymatic and mineral-based reactions in Mn(II) oxidation. Further, the coupled enzymatic and mineral-induced pathways are linked such that enzymatic formation of Mn oxide is requisite for the mineral-induced pathway to occur. These findings highlight the important (yet frequently overlooked) role that reactive metabolites and biominerals play in metal redox biogeochemistry.

He-Ne-Ar isotope systematics of the HIMU reservoir; implications to K and U budget in the mantle

T. HANYU[1]*, Y. TATSUMI[1] AND J.-I. KIMURA[1]

[1]Institute for Research on Earth Evolution, Japan Agency for Marine-Earth Science and Technology, Yokosuka, Japan, hanyut@jamstec.go.jp (* presenting author)

Noble gas isotopes could have the potential to provide the evidence for recycled origin of some mantle reservoirs. We present a new set of He-Ne-Ar isotopic compositions of lavas from the Cook-Austral Islands in the south Pacific, which exhibit HIMU and EM characteristics in terms of radiogenic isotopes. $^{3}He/^{4}He$ of the HIMU lavas are lower than MORB values, as previously demonstrated, but a coherent variation in $^{3}He/^{4}He$ with Pb isotopes indicates two-component mixing to form the lavas. Since the HIMU reservoir plots at the radiogenic Pb isotopic end of the mixing trend, $^{3}He/^{4}He$ of this reservoir must be 6 Ra or less. The other mixing component is the local lithosphere, which is commonly involved in EM lavas.

K/U of the HIMU reservoir is constrained by the relative abundances of radiogenic and nucleogenic ^{4}He, $^{21}Ne^*$ and $^{40}Ar^*$. The HIMU lavas show systematic variations in $^{4}He/^{40}Ar^*$-$^{4}He/^{21}Ne^*$ space, in which they define a trend that is parallel to, but offset from the trend previously observed for other OIBs. Using $^{4}He/^{21}Ne^*$ to correct for elemental fractionation of noble gases, $^{4}He/^{40}Ar^*$ of the HIMU reservoir is higher than the $^{4}He/^{40}Ar^*$ production ratio in the mantle. This indicates that the HIMU reservoir had lower time-integrated K/U (approximately 3000) than the canonical mantle value (13000). Low $^{3}He/^{4}He$ and K/U are best explained by a model where the HIMU reservoir originates from ancient subducted oceanic crust that preferentially lost He and K relative to U by dehydration during its subduction.

Since the subducted oceanic crust is enriched in U, but not in K, the preservation of the subducted oceanic crust in the mantle modifies the previous estimates of K/U and K concentration in the bulk silicate Earth (BSE), that did not take this reservoir into consideration. The estimated K/U of BSE may be changed from 13000 down to 8000-10000, if significant amounts of subducted oceanic crust have accumulated to form an isolated reservoir. This fact partially (but not always totally) reconciles $^{40}Ar^*$ paradox. More importantly, subduction and accumulation of the oceanic crust affects the distribution of fluid-mobile and fluid-immobile elements in the mantle.

Mapping of heavy metal sorption to cell-iron-mineral aggregates on the µm-scale

LIKAI HAO[1*], GREGOR SCHMID[1], ANDREAS KAPPLER[1], MARTIN OBST[1]

[1] University of Tuebingen, Germany, Center for Applied Geoscience likai.hao@uni-tuebingen.de (* presenting author) gregor. schmid@ uni-tuebingen.de, andreas.kapple@ uni-tuebingen.de, martin.obst@uni-tuebingen.de

The distribution of heavy metals such as Ni, Cu, Zn, As, Cd, and Hg in environmental biofilm-system is often controlled by the sorption to organic biomacromolecules and by the sorption to and co-precipitation with abiogenic and biogenic iron minerals [1,2]. Changes in pH or redox-potential in micro-environments can result in the release and mobilization of heavy metals in the environment and thus affect ecosystems and/or human health. Therefore, to understand the fate and environmental behaviour of metals in the environment it is essential to acquire information on the partitioning of the respective metals in complex systems such as biofilms which contain a heterogeneous mixture of intact cells, polysaccharides and iron miernals.

Whereas high-resolution imaging such as electron microscopy or scanning transmission X-ray microscopy are suitable to gain detailed insights into binding mechanisms of heavy metals, they usually do not allow for mapping regions at a spatial scale that is relevant for the environment. Thus, we use metal sensitive fluorescent dyes that were developed for cell-biology [3] in combination with confocal laser scanning microscopy (CLSM) [4] to qualitatively and semi-quantitatively map *in-situ* the distribution of heavy metals such as Ni, Cu and Zn within biofilms formed by Fe(II)-oxidizing bacteria at µm to mm-scales. At the same time we localize and map the organochemical composition of the biofilm using various DNA-, protein-, polysaccharide- and lipid-specific fluorescent dyes [3]. Mineral particles were mapped using the reflection signal of the laser. Correlation analysis allowed for identification of binding sites of heavy metals at the µm to mm scale within pristine and metal-contaminated environmental biofilms. Ni and Zn were mainly bound to bacterial cells and polysaccharides, but Cu was found to preferentially be bound to polysaccharides and iron minerals.

[5]USDA Forest Service, RMRS Fire Sciences Laboratory, Missoula, MT, USA, surbanski@fs.fed.us

Introduction

Northern Eurasia covers 20% of the global land mass and contains 70% of boreal forest. Biomass burning in this region may be a significant source of atmospheric black carbon that would deposit on Arctic ice and accelerate ice melting. We examined the daily fire occurrence in different land cover categories at a 1 km x 1 km resolution from 2002 to 2010 over Northern Eurasia. The results are important in assessing the contribution of fire emissions in this region to the black carbon deposition on Arctic ice. This research is also critical in understanding the impact of climate change on the fire dynamics and emissions in Northern Eurasia.

Results and Conclusion

Northern Eurasia is divided into seven geographic areas. The fire locations were based on the MODIS active fire products and MODIS MOD12Q1 product was used for the classification of land cover types. Agricultural fires dominated biomass burning in Northern Eurasia during the nine-year period, accounting for about 52% of the MODIS fire detections, followed by grassland fires (17%), forest fires (16%), and shrubland fires (8%). Approximately 61% of the active fire detections in Northern Eurasia occurred in Russia. The remainder of fire activity largely occurred in Central and Western Asia (21%) and in Eastern Europe (8%). In Russia, about 51% of the fire detections were agricultural fires, 24% were forest fires, and 17% were grassland and shrubland fires. Agricultural residues are often burned after harvest in the autumn or before plowing in the spring. In Central and Western Asia, about 58% of the fire detections were grassland fires, and 37% were agricultural fires. The years 2003 and 2008 had 43% and 47%, respectively, more fire detections than the annual mean (303,856) from 2002 to 2010. The unusually high fire activity in 2003 and 2008 was a result of extensive burning on cropland in Russia and Central and Western Russia, and over forest and grassland and shrubland in Russia. There is no apparent trend of fire occurrence in the entire Northern Eurasia, within each geographic area, or within each of the land cover types between 2002 and 2010. We will present the results of the study and discuss its significance on the spatial and temporal extent of black carbon emissions from forest, agricultural, and grassland and shrubland fires in Northern Eurasia.

Distribution of helium isotope ratio in the central Indian Ocean

T. HARA[1] *, N. TAKAHATA[1], Y. SANO[1], K. SHIRAI[1], K.OHMORI[2] AND T.GAMO[1]

Introduction

The ocean circulation plays an important role in global biogeochemical cycles. Understanding the dynamics of the deep ocean is essential to study global climate change because the ocean has a great capacity to store and transport heat and material. The $^3He/^4He$ ratio is one of the most sensitive and conservative tracers in chemical oceanography because of the primordial signature, rapid mobility and chemical inertness of the isotopes. We have collected about 80 samples at 10 stations along or near 70°E from 20°N to 60°S at various depths (200m ~ 5000m) in the central Indian Ocean. Sampling was carried out during the KH-09-5 cruise of a Research Vessel, Hakuho Maru. Helium isotopes in this area have not beeen much investigated yet.[1]

Analysis

The $^3He/^4He$ ratios were measured on a conventional noble gas mass spectrometer after extraction, purification and separation using Ti getters and cryogenic charcoal traps.[2] The observed $^3He/^4He$ ratios were calibrated against atmospheric helium. To estimate the influence of air contamination, the $^4He/^{20}Ne$ ratios were measured by an on-line quadrupole mass spectrometer before cryogenic separation of He from Ne.

Results and Discussion

The $^3He/^4He$ ratios increased downward, and maximum excess ^3He of ~17% were observed at mid-depth (2000–3000 m), and then decreased in the bottom water. The distribution revealed a north-south gradient with relatively high anomalies in the northern and equatorial Indian Ocean and low anomaly in the southern Indian Ocean.

The high $^3He/^4He$ ratios at mid-depth possibly derived from the mid ocean ridge in the Indian Ocean. These results are consistent with counterclockwise deep circulation in the north-west Indian ocean. The north-south gradient might be due to the inflow of deep seawater with the lower $^3He/^4He$ ratios in Atlantic Ocean or in Antarctic Ocean.

Modeling a rise of atmospheric oxygen induced by Paleoproterozoic snowball Earth event

MARIKO HARADA[1*], EIICHI TAJIKA[2], AND YASUHITO SEKINE[2]

[1]University of Tokyo, Earth and Planetary Science, Tokyo, Japan, harada@astrobio.k.u-tokyo.ac.jp

[2]University of Tokyo, Complexity Science and Engneering, Chiba, Japan

Recent geological studies suggest that Paleoproterozoic snowball glaciations may have possibly caused a rise in atmospheric oxygen [1,2]. The hypothesis is that a global warming in a glacial aftermath enhances chemical weathering on land and provides nutrients to the ocean, which leads to a cyanobacterial bloom [2]. In order to verify the hypothesized oxidation process quantitatively, we developed a simple atmosphere-ocean biogeochemical cycle model and simulated the atmosphere and ocean perterbation after deglaciation.

We set an initial condition under high atmospheric pCO_2 (~0.7 atm), assuming a situation immediately after the Paleoproterozoic snowball deglaciation. Chemical weathering rate is given as a function of temperature and atmospheric pCO_2, mutipled by weahtering efficiency f (f = 1 at present) which depends on soil biological activity and continental area at the time. Nutrient supply is represented by riverine phosphorous input via chemical weathering, which is assumed to be consumed fully by photosenthesis. For the global oxygen cycle, we adopt a redox system model given by Goldblatt et al. (2006) [3].

Our results indicate that, immidiately after the deglaciatoin, global temterature rises as high as 330 K, resulting in extremely high levels of riverine phosphorous input due to the enhanced chemical weathering (~10–20 times higher than that of today). Assuming all the provided phosphorous are consumed by oxygen-producing photosenthesis via cyanobacteria, total amount of oxygen generated by photosenthesis may reach 10^{23} mol during 10^5 years immediately after the deglaciation. Atmospheric oxygen level rises from less than 10^{-5} PAL (present atmospheric level) to ~1 PAL during the first 5 million years, and then gradually decreases to a stable level of ~0.01 PAL. In this model, oxygen concentration rises up to ~0.1 PAL in the first 100 years, probably because of a large perterbation induced by glaciation and subsequent suppression of methane oxidation, which is a major sink of oxygen, by ozone layer formation. However in reality, such an extremely rapid rise in productivity and O_2 level might have been dampened, considering timescale needed for cycnobacteria to recover after the severe glaciation or phosphous adsorption into iron oxides in the shallow ocean. We will therefore also discuss influences of iron-manganese cycles which couple to the phosporus cycle, as well as variations of marine carbon isotopic composition.

Spectrophotometric analysis for As(V) sorption mechanism in the aluminum hydroxide coprecipitation method

D. HARAGUCHI[1*], C. TOKORO[2] AND S. OWADA[2]

[1]Waseda university, Tokyo, Japan, d.haraguchi@aoni.waseda.jp

[2]Waseda university, Tokyo, Japan, tokoro@waseda.jp

[3]Waseda university, Tokyo, Japan, owadas@waseda.jp

Hydroxide coprecipitation method is widely used in a treatment of wastewater containing dilute toxic anions. But now detail mechanism or quantitative characteristic is not well understood and also demanded. This study discussed a sorption mechanism of dulute arsenic (As(V)) in wastewater using aluminum hydroxide coprecipitation method by analyzing filtrates and precipitates for an artificial wastewater.

Sorption mechanism of As(V) coprecipitation with aluminum hydroxide was investigated using four kinds of experimental methods: (i) sorption instherm formation, (ii) zeta potential mesurement, (iii) XRD analysis, and (iv) FT-IR analysis. We compared between coprecipitation experimental results and simle adsorption ones in which As(V) was just adsorbed on the sysnthized aluminum hydroxide.

In the only coprecipitation experiments, sorption isotherms of As(V) on aluminum hydroxide exhibited a BET type isotherms and sorption densities abruptly increased when the initial As/Al molar ratio was more than 1.5. And zeta potential hardly changed even if sorption densities increased when the initial As/Al molar ratio was more than 1.5. Moreover, the results of XRD and FT-IR analysis represented that patterns and spectra were similar to not the ones of amorphous aluminum hydroxide but amorphous aluminum arsenate when the initial As/Al molar ratio was more than 1.5. On the other hand, these unique tends was not shown in the adsorption experiments [1].

Thus, the inherent phenomena which can sorb more As(V) than single layer adsorption has occurred in the only coprecipitation experiments. The results of XRD and FT-IR analysis suggested that the precipitates have changed depending on the initial As/Al molar ratio and a surface precipitation such as amorphous aluminum arsenate was formed when the initial As/Al molar ratio was more than 1.5, whereas simple tow-dimentional adsorption of As(V) onto the surface of aluminum hydroxide when the initial As/Al molar ratio was less than 1.5. These trends were qualitatively accorded with sorption mechanism of dilute As(V) with ferrihydrite [2].

The weathering forefront for permafrost carbon: priorities for critical zone research

JENNIFER HARDEN[1*], STEPHANIE EWING[2], TORRE JORGENSON[3], CHARLES KOVEN[4], COREY LAWRENCE[1], MARJORIE SCHULZ[1], MARK WALDROP[1]

[1]U.S. Geological Survey, Menlo Park, USA, jharden@usgs.gov

[4]Lawrence Berkeley National Lab, Berkeley, USA, CDKoven@lbl.gov

Little is known about mineral weathering in permafrost soils. Yet as permafrost thaws, mineral stabilization of carbon may become exceedingly important owing to the large stores of permafrost carbon that will thaw over the next century. In areas where permafrost is not present, carbon is often stabilized by organo-mineral binding and complexation driven by mineral weathering. Hydrology and biogeochemistry are key to pathways and transit times of carbon fluxes to the atmosphere. Above the permafrost (the active layer), water and ice contents influence thermal conductance and rates of thawing; decomposition of organic matter increases dramatically upon thaw; organic matter structure is linked to soil moisture and vegetation characteristics. In deeper soils with permafrost, the amounts and forms of carbon have been characterized according to processes of C stabilization (Figure 1), but carbon forms have not been related mechanistically to water, mineral surfaces, and biogeochemistry in a way that addresses processes at meaningful scales.

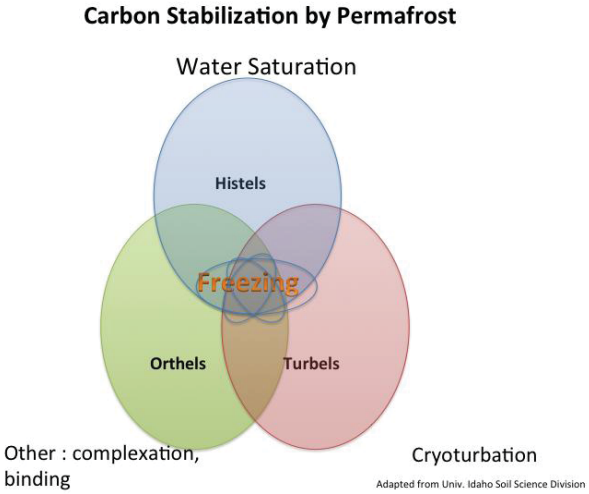

Figure 1. Processes of carbon stabilization by the three suborders of permafrost soils called Gelisols.

Thus the processing and microenvironments of permafrost carbon at the micro and macroscale will be key to understanding how and where permafrost carbon may be stabilized or destabilized upon thaw.

New insights from FOAM: iron and trace metal cycling in highly sulfidic pore waters beneath an oxic water column

DALTON S. HARDISTY*[1], NATASCHA RIEDINGER[1], BEN C. GILL[2], DAVID T. JOHNSTON[3], CHRISTOPHER T. REINHARD[1], NOAH PLANAVSKY[1], DAN ASAEL[4] AND TIMOTHY W. LYONS[1]

[1]University of California, Riverside, Riverside, USA, dhard003@ucr.edu (*presenting author)
[2]Virginia Tech, Blacksburg, USA
[3]Harvard University, Cambridge, USA
[4]University Brest, Brest, France

A 50-cm sediment core was collected from the FOAM site (Friends of Anoxic Mud) with pore waters being extracted immediately on-site. FOAM is a well-described, nearshore study site in Long Island Sound characterized by high TOC and pore water sulfide concentrations of a few mM overlain by an oxic water column. Going well beyond any past work at FOAM, and to complement our Fe analyses, we analyzed a suite of trace metals including Mo, Cr, V, and U. Our data for Fe-speciation show high ratios of pyrite (Fe_{py}) to highly reactive Fe (Fe_{HR}; Fe_{py}/Fe_{HR} >.99), intermediate Fe_{total}/Al (≈.5) and low Fe_{HR}/Fe_{total} (< .3), consistent with near-complete pyritization of the highly reactive Fe delivered with the detrital mineral flux. Importantly, these conditions do not yield high Fe_{HR}/Fe_{total} and Fe_{total}/Al ratios and degrees of pyritization, our standard fingerprints of anoxia/euxinia, despite protracted exposure to high dissolved sulfide concentrations. Data from the FOAM site, in combination with past work in the Black Sea, show the necessity for additional inputs of reactive Fe to generate high Fe_{HR}/Fe_{total}, Fe_{py}/Fe_{HR}, Fe_{total}/Al, and degrees of pyritization, likely via an Fe-shuttle in association with syngenetic pyrite formation under euxinic conditions. Because of the oxic bottom waters, these processes are not significant at FOAM, confirming past work by Canfield et al. [1, 2]. Then, as now, FOAM provides a mechanistic keystone in our understanding of the Fe paleoredox proxies. Trace metal concentrations in FOAM sediments show only intermediate enrichment, despite very high [H_2S] in the shallow pore waters. The muted trace metal enrichments at FOAM confirm that water-column euxinia is uniquely responsible for very high concentrations and further validate the utility of the proxies in our search for euxinia in the ancient oceans. In addition, coupled Fe and Mo isotopes from both the FOAM sediments and pore waters have the potential to improve the paleoproxy potential of Fe and trace metal expressions that distinguish between euxinia and sulfide-rich and sulfide-poor diagenetic environments overlain by oxic bottom waters.

Alteration of zircon in alkaline fluids: Nature and experiment

D.E. HARLOV[1*], A. LEWERENTZ[2], A. SCHERSTEN[2]

[1]GeoForschungsZentrum, Telegrafenberg, 14473 Potsdam, Germany, dharlov@gfz-potsdam.de (* presenting author)
[2]Dept Earth Sciences, Lund University, 22362 Lund, Sweden, alexander.lewerentz@gmail.com, anders.schersten@geol.lu.se

Natural alteration of zircon can take place either via partial dissolution coupled with partial overgrowth or via fluid-aided coupled dissolution-reprecipitation or both processes in tandem [1][2]. Coupled dissolution-reprecipitation results in the zircon being partially to totally replaced by compositionally re-equilibrated zircon, a new mineral phase, or both.

In this study, fragments (50 to 200 μm) from an inclusion-free, relatively non-metamict euhedral zircon (nepheline syenite pegmatite, Seiland magmatic province, northern Norway) were experimentally reacted in 20 mg batches with Ca-bearing fluids (1 mg $Ca(OH)_2$ + 5 mg H_2O) plus 5 mg (ThO_2 + $ThSiO_2$ + SiO_2) in sealed Pt capsules at 900 °C and 1000 MPa for 6 to 11 days (piston cylinder press, CaF_2 setup, cylindrical graphite oven). In the experiment, the fluid reacted with the zircon. This took the form of partial replacement of the zircon with compositionally altered zircon via coupled dissolution-reprecipitation. The reacted zircon is characterized by a sharp compositional boundary between the altered and original zircon. The altered zircon generally contains a micro-porosity. Inclusions of baddelyite (ZrO_2) are seen outlining the reaction front between the altered and unaltered zircon. SIMS analysis of the altered zircon indicates that it is strongly enriched in Th + Si, heavily depleted in U, and heavily to moderately depleted in (Y+REE). In all experiments radiogenic ^{206}Pb (3 to 5 ppm in the unaltered zircon) is strongly depleted in the altered zircon. Hf concentrations in the altered zircon retain the same approximate value as in the original zircon. The results from these experiments indicate that zircon can be compositionally altered via Ca-bearing fluids via coupled dissolution-reprecipitation processes under high-grade conditions and that their internal geochronometer can be reset due to the massive loss of U and radiogenic Pb and the additon of Th.

The baddelyite-zircon textures from these experiments replicate similar, highly-localized zircon-baddelyite textures seen in albitised, 2.9 to 2.7 Ga, amphibolite- and granulite-facies granitoid rocks from SW Greenland [3]. Here Ca was released into the fluid during the albitisation of plagioclase. Baddelyite should not be stable in the presence of SiO_2 (present in both the experiments and in the granitoid rocks) but rather react with SiO_2 to form zircon. However, if sufficient Ca is present in the fluid, it appears to complex with the SiO_2 as $CaSiO_3$ thereby lowering the SiO_2 activity such that baddelyite is stable with co-existing zircon and quartz. The experiments also demonstrated that, with sufficiently high enough concentrations of SiO_2 in the fluid, not all of the SiO_2 will complex with Ca allowing for the activity of SiO_2 to remain at 1. In this case baddelyite did not form in or with the altered zircon.

Multiple sulfur isotope model of temperature dependent isotope fraction in *Archaeoglobus fulgidus*

BRIAN HARMS[1*], KRISTEN MITCHELL[2], KIRSTEN HABICHT[3], JOOST HOEK[1], JAMES FARQUHAR[1]

[1]Department of Geology and ESSIC, University of Maryland, College Park, Maryland, USA (*Correspondence: bharms@umd.edu)
[2]Department of Earth and Environmental Sciences, University of Waterloo, Waterloo, Ontario, Canada
[3]Institute of Biology, Nordic Center for Earth Evolution (NordCEE), University of Southern Denmark, Odense, Denmark

Dissimilatory sulfate reduction (DSR) has a central role in the global sulfur cycle. Understanding how environmental factors and physiological variables influence DSR-mediated sulfur isotope fractionation is therefore crucial for interpting the sedimentary sulfide record. The hyperthermophile *Archaeoglobus fulgidus* grows over a wide range of temperature conditions (54°-92°C [1]), making it an ideal test subject for investigating how aspects of the DSR pathway respond to temperature extremes. A previous study of *A. fulgidus* [1] found that fractionations between sulfate and sulfide were greatest at intermediate temperatures. An inverse correlation between cell specific sulfate reduction rate and fractionation was found in the intermediate temperature range, but this correlation broke down at the extreme hot and cold limits of growth. A potential solution to a flow network model [2] was proposed, one in which sulfate exchange across the cell membrane controlled fractionation at high and low temperatures, and internal sulfur transformations were the dominant influence at intermediate temperatures [1].

Here we present multiple sulfur isotope results from the same culture experiments in [1]. Our calculated flow parameters (f_3 and f_5) give a markedly different trend from that predicted in [1], and our observed $\Delta^{33}S$ values also implicate a DSR flow network in which large fractionations (as in e.g. [3]) are permitted. The mismatch between predictions and results suggests a different physiological response to temperature change than expected. Several possibilities are investigated. Following the framework of [4], we also investigate solutions in which the fractionation factor associated with the reduction of sulfite to sulfide is not a fixed quantity.

Isotopic Variations in the Northern Galápagos Volcanic Province

KAREN S. HARPP[1,2*], WILLIAM SCHLITZER[1], THOMAS MORROW[2], ERIC MITTELSTAEDT[3], AND THE MV1007 SCIENTIFIC PARTY

[1]Colgate University, Hamilton, NY, USA, kharpp@colgate.edu *presenting author
[2]University of Idaho, Moscow, ID, USA
[3]Woods Hole Oceanographic Institution, Woods Hole, MA, USA, emittelstaedt@whoi.edu

The Northern Galápagos Volcanic Province (NGVP), located between the Galápagos Archipelago and the Galápagos Spreading Center (GSC), is ideally located to provide insight into the mechanisms of plume-ridge interaction. The plume is located south of the GSC, close enough to have profound geochemical and geophysical influences on the ridge. During the 2010 MV1007 research cruise, we collected geophysical data and >40 dredges across the NGVP, in a survey bounded by the Wolf-Darwin Lineament (WDL) to the west and Genovesa Island to the east.

Preliminary Sr, Nd, and Pb isotopic data reveal several important observations about the composition of lavas in the NGVP: a) most NGVP lavas are more enriched than those from the northern margin of the Galápagos Platform; b) consistent with previous work in the archipelago [1, 2], geochemical variations of Nazca Plate lavas require 3 distinct isotopic endmembers, a dominant one with elevated $^{207}Pb/^{204}Pb$ and $^{208}Pb/^{204}Pb$ for a given $^{206}Pb/^{204}Pb$ (like WD from [2]), one with moderate Sr, Nd, and Pb ratios (like PLUME from [2]), and a depleted MORB-like composition; c) lavas from Pinta Island eastward are binary mixtures of WD and depleted mantle; d) lavas erupted on the Cocos Plate may be influenced by a 4th endmember with elevated $^{206}Pb/^{204}Pb$ and $^{87}Sr/^{86}Sr$ (i.e., FLO from [2]); and e) there are no systematic spatial variations in isotopic ratios along volcanic lineaments on the Nazca Plate (e.g., the WDL).

Our results have implications for plume-ridge interaction and the composition of the Galápagos plume. The NGVP is dominated by the elevated $^{207}Pb/^{204}Pb$ and $^{208}Pb/^{204}Pb$ component, with only minor influence of the material supplying the western Galápagos shields, the locus of the plume. This suggests that the plume is strongly spatially zoned or that there is an additional source of enriched mantle material limited to the GSC area. The lack of spatial patterns in geochemistry across the Nazca Plate in the NGVP further indicates that enriched material is distributed throughout the mantle between the ridge and the plume and reaches the surface through crustal weaknesses generated by regional stresses [3, 4]. The presence of enriched material in Cocos Plate lavas suggests plume-related material is bypassing the zone of upwelling beneath the GSC as it flows to the north. These results confirm that the Galápagos system may be mirroring Hawaii and other plumes that exhibit strong north/south spatial zonation [5], The Galápagos are distinct from Hawaii, however, in that the more radiogenic Pb component is in the northern arm of the plume instead of the south.

Manganese, Fenton Chemistry, and Disease: The proof is in the inflammation.

ANDREA D. HARRINGTON[1]*, STELLA E. TSIRKA[2], AND MARTIN A.A. SCHOONEN[1]

[1] Stony Brook University, Department of Geosciences, Andrea.Harrington@stonybrook.edu (*presenting author) Martin.Schoonen@stonybrook.edu
[2] Stony Brook University, Pharmacological Sciences, stella@pharm.stonybrook.edu

Exposure related diseases can be, for the most part, broken down into two categories, mutagenic and toxic. While a mutagenic disease results from disruption of normal cell replication, an illness based on particle toxicity is derived from the ability of the material to generate an inflammatory stress response (ISR), dysregurate the cell, and possibly lead to cell death. Particle-derived cellular oxidative stress is likely a key contributor to many occupational health diseases, such as silicosis and coal workers' pneumoconiosis.

Reactive oxygen species (ROS), and the hydroxyl radical in particular, are known to cause oxidative stress. Earth materials can generate ROS in two different ways, via surface defects and oxidative dissolution. The oxidative dissolution of minerals allows for metal cations to enter the solution. Once in solution, these cations can partake in Fenton chemistry.

While iron is the most recognized Fenton metal, new research indicates that chromium, copper, vanadium, recently manganese can also generate ROS, although the reaction mechanisms are not well understood [1-3]. Originally only taking iron into account, the Fenton reaction can now be generalized to [4]:

$$H_2O_2 + M^{n+} \rightarrow M^{(n+1)+} + {}^{\cdot}OH + OH^-$$

where M is a metal cation which can donate one electron and be stable at this new oxidation state [4].

Exposure to manganese is thought to be the root for many neurological diseases, such a Parkinson's, Alzheimer's and Huntington's. However, its role in the development of pulmonary diseases through stimulating inflammation is unknown. In the present study, the ability of different species of manganese to generate ROS and an ISR at the cellular level is examined. Furthermore, the confounding effects of having iron and/or quartz in the system are investigated.

Experiments using dissolved manganese and iron species are performed to compare their abilities to generate ROS and an ISR. These tests are performed utilizing an array of geochemical and biochemical techniques [5,6]. More intricate experiments will be performed using iron and/or manganese as co-contaminates and co-precipitates onto synthetic quartz.

Initial experiments have demonstrated the ability of manganese to elicit an ISR. Furthermore, the higher solubility of manganese compared to iron, which precipitates out into a relatively inert ferric phase, allows for a considerably steady ISR over time and a response that continuously increases with loading.

Documenting magmatic processes at Filicudi Island, Aeolian Arc, Italy: integrating plagioclase textural and in situ compositional data

Michelle Harris[1*], Wendy Bohrson[2]

[1]Central Washington University, Ellensburg, USA harrism@geology.cwu.edu (* presenting author)

[2]Central Washington University, Ellensburg, USA bohrson@geology.cwu.edu

Documenting the physiochemical processes that influence magma composition is critical for forecasting eruption style and managing volcanic hazards. Although studies have documented how compositional diversity develops in magmas on Earth, controversy exists regarding the roles that recharge, assimilation and fractional crystallization (RAFC) play in magma evolution. Studies of Filicudi Island, Italy, document a compositional range from calc-alkaline basalt (51 wt. % SiO_2) to high-K andesite (62 wt. % SiO_2) that cannot be simply related by FC, implying magma recharge and crustal contamination/assimilation played vital roles. Integration of plagioclase textural and in situ compositional data allows documentation of the quantitative roles and chronology of RAFC.

Filicudi Island is one of seven major islands of the Aeolian archipelago in the southern Tyrrhenian Sea, Italy. Stratigraphic studies define four main cycles of activity that range in age from 1.02 to 0.04 Ma (*1*). Cycles are characterized by a succession of plagioclase bearing magmas that show recurrent reversals to more MgO-rich magmas, a lack of systematic correlation between SiO_2 and MgO, and an overall SiO_2 increase with time, implying recharge, assimilation, and fractional crystallization took place. Images obtained from Nomarski Differential Interference Contrast and Back-Scattered Electron methods document five main texture types within seven samples that span the compositional range of Cycle Three, the most widely exposed cycle. Identified textural types include monotonous, complex oscillatory, sieved cores with oscillatory rims, oscillatory cores with sieved rims, and sieved cores and rims.

Detailed core-to-rim traverses of crystals of each textural type using Electron Microprobe analysis document mostly core-to-rim decreases in Anorthite content, although a few significant core-to-rim increases do occur. Similarly, incompatible trace elements generally show increases from core-to-rim with decreasing Anorthite content, or more complex trends, providing evidence that (A)FC processes played a dominant role. Conversely, core-to-rim increases in Anorthite content with associated Fe and Mg increases provide strong evidence that at least one recharge event occurred within the associated magma body. LA-MC-ICPMS analyses will be performed on selected crystals that encompass the range of Anorthite, trace element and textural types to document core-to-rim changes in $^{87}Sr/^{86}Sr$. Isotopic data will further characterize the RAFC history of these magmas as well as will complete a data set that can be quantitatively modeled to provide thermal and mass constraints on this phase of magmatic activity at Filicudi Island.

[3]Lawrence Berkeley National Laboratory, Berkeley, United States of America, sabea@lbl.gov

Mineralization of atmospheric CO_2 within carbonate minerals occurs passively in ultramafic mine tailings via weathering of Mg-silicates and hydroxides [1]. If this process were accelerated, large mines may have the capacity to sequester millions of tonnes of CO_2 annually. Supplying elevated partial pressures of CO_2 (pCO_2) into tailings may accelerate CO_2 sequestration by increasing dissolved inorganic carbon and enhancing mineral dissolution. Passive carbon mineralization has been documented at the Mount Keith Nickel Mine (MKM) in Western Australia [2]. MKM produces tailings consisting primarily of Mg-silicate minerals. Brucite [$Mg(OH)_2$] is present at lower abundance [2], yet is more rapidly carbonated, thus was practical for experiments and modeling.

Gas streams with elevated pCO_2 have been used to enhance brucite carbonation rates in zero-dimensional batch experiments. In tailings, however, multi-dimensional flow means that interactions between transport and chemical reactions will play a role in governing carbonation rates. To investigate carbonation efficiency in tailings under elevated pCO_2 conditions, brucite columns were supplied with 10 vol.% CO_2. Quantitative mineralogical analyses of solids indicate the extent of carbonation declined with distance from the injected CO_2.

Two modeling studies have been undertaken using the reactive transport code, MIN3P [3], to calibrate the model and to elucidate the processes likely to govern the rate and extent of carbonation in tailings. Modeling of column experiments indicated a strong advective gradient in the gas phase was developed due to CO_2 injection, thereby enhancing vertical CO_2 transport. A second modeling study was undertaken in which passive carbonation in an active tailings storage facility at MKM was modeled and calibrated with field data to complement previous work simulating an inactive facility at this mine [4]. The active facility is periodically replenished with slurries of fresh tailings, resulting in lateral flow in addition to the evaporative driven vertical flow occurring in the inactive facility. This more complex flow regime may affect both reactive cation transport and the ingress of atmospheric CO_2, thereby altering the extent of carbonation.

These studies permitted the development of a comprehensive model that describes both passive and accelerated CO_2 sequestration in tailings. Our calibrated model will enable assessment of sequestration potential and help guide implementation of accelerated sequestration strategies at mine sites.

Li Isotopes of Hawaiian Lavas: Kea vs Loa Source Variation

LAUREN HARRISON[1*], DOMINIQUE WEIS[1], MIKE GARCIA[2], ELSPETH BARNES[1], AND DIANE HANANO[1]

[1]Pacific Center for Isotopic and Geochemical Research, University of British Columbia, Vancouver, BC, Canada, lharriso@eos.ubc.ca
[2]Department of Geology and Geophysics, University of Hawai'i, Honolulu, HI, 96822, USA, mogarcia@hawaii.edu

Hawaiian volcanism delineates into two distinctive geographical series, the Kea and the Loa trends, identified by their unique geochemical and isotopic characteristics. Traditionally, these trends have been attributed to mixing of different components in the source of the Hawaiian mantle plume, mainly an enriched end-member (Ko'olau) characterized by the presence of recycled oceanic crust ± sediment, a more depleted end-member (Kea) with high ε_{Nd}, ε_{Hf}, and $^{206}Pb/^{204}Pb$, and a more primitive component defined by high $^{3}He/^{4}He$ (Lo'ihi). Because of the sizeable fractionation of lithium isotopes in low temperature environments, lithum serves as a powerful tracer for the presence of altered oceanic crust and sediments in the sources of oceanic island basalts. Lithium can thus be used to help distinguish the source components of Hawaiian lavas, most importantly for post-shield and rejuvenated lavas, where depleted/recycled components are thought to play a larger role.

This study analyzed fifty-six samples of Hawaiian shield (13), post-shield (36) and rejuvenated lavas (7) for lithium isotopes. Post-shield volcanics exhibit the lightest δ^7Li values, ranging from 0.75 ± 0.33‰ to 5.20 ± 0.20‰, while rejuvenated lavas from Kaua'i, Ka'ula, and West Ka'ena Ridge are intermediate with an average of 3.72‰. Finally, shield basalts exhibit the highest δ^7Li, ranging from 3.03 ± 0.27‰ to 5.19 ± 1.07‰. For both post-shield and shield lavas, δ^7Li is able to delineate between Kea and Loa trends (e.g., post-shield Kea average: 3.67‰ and post-shield Loa average: 2.48‰). Lithium isotopes correlate positively with Pb and Nd isotopes, indicating that Li isotopic signatures survive residence time in the mantle and are suitable tracers of source components [1], in this case ancient subducted oceanic crust and/or sediments, in Hawaiian volcanism. In $^{206}Pb/^{204}Pb$ and ε_{Nd} vs δ^7Li diagrams, Loa shield lavas plot along the extension of Kea shield lavas with lower δ^7Li, ε_{Nd} and $^{206}Pb/^{204}Pb$. Enriched Loa shield lavas from West Ka'ena Ridge, the Mile High Section of Mauna Loa, and subaerial Ko'olau show higher δ^7Li, but with their lower ε_{Nd} and $^{206}Pb/^{204}Pb$, these lavas define a sub-parallel trend that indicates there are at least two enriched end-members in the Loa source, one in Ko'olau [2] and one in Loa trend lavas [3]. Finally, Hualalai post-shield volcanics show the lowest δ^7Li values, ranging from 0.75 ± 0.33‰ to 3.53 ± 0.53‰, which might reflect the presence of recycled oceanic crust.

In this study, lithium isotopes not only suggest the presence of a recycled component in post-shield, rejuvenated, and Loa shield lavas, they also help distinguish Loa enriched source components. Further characterization of the trends in lithium isotopes may unearth some additional insights into the source of Loa-type volcanism [4].

Incorporation of Perrhenate into Nitrate Sodalite

JAMES B. HARSH*[1], JOHNBULL O. DICKSON[1], AND ERIC M. PIERCE[2]

[1]Washington State University, Pullman, WA, USA, harsh@wsu.edu (* presenting author)
[2]Oak Ridge National Laboratory, Oak Ridge, TN, USA

Technetium-99 (Tc), a long-lived radionuclide, is one of the most widespread contaminants within the Hanford subsurface with an estimated inventory of 5.31×10^3 curies. For example, Tc contamination has been found in the sediments beneath the C, S, SX, T, and TX Tank Farms as a result of high-level waste (HLW) solutions that have leaked or spilled from Hanford Tanks. The HLW solutions are characterized as highly alkaline (hydroxide ion concentration > 8.5 M) and high ionic strength solutions (up to saturation with respect to $NaNO_3$). Previous research focused on Sr-90 and Cs-137 has demonstrated that these elements are incorporated into feldspathoid minerals, such as nitrate sodalite $[Na_8(Al_6Si_6O_{24})(NO_3)_2]$, that formed as a result of the contact between Hanford sediments and the HLW solutions (Chorover et al., 2008; Deng et al. 2006). The desire to immobilize Tc in aluminosilicate minerals through the application of subsurface amendments for contaminated sediments as well as the production of mineralized wasteforms further emphasizes the need to understand the long-term stability and release of Tc from aluminosilicate minerals, specifically the feldspathoid mineral sodalite.

Nonradioactive perrhenate (ReO_4^-) was used as a surrogate for TcO_4^- due to its similar ionic potential. Sodalite was synthesized over 24 h at 80C from 1.76 M solutions of NO_3 + ReO_4, with ReO_4 concentrations of 0, 0.18, 0.35, 0.71, 0.88, and 1.76 M with NaOH and 4A zeolite added as sources of Na, OH, Al, and Si. Perrhenate concentrations in the sodalite ranged from 0 to 13 mmol kg^{-1} in the 0 – 0.88 M ReO_4 samples. The 1.76 M sample, without NO_3, contained 760 mmol kg^{-1}. Using the 211 x-ray diffraction peak to determine alteration of crystal structure, no significant shifts occurred, except in the NO_3-free sample where the 211 d-spacing increased by 0.01 nm. Increased reaction time from 1 to 7 d narrowed the peak widths, implying more crystallinity, but ReO_4 incorporation did not change in a consistent manner. We conclude that the larger ReO_4 ion (r = 260 pm) does not form as stable a sodalite structure as the NO_3 (r = 190 pm). Further experiments will determine the role of ion size in the formation of sodalite in the presence of more than one species.

Meridional ocean circulation intensity through MIS 11 from Nd isotopes in South Atlantic cores

ALISON E. HARTMAN[1*], STEVEN L. GOLDSTEIN[1], SIDNEY R. HEMMING[1]

[1]Lamont Doherty Earth Observatory; Columbia University, Palisades, NY, USA, ahartman@ldeo.columbia.edu (* presenting author)

Abstract

The waxing and waning of North Atlantic Deep Water (NADW) in the South Atlantic has been used to monitor changes in meridional overturning circulation. Neodymium (Nd) isotopes are a valuable water mass tracer in this region because the ε_{Nd} value of intermediate and deep waters is dependent on the mixing ratio of southern- and northern-sourced water. A spliced record from deep cores RC11-83 (42.07ºS, 9.717ºE, 4718m) and TNO57-21 (40.6ºS, 7.816ºE, 4918 m) showed higher values (>2ε_{Nd} units) during the LGM compared with today, indicative of a weakening or shoaling of NADW in the South Atlantic during glacial periods[1]. Nearby core TNO57-6 (42.92ºS, 8.88ºE, 3750m) is slightly further south and significantly shallower than RC11-83/TNO57-21 and showed a substantially greater Last Glacial Maximum (LGM) to Holocene offset (>4 ε_{Nd} units)[1,2]. However, further studies have indicated that the methods for obtaining the bottom water ε_{Nd} signal at site TNO57-6 were likely compromised by a contaminating phase within the fine sediment during leaching. We modified our previous procedure, in line with the Cambridge group[3], and are extracting the ε_{Nd} values of dissolved Fe-Mn oxide encrusted, mixed-species, planktonic foraminifera. Confirmation of the results as a bottom water signal is indicated by agreement with the ε_{Nd} values of fish debris from the same depth[3]. The resulting record shows a Holocene ε_{Nd} value around -9.7 with a gradual increase of ~3 ε_{Nd} units to an LGM value around -6.5 ε_{Nd} units. This trend is similar to the TNO57-21/RC11-83 record. We have applied the new procedure down-core, and developed a set of glacial-interglacial pairs for each transition since MIS 11. All interglacial stages show ε_{Nd} values similar to Holocene values (-9.5) and each glacial shows an increase of about 2 ε_{Nd} units, with the exception of MIS 8, which appears to show a smaller increase of ~1 ε_{Nd} unit. We interpret these data as recording changes in the presence of NADW in the South Atlantic between glacials and interglacials, and indicating similar intensities in the export during interglacials through MIS 11, and also in glacials except for MIS 8. The record may also be interpreted as indicating stronger shoaling of the northern component waters during MIS 2, 6 and 10 than during MIS 8, and this will be further investigated. Overall the data indicate similar levels of stability were reached during the warm and cold phases of several glacial-interglacial cycles.

Stable isotope and trace element records in Holocene stalagmites from Java: Paleoarchive of climate change and human activity?

A. HARTMANN[1], E. EICHE[1], T. NEUMANN[1*], J. FOHLMEISTER[2], A. SCHRÖDER-RITZRAU[2], A, MANGINI[2]

[1]Karlsruhe Institute of Technology, Institute for Mineralogy and Geochemistry, neumann@kit.edu (*presenting author)

[2]Forschungsstelle Radiometrie, Heidelberger Akademie der Wissenschaften, 69120 Heidelberg, Germany

Speleothems are important archives to trace paleoclimate and paleoenvironmental changes. This has widely been proven in temperate zones, but there is a lack of studies from the tropics. To further close this gap, active stalagmites, formed since the early Holocene, from Bribin cave located in the Gunung Sewu karst, Middle Java, Indonesia have been analysed in high resolution.

The $\delta^{18}O$ values vary between -6 and -8 ‰ with lowest values approximatily 8.5 ka ago indicating a period of high rainfall amount in the early Holocene. This assumption is supported by a continuous concurrent lowering of corresponding Sr/Ca and Mg/Ca ratios with time, displaying a shorter contact time with the limestone in the Karst.

During the early and mid-Holocene, relatively low $\delta^{13}C$ values of 12.2 ± 0.24 ‰ were recorded which is indicative of a predominant contribution of carbon from C3 plants of the overlying tropical rain forest. However, the $\delta^{13}C$ values show a dramatic, but almost continuous increase from -12.0 to -7.8 ‰ over the last ~1.1 ka. This increase may reflect a change in vegetation density (less isotopically light plant material) and/or composition (C4 instead of C3 plants) at the surface.However, during the corresponding period of time, no distinctive trend was detectable for the $\delta^{18}O$ values with oscillations around -6.8 ± 0.25 ‰. Consequently, a possible change in vegetation cannot be explained by considerable climatic changes alone which would have also influenced the $\delta^{18}O$ signal. Mg/Ca and Sr/Ca ratios partially positively correlate with the $\delta^{13}C$ record over the last 1.1 ka indicating that some changes in the water balance still might be of importance resulting in longer or shorter contact time with the karstic limestone. An alternative interpretational approach may relate the marked $\delta^{13}C$ increase of the last millenium to human activities. Pollen and sedimentological studies from the area strongly suggest that extensive and organized forest clearance has been taking place on Java for the last 1.5 or 1.2 ka, respectively [1].

Steps towards a global chemical weathering model framework: The role of erosion and supply limitation

J. HARTMANN[1*], N. MOOSDORF[1], R. LAUERWALD[1], A.J. WEST[2], S. COHEN[3], A.J. KETTNER[3]

[3] Community Surface Dynamics Modeling System (CSDMS), Institute of Arctic and Alpine Research (INSTAAR), University of Colorado, Boulder CO, USA, sagy.cohen@colorado.edu, kettner@colorado.edu

Chemical weathering is an integral part of the rock cycle, and its relationship with physical erosion has been a subject of long-standing interest. Empirical correlations between erosion and weathering have been observed for headwater catchments [1] but such correlations have been more difficult to identify at the scale of Earth's largest river basins [2]. This may be the result of the many different factors that influence weathering, including the strong observed dependence on runoff [2, 3].

In this study, we explore the hypothesis that low rates of erosion and associated development of deeply weathered soils, particularly in the humid tropics, reduces chemical weathering over large spatial scales, significantly influencing fluxes from large river basins. As a starting point, we use functional equations for chemical weathering that have been trained empirically based on data from the Japanese Archipelago [3], across a range of different lithologies [4]. These equations were applied to large catchments in tropical areas, and the importance of supply limited weathering was assessed in two ways: (i) using a correction factor based on maps of the distribution of deeply weathered soils and wetlands, and (ii) by comparing weathering fluxes with modeled physical erosion rates [5].

In general, weathering fluxes calculated using the island arc model are significantly over-estimated for the low-lying tropical river basins. An average soil correction factor of 90% was found to account for this supply limited effect. The reduction in chemical weathering rates scales with calculated physical erosion in a comparable pattern to that identified for headwater catchments with felsic lithologies [1].

The results of this study highlight the importance of accounting for the scaling of chemical weathering with erosion at the scale of Earth's largest river basins. Weathering fluxes from island arcs are among the globally highest, because of the young and fresh mineral surfaces, but the weathering equations derived in these settings can be applied to estimate weathering fluxes globally by accounting for supply limitation based on physical erosion rates.

Abstract

For decades, the source of Earth volatiles, especially water, has been a subject of debate. Proposed explanations include accretion of material in the vicinity of the Earth orbit or delivery by impacts of asteroids or comets during the late heavy bombardment (LHB). The source of water reservoirs can be accurately traced by measurements of the deuterium-to-hydrogen isotopic ratio (D/H). Previous measurements of this ratio in several Oort cloud comets resulted in a value twice as high as that in the Earth oceans, leading to the generally accepted conclusion that comets are unlikely to be the primary source of ocean water. Together with orbital modeling, these measurements suggested instead that asteroids with composition similar to that of CI meteoroids were the main water source. As part of our solar system observation programme [1], using the HIFI instrument [2] on the Herschel Space Observatory [3], we have obtained the first measurement of the D/H ratio in a Jupiter-Family comet (103P/Hartley 2) [4]. It turned out that 103P's D/H-ratio is consistent with VSMOW. This result substantially expands the reservoir of Earth ocean-like water to include some comets, and is consistent with the emerging picture of a complex dynamical evolution of the early Solar System. We discuss the implications of these observations for the origin of water and the evolution of its distribution in the solar system.

High-pressure dehydration of antigorite-serpentinite and its effect on boron isotope fractionation in the shallow mantle wedge.

The ultramafic rocks of Cerro del Almirez Massif in Spain preserve field evidence for the subduction-related, prograde transition from antigorite-serpentinite (ant-serp) to chlorite-harzburgite (chl-harz) [1]. This study investigates the influence of dehydration reactions on B isotope fractionation in the sub-arc region, where fluid loss accompanies prograde metamorphism under well constrained P-T conditions (650 °C, 1.7 GPa [2]).

B isotopes are strongly fractionated during the dehydration of ant-serp, with a sharp decrease of $\delta^{11}B$ across the ant-serp to chl-harz isograd. Ant-serp has a $\delta^{11}B$ of +22.6 ‰ (± 1.6; n=2), similar to the heaviest $\delta^{11}B$ in forearc serpentinites of the active Mariana subduction zone [3, 4]. Transitional ant-chl-ol-opx serpentinite samples preserve a $\delta^{11}B$ of +3.3 ‰ (± 0.3), and the dehydration reaction product, granofels-textured chl-harz, has a $\delta^{11}B$ of -3.5 ‰ (± 0.3). Spinifex-textured chl-harz formed by crystallisation of atg-breakdown products and sampled some distance from the isograd, has a $\delta^{11}B$ of +2.7 ‰ (± 0.4). The anomalously heavy $\delta^{11}B$ of the spinifex-textured chl-harz may be attributable to interaction with a second, boron-bearing fluid associated with the formation of the spinifex textures or to a less efficient fractionation process due to the fast mineral and textural transformations that took place.

The drop in $\delta^{11}B$ approaching the isograd demonstrates that massive B isotope fractionation occurs in the shallow segments of the slab-mantle interface during the dehydration of ant-serp. Moreover, the effects survive to higher P-T conditions. The continuing stability of chlorite beyond the antigorite breakdown reaction limits the release of H_2O, and therefore B, to about 6–7 wt% H_2O, whereas without the "chlorite-in" reaction the dehydration would yield > 12 wt% H_2O loss and thus a larger B flux). This likely results in a chlorite-hosted, B-rich reservoir with a heterogeneous $\delta^{11}B$. This reservoir may contribute B to the fluids necessary to trigger melting under volcanic arcs and in addition to the proposed deeply subducted serpentine [5] may contribute to the heavy and often very heterogeneous $\delta^{11}B$ signatures of island arc volcanoes

Identification and characterization of phase governing Eu(III) uptake in granite by microscopic observations

Y. HASEGAWA[1], K. FUKUSHI[1*], K. MAEDA[1], Y. YAMAMOTO[2], D. AOSAI[2] AND T. MIZUNO[2]

[1]Kanazawa Univeristy, Kanazawa, Japan, fukushi@kenroku.kanazawa-u.ac.jp (presenting author)
[2]Japan Atomic Energy Agency, Mizunami, Japan

Sorption behaviors of trace elements on single mineral surface have been extensively studied. However, there have been very few researches for the trace elements sorption on complex mineral assemblages such as rocks, sediments and soils. In order to make predictions for the trace elements migration on geologic media, it is crucial to understand the molecular-scale interaction of trace elements with complex mineral assemblages, and to construct the thermodynamic sorption models based on the molecular-scale information. In the present study, the sorption of trace level of Eu(III) on complex mineral assemblages, slightly altered granite, as function of pH was studied by microscopic approaches.

The granite sample was collected from a borehole at a depth of 400m from the Mizunami Underground Research Laboratory constructed by Japan Atomic Energy Agency in central Japan. The granite sample was visually fresh. However, the microscope observation as well as the X-ray diffraction patterns of clay fraction shows that the occurrences of smectite, chlorite, vermiculate, calcite and hydrous iron oxides. The thin sections of the granite were prepared for Eu(III) sorption experiments. The thin sections were reacted for 24 hours in solutions of which pH were adjusted to 4, 5 and 6 under 0.01 M NaCl support electrolyte and analyzed by electron probe micro analyzer (EPMA). Then, the same thin sections were reacted for 24 hours in solutions of which 1.5 ppm of Eu(III) was added into solutions mentioned above. The resulting thin sections were served for observation and analyses by EPMA.

EPMA analyses of the thin sections after Eu(III) sorption shows that the Eu contents in quartz, plagioclase, K-feldspar, chrolite, calcite and iron hydroxide were less than detection limit. In contrast, smectite always contains up to 4 wt% of Eu. Part of biotite grains also contains up to 8 wt% of Eu. Because the Eu concentration in solution is 1.5 ppm, the concentrated factors of Eu in smectite and biotite are more than ten thousands. Quantitatively, the amount of smectite in the granite is negligible. We concluded that biotite is most important phase governing Eu(III) uptake on the granite. The texture of Eu enriched parts in the biotite grain were different from the original texture. The Eu enriched parts were distorted and the distinct cleavages appear. There is good negative correlation between K and Eu in the affected biotite grain. The relationship shows the uptake mode of Eu on biotite is ion-exchange of K in biotite and Eu(III) in solution. The number of the Eu affected biotite grain increases with decreasing pH. This indicates that the intercalation of Eu(III) to K in biotite favors at low pH conditions. The macroscopic sortpion behavior of Eu(III) on granite (Maeda et al. this volume) is consistent with the microscopic observations.

Organic-poor Neoarchean Banded Iron Formations from the Slave and North China Cratons

BREANA HASHMAN[1], DOMINIC PAPINEAU[2,3], WOUTER BLEEKER[4], AND YUSHENG WAN[5]

[1] Department of Earth Sciences, Dickinson College, United States, hashmanb@dickinson.edu
[2] Department of Earth and Environmental Sciences, Boston College, United States.
[3] Geophysical Laboratory, Carnegie Institution of Washington, United States.
[4] Geological Survey of Canada, Ottawa, Canada.
[5] Beijing SHRIMP Center, China.

Geochemical data suggest that Banded Iron Formations (BIFs) preserve a record of both abiological and biological processes. Rare earth elements, compositional, and mineralogical data of BIFs over the last thirty years have led Klein (2005) to suggest that BIFs are hydrothermally-influenced chemical precipitates. This view complements that of Li et al. (2011) who used the presence of Fe (III) acetate salt, and apatite+magnetite associations to suggest that bacteria played a role in the formation of Paleoproterozoic BIFs from Western Australia. Ferruginous metasedimentary rocks from the Eoarchean Akilia Association in Greenland have apatite+graphite mineral-pairs that might represent biosignatures (Papineau et al., 2010; Mojzsis et al., 1996), but recent work has shown that these mineral associa¬tions can also be fluid-deposited later in the history of BIFs (Papineau et al., 2011). In order to further understand the genesis of these rocks, a study was performed on ca. 2.85 Ga BIFs from the Slave Craton in Canada and on ca. 2.53 Ga BIFs the Anshan province of the North China Craton.

Mineral occurrences of possible biological relevance like apatite, sulfides, and carbonates were mapped in petrographic thin sections from both localities and found to typically occur in bands parallel to bedding. This is consistent with an authigenic origin from the sedimentary or diagenetic environment. No apatite-graphite associations were found in BIFs from either location, although these mineral-pairs were found in Neoarchean turbidites from the Slave Craton. Only BIFs from Anshan province contained minor amounts of carbonates, typically occurring in bands, with isotopically light $\delta^{13}C_{carb}$ values ranging from -9‰ to -27‰. Diagenetic oxidation of organic matter likely accounts for this carbonate as well as for the low amount of organic carbon in the samples. Only one BIF sample from the Slave had detectable levels of organic carbon with only about 0.02wt% TOC and $\delta^{13}C_{org}$ value of -25.7‰. Current work is focused on major and minor element compositions to establish detailed comparisons with other Archean BIFs.

Mid-Miocene volcanism in the Owyhee Mountains (ID) and implications for coeval epithermal precious metal mineralization

ZACHARY HASTEN[1*], MATTHEW BRUESEKE[1], JAMES SAUNDERS[2], AND WILLIS HAMES[2]

[1]Kansas State University, Department of Geology, Manhattan, Kansas, USA, zhasten@k-state.edu (* presenting author) and brueseke@k-state.edu
[2]Auburn University, Department of Geology and Geography, Auburn, Alabama, USA, saundja@auburn.edu and hameswe@auburn.edu

The inception of the Yellowstone hotspot is associated with a period of extensive mid-Miocene volcanism in and adjacent to the northern Great Basin (NGB) and the Oregon Plateau (OP). This volcanism is also associated with spatially and temporally contemporaneous precious metal mineralization throughout the region. This relationship between mid-Miocene volcanism and gold/silver mineralization is present in the Silver City district, Owyhee Mountains ID (OM), USA. This study focuses on the mid-Miocene magmatism in OM and its relationship to coeval volcanism in the region as well as the relationship and controls on the accompanying gold and silver mineralization. The mid-Miocene magmatic suite in OM is compositionally diverse and ranges from locally erupted Steens Basalt through high-Si rhyolite. Field relationships and geochemistry of the silicic units indicates that there were at least two chemically and spatially distinct magmatic reservoirs underlying the OM. The distinct reservoirs produced at least three physically and chemically identifiable effusive silicic units: the previously identified Silver City rhyolite [1], a quartz latite unit [2], and a transitional (between the two) silicic unit. While some major and trace element concentrations overlap between these units, other trace element data, including Zr, Nb, Ba, and Nd, show well defined separations. The OM silicic volcanic suite also chemically physically resembles lava flows found in other coeval, regional eruptive systems. Sr-Nd-Pb isotope data currently being obtained will provide additional constraints that will help constrain the petrogenesis of the silicic units, including whether they were sourced from Cretaceous granitoid upper crust and how the intermediate magmas formed. Previous work in OM has yielded K-Ar and $^{40}Ar/^{39}Ar$ ages of ~16.6 to 14 Ma [3], while recent $^{40}Ar/^{39}Ar$ dating of adularia from epithermal veins has provided mineralization ages ranging from 16.1 to 15.5 Ma, with the majority of mineralization occurring around 15.7 Ma [4]. Already obtained Pb isotope data from OM gold and gangue samples will be compared to Pb isotope compositions of OM volcanic units and local crust to better understand the role that mid-Miocene volcanism plays in the mineralization process and the fundamental relationship between the source of the ores (e.g. mantle or crust) and the source of the magmas.

Stability of Reduced Carbon in the Mantle

PATRICK T. HASTINGS JR.[1*], ANTHONY C. WITHERS [1] AND MARC M. HIRSCHMANN[1]

[1]University of Minnesota, Minneapolis, United States, phasting@umn.edu (* presenting author)

Reduced carbon in the mantle is commonly thought to be chiefly in diamond, but experiments suggest that at >250 km the mantle contains small amounts (0.1-1 %) of FeNi alloy. [**1, 2, 3**]. Thus, alloy may be a significant host of reduced C [**4**], but little is known about C solubility of FeNi alloy under mantle conditions.

To determine the carbon solubility in FeNi alloy and melt, we conducted experiments in the system Fe-Ni-C with bulk compositions having 5 wt. % C and variable Fe/(Fe+Ni) at 3 to 7 GPa and 1000 – 1400°C. Experiments at 3 GPa and 1000-1250 °C were performed in an end loaded piston cylinder apparatus; those at 5 and 7 GPa and 1200-1400°C were performed in a 1000 ton Walker-style octahedral multianvil.

At 3 GPa, Fe-rich melts contain up to 4.5 wt. % C, but Ni-rich (>25 mole% Ni) compositions remain subsolidus at 1250°C. The solubility of carbon in pure Fe and Ni metal are 2 wt. % and 1 wt. % respectively, but in the alloy passes through a minimum of 0.4 wt. % for $Fe_{0.2}Ni_{0.8}$. Assuming that these concentrations apply at higher temperatures and pressures (as will be tested by future experiments) allows a first estimate of the potential storage of C in FeNi alloy in the mantle. If the mantle at 250 km contains 0.1-0.2 wt.% Ni-rich (Fe0.4Ni0.6) alloy, increasing with depth to 1 wt.% Fe-rich (Fe0.88Ni0.12) alloy at 700 km [**1,2**], then maximum storage of C in alloy rises from 5 ppm in the deep upper mantle to 180 ppm in the shallow lower mantle. For mantle similar to the MORB source, with ~10-30 ppm C [**5**], alloy cannot store all C in the deep upper mantle but can in the lower mantle. For OIB sources with 33-500 ppm C [**5**], complete storage in alloy is less likely. Additional phases will be diamond in the upper mantle, as our experiments and previous work **[6]** indicate that carbide is not stable in equilibrium with Ni-rich alloy, and carbide melt in the lower mantle.

Rare earth elements in Andaman Island surface seawater: Geochemical tracers for the monsoon

ED HATHORNE[1*], MARTIN FRANK[1], P.M. MOHAN[2]

[1]GEOMAR | Helmholtz Centre for Ocean Research Kiel, Wischhofstr. 1-3, Kiel, Germany, ehathorne@geomar.de (* presenting author)

[2]Department of Ocean Studies and Marine Biology, Pondicherry University, Port Blair 744 103, Andaman & Nicobar Islands, India

The Asian summer monsoon affects the lives of billions of people. With the aim of identifying geochemical tracers for the monsoon related freshwater input from the major rivers draining into the Bay of Bengal and Andaman Sea we have taken surface seawater samples from various locations up and down the Andaman Islands during 2011. Importantly, in some locations samples have been taken in March, July and November, covering most of a seasonal cycle and different monsoon phases. Samples were collected from the side of small wooden boats or while swimming and were filtered within a few hours at 0.45 or 0.22 microns using the vacuum produced by a water jet or a hand operated peristaltic pump. Filtered and unfiltered samples were acidified to < pH 2 and analysed for Y and the REEs with an automated online preconcentration ICP-MS technique [1].

The local input of REEs from streams and sediment rich areas such as mangrove environments is clearly identified by middle REE enrichments in the shale normalised patterns of some samples. These middle REE bulges accompany large increases in dissolved REE concentrations at some locations, especially for the July samples obtained during the peak monsoon season with frequent storms. Y/Ho fractionation aslo occurs during the local input of dissolved REEs with affected samples having lower Y/Ho ratios. Conversly, some samples, in particular those taken after heavy rainfall in March, show strong REE scavenging accompanied by the prefferential removal of dissolved light REEs and higher Y/Ho ratios.

The time series at a location away from local input sources shows remarkably similar REE patterns and concentraions in March and July. Then in October-November, following the peak in monsoon river discharge, the dissolved REE concentration increases by almost a factor of 2. The notable exception to this seasonal pattern is the Ce anomally which is around 0.3 in March and November but 0.6 in July, implying less oxidative removal of Ce(IV) during the peak summer monsoon rains. With the exception of elevated dissolved Ce concentrations, the North Pacific Deep Water normalised REE patterns are similar to those reported for offshore samples from the Bay of Bengal and Andaman Sea [2]. These seawater normalised patterns are distinctive having a middle REE enriched arc with similar light and heavy REE values suggesting the input from large rivers in the region is traceable using seawater REE chemistry.

Ecodynamics of trace metals in assisted phytoextracted contaminated soils

N. Hattab[1*], M. Motelica- Heino[1], X. Bourrat[1]; R. Guégan[1] and M. Mench[2]

[1]ISTO, UMR 6113 CNRS Université d'Orléans, France, nour.hattab@univ-orleans.fr(*). mikael.motelica@univ-orleans.fr Xavier.Bourrat@univ-orleans.fr regis.guegan@univ-orleans.fr

[2]BIOGECO, UMR INRA 1202, Université de Bordeaux 1, av. des Facultés, 33405, Talence, France, mench@bordeaux.inra.fr.

Introduction

Many domestic, industrial and agricultural activities result in soil contamination by trace metals(Adriano,2001).The methodological guide of the French Geological Survey (BRGM) has reported the lack of knowledge on metal(loid)s in soils. Total metal(loid) concentrations in soils establish the hazard source but delivers little information on the risks. Moreover the physico-chemical analysis is not enough to evaluate the toxicity of soils on living organisms . In contrast the simultaneous investigation of the ecodynamic of trace metals and their ecotoxicological effects on an instrumented site shows several advantages. Additionally the characterisation of the ecotoxicological impact(s) by biotests representative of the various organisation levels of the ecosystems is a complementary step in the environmental risk assessment.Several investigations were performed to assess the (im)mobilisation mechanisms of metal(loid)s in CCA contaminated soils and the effects of the mineral and/or organic amendments and phytoextraction strategies.

Material and methods

The studied site is located in South-western France, Gironde County (44°43'N; 0°30'O). This site has been contaminated with high concentrations of CCA (Cu,Co,As). The site is divided into five pieces depending on the increasing of the concentration of Cu contamination in topsoils. One kilo of soil from each sub plot was put in the pots. Grains of dwarf beans (Phaseolus vulgaris L. cv vroege Limburgs) were sown in all pots and cultivated (18 days) under controlled conditions. Then the moisture of soil was raised to 80% at the beginning of germination stage of grains. In the end of the period the plants were harvested and biometrical parameters, i.e. fresh weight (FW) of roots, shoots and primary leaves, and leaf surface area, were determined together with the leave dry weigth. The solution of soil was extracted by Rhizons and DGT (diffusive gardients in thin films) were deplyed for 24h in the soils to assess the remobilsiation of trace metals.

Results and conclusion

Results suggested that plant extractable amounts of Cu are increased by the incorporation of organic and mineral amendments in the soils. Additionaly both the organic compost and addition of dolomite provide a mechanism for metal retention in the soil.

Modern climate is characterized by a strong bias in temperature toward the northern hemisphere, a feature that has been described as the result of Atlantic Ocean circulation and/or the concentration of continental area north of the equator. Sediments from the Cariaco Basin off Venezuela and the northeastern Arabian Sea record this asymmetry, which manifests itself in the position and strength of the Intertropical Convergence Zone (ITCZ) over the Cariaco Basin and in summer monsoon strength over the Arabian Sea. New sediment core records of unprecedented temporal resolution indicate an unbroken correspondence between warm climate conditions over Greenland, a northerly position of the Atlantic ITCZ, and a strong Indian summer monsoon over the last 110,000 years. Given that Greenland temperature changes cannot be explained by insolation changes or by the lower latitude forcings, the tight coupling among records can only be explained by a dominant role of the North Atlantic in the hemispheric asymmetry of climate. The abruptness of the Cariaco Basin and Arabian Sea changes requires fast communication from the North Atlantic via the atmosphere.

Over millennia, the maintenance of North Atlantic conditions and their influence on global climate points to an underlying control of the Atlantic Meridional Overturning Circulation (AMOC) associated with Heinrich events. However, it apparently cannot explain some of the climate structure of the Dansgaard-Oeschger cycles: Heinrich events populate only a fraction of the cold stadials, and they occur at the end – not the beginning – of those stadials. Our new sediment records indicate that, during peak stadials, a southward shift in the trade winds caused the boreal summertime ITCZ to remain south of the Cariaco. This ITCZ shift would have reduced summertime equatorial Atlantic upwelling, reducing ocean heat transport to the North Atlantic. This positive feedback between subpolar North Atlantic cooling and ITCZ position represents a mechanism for Dansgaard-Oeschger cycles that complements AMOC changes.

Pliocene warmth: ocean gateways and polar oceans

GERALD H. HAUG[1], DANIEL M. SIGMAN[2], RALF TIEDEMANN[3]

[1]Geological Institute, ETH Zürich, 8092 Zürich, Switzerland, gerald.haug@erdw.ethz.ch
[2]Department of Geosciences, Guyot Hall, Princeton University, Princeton, NJ 08544, USA, sigman@princeton.edu
[3]Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany, Ralf.Tiedemann@awi.de

Paleoceanographic time series from numerous sediment cores retrieved in the Atlantic and Pacific Oceans and in the Caribbean Sea show that the Panamanian Seaway closure had a major impact on ocean circulation beginning at 4.6 Ma. The Gulf Stream intensified and introduced warm and saline water masses to high northern latitudes, which led to Pliocene warmth at 4.6 Ma. The world during the Pliocene warm interval was globally warmer than the past interglacial maxima and was characterized by a Northern Hemisphere without major ice shields. Since 2.7 Ma, the cycle between ice ages and warm interglacials has dominated the climate on Earth. Our understanding of the Pliocene warm period and the ice age cycles is that subtle variations in Earth's orbit and rotation are amplified by internal feedbacks, yielding dramatic climate change over hundreds to thousands of years. The time interval between 4.5 and 3.1 Myr was dominated by a pronounced long-term minimum in the amplitude of the 41 kyr cycle in the obliquity of Earth's rotation which would have failed to produce particularly cold northern hemisphere summers, the key requirement posited by Milankovitch for the onset of major northern hemisphere glaciations. During this time interval, there may have been several aborted shifts toward glaciation, for example between 4.1 - 3.9 Myr and 3.5 - 3.3 Myr. During late Pliocene and early Pleistocene, a high amplitude in the obliquity cycle resulted in periods of low tilt angle, which, in turn, would have yielded periods with cold summers in the Northern Hemisphere. Thus, it has been suggested that the progressive increase in the amplitude of the obliquity cycle tipped the scale between 3.1 - 2.7 Myr, allowing for long-term expansion of Northern Hemisphere ice. In short, our long-held view of the temperature requirement of glaciation is largely consistent with the timing of the onset of Northern Hemisphere Glaciation.In addition, atmospheric carbon dioxide appears to represent the key internal feedback to explain Pliocene warmth, being more abundant during the Pliocene thermal maximum (≥400ppm) than during warm interglacial periods (280-300ppm) and scarce during ice ages (180-200ppm). However, it is not conclusively explained what caused atmospheric carbon dioxide to change. Carbon dioxide is sequestered in the ocean interior by the photosynthetic production of organic carbon that subsequently sinks out of the low latitude surface ocean before being converted back to carbon dioxide. However, rapid vertical mixing in warmer polar ocean regions such as the Antarctic and the Subarctic North Pacific allows this deeply sequestered carbon dioxide to escape back into the atmosphere through the polar ocean surface. Measurements of the N isotopes and biogeochemical properties in sediment cores indicate that vertical stratification of the polar ocean reduced this polar CO_2 leak during cold times, has provided a satisfyingly simple physical explanation for this cooling-induced stratification. This hypothesis has been recognized as the critical piece in the Plio/Pleistocene CO_2 puzzle.

High-resolution chemostratigraphy of the 2.46 Ga Joffre banded iron formation, Western Australia: implications for the hydrosphere-atmosphere-lithosphere in the early Palaeoproterozoic

RASMUS HAUGAARD*[1]; ERNESTO PECOITS[1]; STEFAN V. LALONDE[2]; NATALIE AUBET[1]; MARTIN J. VAN KRANENDONK[3]; KURT O. KONHAUSER[1]

[1]Earth and Atmospheric Sciences, University of Alberta, Edmonton, Alberta, Canada, T6G 2E3. (*Correspondance: rasmus@ualberta.ca)
[2]Universite´ Europe´ene de Bretagne, Institut Universitaire Europe´en de la Mer, Plouzane´ 29280, France.
[3]University of New South Wales, Kensington NSW 2052, Australia.

Here we present new geochemical data of a 355 m long drill core from the single largest banded iron formation (BIF) known, the 2460 Ma [1] Joffre BIF, Western Australia. By directly preceding the 2.45-2.32 Great Oxygenation Event (GOE), this BIF was deposited prior to one of the most important periods in Earth history. The Joffre BIF consists predominantly of chert-hematite-riebeckite microbands (<1mm) alternating with chert-Fe dolomite-siderite-crocidolite mesobands (>1cm) and denser magnetite-hematite mesobands, respectively. The precursors of these mineral phases were laid down on a large stable and clastic-starved continental shelf [2]. Very fine-grained occasionally oolitic, bands of potassium-rich greenalite and stilpnomelane occur throughout, documenting input of tuffaceous material from evolved volcanic sources, similarly to the Woongarra rhyolite, in the vicinity of the depository. Preliminary geochemical results show that K_2O and Ba are strongly correlated to immobile elements such as Al_2O_3, TiO_2, Zr, La, Nb, Hf and various trace metals such as V, Cr, Ni and Co, suggesting minimum degree of K- and Ba-mobilisation. Relative to the profound Cr enrichment in the overlying Weeli Wolli BIF [3], very low Cr content (3-10 ppm) are found within Joffre BIF which indicate that the atmospheric O_2 and the oxidative weathering of continental pyrite was suppressed at the time. In contrast to the underlying Dales Gorge BIF, elevated values are found of P_2O_5 (up to 2.4 wt.%), B (up to 33 ppm), Li (up to 9 ppm) and Au (up to 8.4 ppm). Since none of these elements are hosted within the tuffaceous material they likely were sourced from elevated submarine hydrothermal activities related to the emplacement of the 2449 +/- 3 Ma large, bimodal igneous province of Weeli Wolly-Woongarra Formations [4].

Interpreting phosphate mobility on Mars and the implications for habitability

ELISABETH M. HAUSRATH[1*] ; CHRISTOPHER T. ADCOCK[1]; VALERIE TU[1]

[1]University of Nevada, Las Vegas, Las Vegas, NV USA
Elisabeth.Hausrath@unlv.edu

Phosphate is a crucial nutrient on Earth, used by life in ATP, DNA, RNA and phospholipid membranes [1]. Phosphate has also been proposed as essential in the prebiotic formation of RNA on Earth [2]. Interpreting phosphate behaviour on Mars is therefore important in characterizing habitability. Phosphate mobility on Mars, however, differs in important ways from phosphate mobility on Earth. In addition to fluorapatite, common on Earth, chlorapatite and merrillite are important primary phosphate minerals in martian meteorites [3-5]. Amorphous and poorly crystalline secondary phases have been documented on Mars [6, 7], suggesting that amorphous phosphate phases may similarly be important to the phosphate cycle on Mars. Environmental conditions affecting the behaviour of secondary phosphates such as oxidation state, pH, and water: rock ratios also likely differ between Earth and Mars. In order to interpret phosphate mobility on Mars, we are therefore performing dissolution experiments, investigating apatite weathering in the field, and modeling using the reactive transport code CrunchFlow.

Mineral dissolution rates are being measured of the phosphate-rich primary minerals fluorapatite, whitlockite, merrillite and chlorapatite, which are found in Mars meteorites. Due to the likely importance of amorphous phases, dissolution rates are also being measured of amorphous Al- and Fe-phosphate. Thin sections of weathered basalt from the phosphate-rich Mars analog Craters of the Moon, ID [8] are being examined to interpret phosphate mobility during incipient weathering. These data are then being used in reactive transport modeling of phosphate behavior under Mars-like conditions.

Measured dissolution rates suggest that whitlockite dissolves more quickly than fluorapatite at pH values < 4. Preliminary results suggest that amorphous Fe-phosphate dissolves more rapidly than its crystalline counterpart. Phosphate availability on Mars may therefore be greater than on Earth, with important implications for habitability. Reactive transport modeling indicates that secondary phosphate phases may preserve important environmental characteristics of habitability, including pH, water: rock ratio, and oxidation state. Future analyses of phosphate on Mars will likely yield important characteristics of possible habitability.

The Crystallization of a Layered Mafic Sill from the Neoproterozoic Franklin LIP, Victoria Island, Arctic Canada

HAYES, B.[1*], BÉDARD, J.H.[2], LISSENBERG, C.J.[1]

[1]School of Earth & Ocean Sciences, Cardiff University, UK, hayesb@cardiff.ac.uk (* presenting author)

[2]Geol. Survey of Canada, Québec, Canada

A diabasic sill with an olivine-enriched base from the Neoproterozoic (ca. 723 & 716 Ma) Franklin LIP has been studied in detail through the combined use of whole-rock and in-situ mineral compositions, accompanied with detailed petrology and textural observations. The Franklin LIP has a well-exposed, unmetamorphosed, sill-dominated plumbing system, outcropping within the Shaler Supergroup, in the Minto Inlier of Victoria Island. The Shaler stratigraphy is riddled with sills and is capped by the ≤1 km thick Natkusiak flood basalts. A significant amount of magma has passed through this plumbing system, with a large portion of it remaining as sills in the crust. Whole-rock data from numerous sill chills sampled across the Minto Inlet region indicate two populations of magmas: 1) a younger diabasic event with flatter REE profiles; and 2) older diabasic sills characterized by LREE enrichment, some of which have olivine-enriched zones near their base. Of the latter type, the >40m thick Uhuk massif is thought to be one of several fault-controlled magmatic feeder zones within the Franklin LIP, and has a thick ol-rich layer. The >20m thick 'Lower Pyramid sill' from the Boot Inlet region, occupies the same stratigraphic position as the Uhuk massif, and we propose an explicit correlation of the two, with the Lower Pyramid representing a well-preserved distal (>40 km) injection of the same magma.

The Lower Pyramid sill has been divided into 7 facies zones; 1) a lower chilled margin (LCM); 2) a lower border zone (LBZ); 3) an olivine-cumulate zone (OZ); 4) a pyroxene-cumulate zone (PZ); 5) a diabase zone (DZ); 6) an upper border zone (UBZ); and, 7) an upper chilled margin (UCM). Due to the relatively rapid cooling regime of this sill and the occurrence of an olivine-rich base, the Lower Pyramid sill provides a snapshot into differentiation mechanisms operating within basaltic magma reservoirs. Using detailed petrography, coupled with whole-rock and in-situ mineral chemistry, a model of crystallization is proposed. During the initial emplacement of magma within the sill, melt chilled rapidly against the 'cold' host rock preserving a parental melt composition with 13% MgO. This was followed by crystallization of the LBZ and UBZ. The UBZ is characterized by acicular clinopyroxene with long axes oriented towards the roof, indicative of rapid heat loss in the upper sill margins. After the initial emplacement of the sill, olivine (trapped in the LCM and LBZ), clinopyroxene and plagioclase began to crystallize. As the early melt emplacement event continued to crystallize, the sill was re-intruded by a relatively primitive magma (~22% MgO) charged with olivine crystals, injected along the interface between the LBZ and the DZ. This incoming melt interacted with the rocks of the host intrusion, resetting some of its crystal composition values (An in plagioclase and Mg in clinopyroxene). The distribution of such zoning seems to suggest a complex interaction of melt and crystals in a cooling permeable mush when the olivine-slurry came in. There is also an increase seen in Fo and NiO content within olivine at the boundary of the olivine-zone, which contrasts with the more normal fractionation trends displayed in the LCM and LBZ. Some olivine crystals within the LBZ and the OZ display NiO-Fo decoupling trends, with NiO peaks towards the rim, which may well be caused by the influx of primitive melts sourced from the olivine-slurry, soaking into the LBZ mush below. The upper section of the olivine-zone has a 'harristic'-like texture suggesting that the DZ mush may have been largely crystallized and fairly cold at the time of the olivine replenishment event. As the OZ crystallized, residual melts enriched in SiO_2-Al_2O_3-CaO-Na_2O-K_2O might have percolated up through the OZ mush to pond below the diabasic rocks and affected the PZ, characterized by evolved plagioclase and clinopyroxene rims. Both plagioclase and clinopyroxene core compositions within the PZ fall on the same trends as the corresponding cores in the LBZ and DZ, which may also imply that there was a population of micro-phenocrysts entrained within the original magma. The DZ above the PZ is dominated by typical ophitic gabbros indicating the co-crystallization of plagioclase and clinopyroxene, with both cumulus and interstitial Fe-Ti oxides (as well as biotite and amphibole).

The nature of boundary scavenging in the North Pacific Ocean

CHRISTOPHER T. HAYES[1*], ROBERT F. ANDERSON[1], MARTIN Q. FLEISHER[1] AND RAINER GERSONDE[2]

[1]Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, cth@ldeo.columbia.edu (* presenting author)
[2]Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany, Rainer.Gersonde@awi.edu

The radionuclides ^{231}Pa and ^{230}Th are useful tracers in the ocean of chemical scavenging, or the process of removal from the water column by adsorption onto sinking particles. This is because of their well-known and uniform source from the decay of U. The residence time of ^{231}Pa in the water column (50-200 yrs) is roughly five times greater than that of ^{230}Th (10-40 yrs), and thus their combined distributions provide information on scavenging processes occuring over different timescales. The increase of the ^{231}Pa/^{230}Th ratio in surface sediments toward ocean margins has been used as evidence that ^{231}Pa is laterally transported (to a greater degree than ^{230}Th because of its longer residence time) by diffusive fluxes from areas of low scavenging intensity to areas of high scavenging intensity [1]. This process is termed boundary scavenging [2] and potentially affects all scavenged elements whose residence time is long enough to allow basin-wide isopycnal diffusion. Little data exist, however, to support this phenomenon on the basis of ^{231}Pa/^{230}Th in the water column. Along lateral gradients in scavening intensity, the theory predicts inversely corresponding lateral gradients in [^{230}Th] (high scavenging, low [^{230}Th] and vice versa), and smaller lateral gradients for [^{231}Pa], reduced by isopycnal transport.

From the Innovative North Pacific Experiment (INOPEX) cruise of 2009, profiles of dissolved ^{230}Th and ^{231}Pa situated along strong lateral productivity gradients in the subarctic Pacific show virtually no lateral concentration gradients for either radionuclide, at odds with the traditional boundary scavenging explanation. From the subarctic to subtropical and tropical North Pacific, based on published data from this area, much larger lateral gradients in [^{231}Pa] and [^{230}Th] exist, even over lateral productivity gradients of similar magnitude to those within the subarctic. From subtropics to subarctic, in the upper 2.5 km, the lateral gradient is larger for [^{231}Pa] than for [^{230}Th], exactly the opposite of the expectation based on their residence times. We link this behavior to the geographical distirbution of biogenic opal, a strong scavenger of Pa. Below 2.5 km depth, however, ^{231}Pa has a more uniform distribution across the North Pacific, whereas ^{230}Th displays a relatively large contrast primarily between areas north and south the subarctic front. While more water column data are needed to determine the influence of inflow from the South Pacific, it is suggested that in deep waters isopycnal diffusion dominates over the lateral gradient in scavenging intensity for ^{231}Pa. The sensitivity of ^{230}Th and ^{231}Pa to differences in scavenging intensity across gyes but not within them suggests a new biogeographic dimension to boundary scavenging that deserves more attention.

Global warmth during the Pliocene: a CO_2 paradox?

ALAN HAYWOOD[1*], DANIEL LUNT [2], AISLING DOLAN[3], DANIEL HILL[4]

[1]School of Earth and Environment, University of Leeds, earamh@leeds.ac.uk (* presenting author)
[2]School of Geographical Sciences, University of Bristol, d.j.lunt@bris.ac.uk
[3]School of Earth and Environment, University of Leeds, eeamd@leeds.ac.uk
[4]School of Earth and Environment, University of Leeds, d.j.hill@leeds.ac.uk

Multiple sources of geological proxy data indicate higher than modern surface temperatures, relative to present-day, during intervals of the Pliocene. Recently there has been a suggestion that the increase in global annual mean temperature of the planet for the Pliocene (~2 to 3°C) is inconsistent with CO_2 forcing alone, since it would require a very high climate sensitivity. Other mechanisms that are not currently, or only poorly, represented in climate models have been invoked as a means to provide a significant contribution to Pliocene warmth, in addition to CO_2.

This argument is based upon the premise that we define climate sensitivity during the Pliocene in the same way that we define climate sensitivity in response to a CO_2 doubling during this century. This premise may be invalid because in the deep palaeo proxy records provide evidence for the response of climate to a carbon cycle perturbation over far longer timescales than are used to understand 21st century climate sensitivity. Over such timescales feedback s from slow responding components of the climate system (e.g. vegetation and ice sheets) have the ability to enhance any surface temperature rise caused by CO_2.

Here we demonstrate this concept through the presentation of a suite of climate model simulations using the Hadley Centre Coupled Climate Model Version 3, in which fast and longer term feedbacks to a CO_2 rise to 400 ppmv are considered. The direct climate response in the short-term indicates a climate sensitivity in line with the best estimates of the IPCC for the coming century (~3°C). Feedbacks from vegetation and ice sheets to the CO_2 forcing (probably in response to orbital forcing as well) are able to significantly increase the total change in global mean temperature. Our results are corroborated by initial model outputs produced by the Pliocene Model Intercomparison Project.

Overall we conclude that the Pliocene paradox can easily be resolved when different timescales of environmental response to a given carbon cycle perturbation are considered.

What minerals were present at life's origins?

ROBERT M. HAZEN[1]
[1]Carnegie Institution of Washington,
Geophysical Laboratory, Washington, D.C. 20015, USA
(*correspondence: rhazen@ciw.edu)

Scenarios for life's origins often invoke varied minerals in such roles as catalysts or reactants for molecular synthesis, templates for selection and concentration of potential biomolecules, and protective environments for protolife [1-4]. However, any such model for biogenesis must consider the relatively limited prebiotic mineral diversity. We estimate that prebiotic Earth held no more than ~500 different mineral species, compared to more than 4500 recognized today [5,6]. Modes of mineral paragenesis at 4.0 Ga were severely limited compared to the last 3.0 billion years. Important mineral-forming mechanisms not established at 4 Ga include atmospheric oxidation, emplacement of complex pegmatites, subduction zone volcanism, and the rise of the terrestrial biosphere, which collectively led to as many as 4000 of the known species.

In spite of these constraints, most minerals previously invoked in origins-of-life research are plausible participants in prebiotic reactions. In particular, clay minerals, so often employed in origins studies for their ability to adsorb and template organic molecules, would have been present, though distributions of clay mineral species were significantly different from the modern world. Serpentinization would have produced abundant serpentine and talc, as well as brucite, while anoxic weathering of volcanic deposits may have yielded montmorillonite and kaolinite. This suite of clay minerals contrasts with the modern production, which is dominated by terrestrial clay minerals through oxic and biological weathering. Most common rock-forming silicates, including Fe-Mg olivine, pyroxene, amphibole, and mica, as well as all major varieties of Na-K-Ca feldspar and feldspathoid would have been present, as well. Though volumetrically much less important, reactive Fe-Ni phases, including metal alloys, sulfides, and the phosphide schreibersite were all available continuously in the near-surface environment in the form of iron meteorites. Similarly, quartz, carbonates, and phosphate minerals, though present, appear to have been volumetrically insignificant, and it is not obvious that any borate minerals were available prior to 3.5 Ga [7].

Noble gas isotopes in Cenozoic mantle xenoliths from the North China Craton

HUAIYU HE[1,*], FEI SU[1], YING WANG[1], LIANGLIANG WANG[1], AND RIXIANG ZHU[2]

[1]Key Laboratory of the Earth's Deep Interior, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China, huaiyuhe@mail.iggcas.ac.cn
[2] State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China, rxzhu@mail.iggcas.ac.cn

Section 17k

The North China Craton (NCC) is one of the oldest cratons on Earth (3.8 Ga) and is also one of the major Archean cratons in eastern Eurasia. However, the craton experienced fundamental lithospheric rejuvenation in late Mesozoic and Cenozoic, resulted in replacement of the old, cold, thick (>180 km), and depleted lithospheric mantle by young, hot, thin (70-80 km), and fertile lithospheric mantle. The NCC can be divided into eastern part (ENCC) and western part (WNCC) by the NS trending Daxing'anling - Taihangshan Gravity Lineament (DTGL) that separates two topographically and tectonically different regions.

The ENCC experienced widespread lithospheric thinnin. The preexisting Tan-Lu Fault Zone, main active strike-slip fault zone in eastern China, is believed to have acted as a major channel for the ascending of asthenosphere and played an important role in the Mesozoic-Cenozoic thinning of the North China Craton lithosphere. WNCC, lithospheric removal was possibly relative limited, and the elevation are about 1000m higher than ENCC. The difference of lithospheric thin between ENCC and WNCC is also supported by the contrast of thickness of crust and lithospheric mantle, heat flow and gravity anomaly. Geophysical and geochemical study suggest that the asthenospheric upwelling beneath the ENCC at late Cretaceous and upwelling beneath the WNCC recently.

Noble gas isotopic ratios would provide unique and important constraints for the evolution of the subcontinental mantle and delineate similarities and differences between the MORB reservoir and the subcontinental mantle.We present one-step crushing noble gas isotope data from corundum and co-existed mantle xenoliths and megacrystals from the middle part of the Tan-Lu Fault Zone, ENCC and from Yangyuan, WNCC. The $^{3}He/^{4}He$ ratio is 7.6–8.3 times the atmospheric ratio (Ra) in corundum, indicating contribution of fluid from convective asthenosphere. The olivine and opx in lherzolite show high helium content and homogeneous isotopic helium ratio, 6.9–7.0 Ra for ENCC and 7.6-8.5 Ra for WNCC.

Conclusion

Combined with isotope correlation diagrams, the systematic difference in ^{4}He abundance, the $^{3}He/^{4}He$ and $^{4}He/^{40}Ar^{*}$ ratios of cpx, opx and olivine in pyroxenite and lherzolite suggest refertilization of lithospheric mantle in the ENCC maybe early than WNCC.

Canadian oil sands; a window on the deep petroleum biosphere

IAN M. HEAD[1] *,

NEIL D. GRAY[1], ANGELA SHERRY[1], MICHAEL J. MAGUIRE[1], RUSSELL J. GRANT, CASEY R.J. HUBERT[1], CAROLYN AITKEN[1], D. MARTIN JONES[1], THOMAS OLDENBURG[2], BARRY BENNETT[2] AND STEVE LARTER[2]

Covering an area over 100,000 km^2 the Canadian oil sands deposits are a vast testament to the consequences when the biosphere meets the geosphere. By integrating laboratory and field based studies of the microbiology, geochemistry and geology of the Canadian oil sands we have developed a more complete understanding of the processes that led to their formation and factors that may control in-reservoir petroleum biodegradation. Studies of methanogenic oil degradation in the laboratory suggest that in the initial stages of biodegradation when the bulk of the crude oil hydrocarbons, principally saturated hydrocarbons, are removed, oil degradation is driven by consortia of bacteria from the *Syntrophaceae* and methanogenic archaea. However field studies of the microbial communities currently predominant in the heavily biodegraded oil sands paint a very different picture with apparent predominance of known hydrocarbon degrading taxa conventionally considered to be aerobes. In addition, the communities in produced water samples contrast with communities detected in core samples and are dominated by *Epsilonproteobacteria* which are typically thought to play a role in sulfur cycling. The reasons for the contrasting views obtained using different approaches and sampling strategies will be explored and linked to geochemical patterns characteristic of heavy oil reservoirs.

Based on the occurrence of geochemical gradients in biodegraded petroleun reservoirs it was initially inferred that the petroleum reservoir microbiota should be most abundant and active at the base of the reservoir where oil staurated rock transitions to water saturated rock [1]. This theory appears to hold up to empirical scrutiny and we have shown that bacterial 16S rRNA gene abundance is around 2 orders of magnitude greater in these oil water transition zones. We will discuss our most recent findings integrating geochemical and metagenomic results to gain further insights into the potential role of the microbiota currently dominant in oil sands reservoirs and the implications for the petroleum deep biosphere and other hydrocarbon-impacted anoxic environments.

Orbitrap high resolution mass spectrometry characterization of Athabasca oil sands acids in environmental samples

JOHN V. HEADLEY*[1], KERRY M. PERU[1], BRIAN FAHLMAN[2], JONATHAN BAILEY[1] AND DENA MCMARTIN[3]

[1]Environment Canada, Saskatoon, Canada, John.Headley@ec.gc.ca

[3]Environmental Systems Engineering University of Regina, Regina, Canada, DenaMcMartin@uregina.ca

Type The Athabasca oils sands region of Alberta, Canada is one of world's largest bitumen reserves with a proven 170 billion barrels of crude oil. Approximately 3 barrels of river water are used during the alkaline/hot water extraction process of the mined oil sand for every barrel of oil produced. During the extraction process, acidic bitumen components (including naphthenic acids) are solubilized in the water. This oil sands process water (OSPW) is stored in tailings ponds in accordance with a zero discharge policy. There is a growing need for development of analytical methods that can distinguish between compounds found within industrially derived OSPW from those derived from natural weathering of oil sands deposits. This is a difficult challenge as possible leakage beyond tailings ponds containments will likely be in the form of a mixture of water soluble organic acids that are similar to those leaching naturally to aquatic environments. An overview is given on the progress of analytical developments and the current state of mass spectrometry analysis of environmental samples. The potential for Orbitrap high resolution mass spectrometry and accurate mass measurements for chemical fingerprinting of oil sands acids from tailing ponds, interceptor wells, groundwater and reference river surface waters is evaluated. Particular emphasis is given to (i) new developments which recognize that the oil sands acid fraction contains more components than the traditional structures of naphthenic acids; and (ii) the influence of extraction procedures on what is being measured. Significant differences in high resolution mass spectrometry results were observed for the same sample set that are attributed to the extraction procedure and/or extraction solvent of choice.

C, N, O abundances and isotopic compositions in the Sun

V.S. HEBER[1], D.S. BURNETT[2], Y. GUAN[2], A.J.G. JUREWICZ[3], S. SMITH[4], C. OLINGER[5], K.D. MCKEEGAN[1*]

[1]Dept. Earth and Space Sciences, UCLA, Los Angeles, CA, USA, mckeegan@ess.ucla.edu ; [2] California Institute of Technology, Pasadena, CA, USA; [3]Arizona State University, Tempe, AZ, USA; [4]Evans Analytical Group, Sunnyvale, CA, USA; [5]Neutron Science and Technology, LANL, Los Alamos, NM, USA.

For most elements, their solar (≡cosmic) abundance and primordial isotopic composition have historically been determined via precise laboratory measurements of primitive meteorites. However, this approach is not possible for highly volatile elements which are strongly depleted, relative to the solar photosphere, even in CI chondrites. Similarly, isotopic compositions, especially for N and O, are so variable among planetary bodies and components of meteorites that distinguishing an average starting composition for the solar nebula was impossible prior to the Genesis mission [1]. By analyzing solar wind (SW) captured in high purity targets, the Genesis science team established that the nitrogen [2] and oxygen [3] isotopic compositions of the Sun are grossly different than those of Earth and almost all planetary materials of the inner solar system. The mechanisms to establish isotopic fractionations of ~40% (N) and ~7% (non-mass-dependent for O) from the average solar nebula starting composition are still being investigated and it is interesting to consider the isotopic shifts in the light of elemental depletions in planetary matter. For this and other purposes, it is necessary to know the solar elemental composition of elements heavier than He.

Photospheric determinations of the solar abundances of the most significant volatile elements (C, N, O) have recently undergone serious revision downward by factors of 1.7 (O), 1.7 (N) and 1.3 (C), thus reducing the solar "metallicity" from 0.0201 to 0.0134 [4]. While solving some long-standing astronomical problems related to the Sun's composition and age, the new results are at odds with models of the solar interior based on helioseismology [see 4]. This discrepancy remains unresolved. We analyzed Genesis Si and SiC targets to determine the fluences of C, N, and O in captured SW. These data can be related to absolute abundances in the Sun when considered with H fluence and a model of ion fractionation in formation and acceleration of the SW.

Fluences of C, N, and O were obtained by back-side depth profiling of passive (Si) collectors that had been mechanically thinned [5]. Even with this approach, background corrections were relatively high: ~4 % for ^{12}C, ~20% for ^{16}O and ~6% for ^{14}N. The O fluence can be measured with lower background on the SiC target of the SW Concentrator by utlizing the known concentration factor as a function of radius determined from ^{20}Ne data [6]. Preliminary results for the inter-element ratios C/O and N/O agree within uncertainty with the new photospheric compositions, suggesting that high first ionization potential elements are not fractionated relative to each other and lending confidence to the new photospheric abundances.

Ion specific effects at the calcite(104) – water interface

FRANK HEBERLING [1*], PETER J. ENG [2], JOHANNES LÜTZENKIRCHEN [1], JOANNE E. STUBBS [2], THORSTEN SCHÄFER [1], HORST GECKEIS [1]

[1] Institute for Nuclear waste Disposal, Karlsruhe Institute of Technology, Karlsruhe, Germany, (* presenting author, Frank.Heberling@kit.edu)

[2] GSECARS, The University of Chicago, Chicago, United States of America

In this study the influence of Li^+-, Na^+-, K^+-, Rb^+-, and Cs^+-chloride solutions on the calcite zeta-potential is investigated and surface diffraction data that can be used to relate the observed ion specific effects to the calcite(104) – water interface structure is presented.

Specular and off-specular resonant surface diffraction data are used to locate and quantify Rb^+ ions at the calcite(104) – water interface. In a 0.01 molar RbCl solution equilibrated with atmospheric CO_2 and calcite (pH = 8.2), we observe the main Rb^+ species (~0.17 mono layers (ML)) 3.2 Å above the surface, associated with the second well ordered water layer at the interface, a position that might mark the upper end of a Stern layer at the calcite(104) surface [1]. An unexpected result is that there seems to be inner-sphere adsorbed Rb^+ (< 0.1 ML) closely associated with the surface carbonate groups. Additionally there are outer-sphere Rb^+ species at ~5 and ~11 Å above the surface, likely associated with Rb^+ in the diffuse layer above the calcite surface. In order to test to what extent these results are specific for Rb^+ or whether they can be transferred to the other alkali-metal cations we measured specular surface diffraction data on calcite(104) in contact with equilibrated 0.01 molar alkali chloride solutions across the whole series from Li^+ to Cs^+, and indeed certain trends are observable. The analyses of these data is still ongoing and it is not yet clear if changes are due to the increasing number of electrons in the series Li^+ – Cs^+ or due to actual changes in interface structure.

Streaming potential measurements performed on an Anton Paar SurPASS electrokinetic analyzer show that, if we successively add Ca^{2+} to a solution containing 0.01 mol/L of an alkali metal chloride as background electrolyte at fixed pH (~9), remarkable changes in the behavior of the calcite zetapotential are observed across the series of 0.01 molar alkali chloride solutions: the Ca^{2+} concentration at which zero zetapotential is measured is 0.5 mmol/L in CsCl solution and increases continuously across the series of alkali metals, up to 2.5 mmol/L in LiCl solution. For Ca^{2+} concentrations >5 mmol/L the calcite zetapotential reaches a plateau. The plateau zetapotential value lies at 5 mV in the LiCl system and at 20 mV in the CsCl system. These two effects clearly demonstrate the ion specific effect of the alkali metal cations on the affinity of Ca^{2+} ions to the calcite(104) surface. The calcite zetapotential measured as a function of pH in the absence of added Ca^{2+} is the same in 0.01 molar solutions of all alkali metal chlorides investigated. These results may have important implications e.g. for calcite growth-, adsorption-, or surface complexation models.

Structural Development and Petrogenesis along the Southern Central Indian Ridge

K. U. HEESCHEN[1]*, U. SCHWARZ-SCHAMPERA[1], AND H. FRANKE[1],

[1] Federal Institute for Geosciences and Natural Resources (BGR), D 30655 Hannover, Germany, Katja.Heeschen@bgr.de (* presenting author)

The southern Central Indian Ridge (S-CIR) was the target of the cruise INDEX 2011, which was aming to examine the bathymetry, structural geology, magnetic signatures, and crustal development of the area with special emphasis on the petrogenesis and hydrothermal processes.

The S-CIR is characterized by intermediate to slow spreading rates and a highly variable regional to small-scale structural pattern of seafloor spreading [1] with recent volcanic activity focussing on cone-shaped volcanoes and neovolcanic ridges in the central valley or along its flanks. The structural development has triggered complex petrogenetic processes including differentiation and fractionation processes as well as the exhumation of deep oceanic lithosphere. The ridges in the Indian Ocean generally show strong indications for intense plume-ridge interactions, all of which leads to the formation of a wide and variable range of rock compositions [2, 3]. The deep and active fault systems and sustainable heat supply have also triggered a range of fossil and recent hydrothermal activity alongside the rift valley.

For the detailed petrological and geochemical study a large variety of rock samples were collected along the S-CIR using dredge and TV-grab. The rock suite includes basalts, gabbros, and ultramafic rocks from five different ridge sections along the active spreading center. Next to the analysis of major and trace elements in bulk samples of fresh rocks and volcanic glass, microanalytical studies allow for the analysis of specific minerals for petrogenetic purposes.

First results gained from bulk analysis of the mafic rocks indicate small but explicit differences with respect to the differentiation and fractionation processes, especially pronounced in the major and trace element composition. This is true for the rock suites from different ridge sections investigated during INDEX2011 as well as deviations from data published on the CIR [e.g. 2]. More specifically their character appears less differentiated, however, fractionation and the involvement of mantle heterogeneities or variable depths sources are suggested by elevated concentrations of incompatible and volatile elements.

Abstract

Ombrotrophic peatlands integrate atmospheric deposition and are therefore used as archives to interpret variations of natural and anthropogenic mercury (Hg) emission sources. However, the question remains whether peat Hg profiles reflect local, regional or global Hg deposition. On a global scale, coal combustion is today the major anthropogenic Hg source to the atmosphere. The unique range of Hg isotopic compositions observed in coal deposits suggests that Hg isotope signatures may offer a new tool to track coal Hg emissions and deposition. We examined 3 peat cores from the Pinet peat bog (French Pyrenees, 42°51'52N, 1°58'29E, 880m a.s.l.). for variability of Hg accumulation rates and Hg isotopic signatures. Loss on ignition, water content, density and radionuclides were measured in each core. The 3 cores have been dissected in slices of 1cm allowing a temporal resolution of 20 years at the bottom part and less than 2 years in the top part. The Pinet peat bog is relatively sheltered from direct emission sources and integrates therefore mostly Hg transported over long distances. However, local mining and smelting activities in neighboring valleys might have been additional sources during the last 200 years. A combined ^{210}Pb-^{14}C age-depth model was applied to all cores and revealed that the Wardenaar cores of approximately 75cm-length go back in time until 2300BC. Mercury accumulation rates (Hg AR) are around 1.5µg.m^{-2}.y^{-1} before times of significant industrial emissions (2300 to 1900BC), consistent with other European peat records. First signs of anthropogenic impacts are evidenced by an increase of Hg AR to 8µg.m^{-2}.y^{-1} (1650 to 1900AD). Hg AR continue to increase in the 20th century to values of 38µg.m^{-2}.y^{-1}. Major Hg AR peaks of 42, 52, 62 and 100µg.m^{-2}.y^{-1} occur in the periods 1956, 1979, 1994 and 2001 respectively. Only very recently a decrease in Hg AR of 28% is visible. This decrease might be attributed to reduced Hg emssions following the implementation of antipolution policies.

A modified combustion and trapping method was used to isolate and purify Hg from the organic peat matrix before analysis of Hg isotopes using MC-ICPMS. Mercury's isotopic signatures in the Anthropocene (δ^{202}Hg: -0.84 to -1.65‰) are different from the Holocene (δ^{202}Hg = -0.5‰) and correspond to that of average coal (δ^{202}Hg = -1.3‰; [1,2]).

The Art of augering, observing, and connecting processes across threshold landscapes

ARJUN M. HEIMSATH[1*], JEAN L. DIXON[2], ROMAN A. DIBIASE[3], AND KELIN X. WHIPPLE[1]

Abstract

We focus here on the soil-mantled landscapes found in high-relief, steeply sloped landscapes typically thought to be at a critical threshold of soil cover. Soil found across such landscapes fits the conceptual framework of a physically mobile layer derived from the underlying parent material with some locally-derived organic content. The extent and persistence of such soils depends on the long-term balance between soil production and erosion. We present cosmogenic Be-10-derived soil production and erosion rates that show that soil production increases with catchment-averaged erosion, suggesting a feedback that enhances soil-cover persistence, even in threshold landscapes [1]. Soil production rates do decline systematically with increasing soil thickness, but hint at the potential for separate soil production functions for different erosional regimes. We also show that a process transistion to landslide-dominated erosion results in thinner, patchier soils and rockier topography [2], but find that there is no sudden transition to bedrock landscapes.

These findings focusing on the physical processes of soil production and transport are coupled with extensive measurements of major and trace elements in soils, saprolites and bedrock across different physiographic regimes ranging from low to high gradient in the same field area of the San Gabriel Mountains, California. Connecting the processes shows that average chemical depletion fractions (soil loss relative to parent material) decrease with increasing elevation and decreasing temperature, reflecting a combination of climate influence and potential dust flux. On low-gradient slopes weathering rates increase with increasing erosion rates, reflecting the influence of mineral supply, while on high-gradient slopes both weathering intensity and rates decrease with increasing erosion rate [3].

Finally, we draw an important conclusion connecting the physical processes producing and transporting soil and the chemical processes weathering the parent material by measuring parent material strength. We observe that parent material strength increases with overlying soil thickness and, therefore, the weathered extent of the saprolite. Soil production rates, thus, decrease with increasing parent material competence. These observation highlight the importance of quantifying hillslope hydrologic processes where our multi-facted measurements are made. Art did it!

Copper partitioning during magmatic-hydrothermal phase separation — revisited: Fluid inclusions in coeval quartz, topaz and garnet

SEO, JUNG HUN[1,2] AND HEINRICH, CHRISTOPH A.[1*]

[1]ETH Zurich, Switzerland, heinrich@erdw.ethz.ch (* presenting author)
[2]Present address: Seoul National University, Korea, seo28@snu.ac.kr

Recent experimental studies have raised concerns that Cu concentrations in natural quartz-hosted magmatic-hydrothermal fluid and melt inclusions can be modified after entrapment. Li, Cu^+, Na^+, Ag^+ and probably H^+ may undergo selective diffusional exchange between inclusions hosted by quartz and the surrounding aqueous fluid [1, 2]. Using LA-ICPMS multi-element analysis including sulfur, we have analysed coexisting brine and vapor inclusions hosted in topaz and garnet, from samples where previous analyses had been obtained from similar and likely coeval inclusions hosted by quartz [3]. We found that the concentration of Cu in the quartz-hosted fluid inclusions deviate from those hosted by garnet or topaz in the same sample. In particular, the selective enrichment of Cu found in quartz-hosted vapor inclusions is not observed in the topaz-hosted counterparts, whereas S and all other metals have overlapping concentrations in each of the samples, irrespective of host mineral.

Our data from natural samples are in line with the experimental study of Lerchbaumer and Audétat [2], indicating selective inward diffusion of copper into the quartz-hosted vapor inclusions after their entrapment and during cooling from ~450°C. Electrolytic diffusion experiments have previously demonstrated that small monovalent cations, such as Li^+ and to lesser degrees Na^+, can selectively diffuse along the channels oriented parallel to the c-axis of the quartz structure [4].

Post-entrapment modification of natural fluid inclusions depends on a chemical driving force. In cooling magmatic-hydrothermal systems, a chemical potential gradient in μ_{Cu^+} can be established by the high original H_2S content of magmatic vapor inclusions, in excess relative to chalcophile metals [3] as confirmed by our new data from garnet and topaz inclusions. Cu^+ may be driven to diffuse from a gradually H_2S-depleted grain-boundary fluid outside the quartz crystals (where Cu^+ activity remains high due to consumption of H_2S by reaction with ferromagnesian silicates to pyrite) towards the vapor inclusions in which Cu^+ activity gradually decreases by precipitation of a daughter crystal of chalcopyrite, $CuFeS_2$. This S-driven exchange mechanism explains why S/Cu ratios in natural fluid inclusions are commonly close to the stoichiometric proportion of Cu:S = 1:2, as in chalcopyrite [3].

Suitability of IAEA-603 as a replacement of NBS19 for small sample carbonate analysis

JEAN-FRANÇOIS HÉLIE[1*], CLAUDE HILLAIRE-MARCEL[1], MANFRED GROENING[2]

[1] GEOTOP-UQAM, Montréal, Canada,
[1]helie.jean-francois@uqam.ca (* presenting author)
[1]hillaire-marcel.claude@uqam.ca
[2]IAEA Terrestrial Environment Laboratory, Vienna, Austria,
[3]m.groening @iaea.org

The VPDB scale is anchored by NBS19 and LSVEC with absolute values for $\delta^{13}C$ [1]. For $\delta^{18}O$ values, the only carbonate material with an absolute value is NBS19 [2]. It is thus a critical reference material. NBS19-TS is now exhausted and IAEA is proposing IAEA-603 as a replacement, produced from Carrara marble. Most of the carbonate international reference materials are distributed with a grain size of about 200 to 500 µm to minimize water adsorption. Thus, the analysis of 100 µg of these international reference materials is often given by 1 grain resulting in less than desirable reproducibility. IAEA will not distribute smaller grain sizes due to possible isotopic exchange at a large surface area exposed to CO2 and moisture, and grinding by individual laboratories may result in heating and conversion of calcite to aragonite accompanied by a small but measurable fractionation. Here, we evaluate the suitability of IAEA-603 for calcium carbonate isotopic analysis at the 100 µg level. About 15 kg of ground and sieved material was uniformly divided into 31 bottles by IAEA. A subsample of each bottle was ground and sieved resulting in 4 differend fractions: i) the original material (200 to 500 µm), ii) a fraction <90 µm, iii) a fraction between 90 and 125 µm and iv) a fraction >125 µm. All 4 fractions were analyzed for $\delta^{13}C$ and $\delta^{18}O$ of all 31 subsamples on an Isoprime™ triple collector IRMS in dual inlet mode coupled to a MultiCarb™ system. Preliminary results show that average values vary little from one fraction to another (table 1). However, the largest standard deviations are obtained with the original material and the lowest one for the fraction of less than 90 µm. X-ray diffraction analysis of a subsample and all of its fractions shows that only calcite is present in all fractions. Following these preliminary results, IAEA has decided to wash the original material to remove the fine dust fraction, and subsamples of the washed material will be analyzed following the same protocol.

Table 1. Average $\delta^{13}C$ and $\delta^{18}O$ and standard deviations of all subsamples

	$\delta^{13}C$ ‰ vs VPDB	STDev (1σ)	$\delta^{18}O$ ‰ vs VPDB	STDev (1σ)
Grains	2,466	0,024	-2,437	0,038
<90	2,469	0,012	-2,405	0,027
90-125	2,461	0,016	-2,371	0,025
>125	2,455	0,021	-2,408	0,033
all	2,466	0,018	-2,406	0,038

Mechanisms of chemical weathering: nanoscale-analytical measurements yield evidence for a weathering continuum

R. HELLMANN[1*], J.P. BARNES, D. DAVAL

[1]ISTerre, University of Grenoble 1 and CNRS, Observatory for Earth, Planetary and Space Sciences (OSUG), F-38041 Grenoble Cedex 9, France; roland.hellmann@obs.ujf-grenoble.fr (* presenting author)
[2]CEA-Leti, Minatec Campus, 17 rue des Martyrs, F-38054 Grenoble Cedex 9, France; barnesjp@cea.fr
[3]LHyGeS, University of Strasbourg/EOST-CNRS, F-67084 Strasbourg, France; ddaval@unistra.fr

Chemical weathering in the field occurs under complex conditions, characterized by variable degrees of aqueous chemical saturation and chemically complex fluids that may contain significant concentrations of ions, metals, ligand complexing agents, inorganic and/or organic acids or bases. In addition, weathering may also occur in very specific environments, such as in µm-sized pore spaces or in contact with mycorrhiza. Becasue of the complexity inherent to natural chemical weathering environments, it is not surprising that many types of alteration have been documented; two of the commonest reveal a) mineral-mineral replacement b) formation of amorphous, silica-rich surface layers. The question addressed in this talk is whether it is possible to define a unique nanoscale mechanism that controls chemical weathering.

Here we present recent measurements of the structure and chemical composition of mineral surface interfaces associated with the natural weathering of granite and serpentinite. The samples investigated were extracted from environments that are characterized by subaerial, shallow soil, and biological/abiological alteration. As detailed in a recent publication (Hellmann et al., 2012), one of the most promising techniques for studying chemical weathering at the nanoscale is based on sample preparation by focused ion beam (FIB), and measurements using high resolution transmission electron microscopy techniques, in particular HRTEM, STEM-HAADF, and EFTEM/EELS. The latter technique is particularly useful for providing nm-scale chemical maps of mineral surface interfaces.

The mineral surface interfaces that were investigated show evidence for spatially coincident and very abrupt structural and chemical changes (nm-scale sharp gradients) at the boundary between the unaltered parent mineral and the silica-rich amorphous surface layer. This type of chemical weathering was observed in all samples. The sharp structural and chemical boundaries that we measured are compatible with an interfacial dissolution-reprecipitation mechanism, and not solid-state volume interdiffusion associated with preferential cation loss and leached layer formation. Based on these results, as well as published studies on mineral-mineral replacement, we propose a chemical weathering continuum based on a dissolution-reprecipitation mechanism that unifies the different types of weathering observed in nature.

What mechanism controls rhenium deposition from euxinic waters?

GEORGE R. HELZ*[1]

[1] University of Maryland, College Park MD 20742 USA, helz@umd.edu (* presenting author)

Rhenium is often enriched in black shales and euxinic basin sediments by 100 to 1000 times over its crustal abundance. Enrichment previously has been attributed to reduction of ReO_4^-, the principal Re species in natural waters. The product is assumed to be an insoluble Re(IV) oxide or sulfide. So far, the specific biotic or abiotic mechanism of reduction has escaped identification. Pure cultures of sulfate and iron reducing bacterial fail to precipitate Re, but precipitation has been observed in Re-enriched natural sediments under sulfate reducing conditions. In this talk, I explore an alternate, non-reductive mechanism of fixing Re in sediments: sulfidation of ReO_4^- to particle-reactive thioperrhenates ($Re^{VII}O_nS_{4-n}^-$) or to Re^{VII} sulfide precipitates or coprecipitates. Using UV-vis spectroscopy, equilibrium constants for formation of ReO_3S^- and ReS_4^- as well as a solubility constant for a colloidal Re_2S_7 polymer have been measured for the first time. From these constants, I conclude that most euxinic environments contain insufficient sulfide to stabilize thioperrhenates as major species. Similarly, Re_2S_7 polymers are too soluble to form in near-neutral pH waters, although they might form in acidic mine waters or during supergene-hypogene enrichment processes. To explain remarkable similarities between Mo and Re vertical profiles in the Black Sea, I propose that both elements become thiolated and coprecipitate at surfaces of the Fe-Mo-S colloidal phase that has previously been proposed to explain Mo deposition from euxinic basins. Coprecipitation implies that the critical step for Re removal from euxinic basins involves neither reduction nor thiolation of ReO_4^-, but instead saturation of sulfidic waters with the Fe-Mo-S phase. Coprecipitation favors removal of Mo more than Re from the aqueous phase, explaining increasing aqueous phase Re/Mo ratios as these elements are depleted from sulfidic waters. This process is well-described by the Raleigh fractionation law. Similar partition coefficients describe the evolution of Re/Mo ratios quantitatively both in sulfidic Black Sea waters and in sulfidic Hingham Bay pore waters. This implies that Re chemistry in sulfidic pore waters does not differ from that in sulfidic water columns in any fundamental way, contrary to some previous views. This mechanism accounts for the remarkable coherence in the profiles of Re and Mo in the Black Sea and for the failure of Re to be precipitated in pure sulfate reduction cultures that lack Mo.

Inter-laboratory Evaluation of $^{40}Ar/^{39}Ar$ Data for Sanidines from the Fire Clay Tonstein

[7]Rutgers University, Piscataway, NJ, USA

Because the $^{40}Ar/^{39}Ar$ method requires age standards, an important step towards improving the overall precision and accuracy of the method is to develop standard materials for inter-laboratory comparisons that span a wide array of age. It has been previously demonstrated that sanidines of the Carboniferous Fire Clay tonstein give analytically indistinguishable plateau ages over a 300 km distance in the Appalachian Basin [1]. Here we show that sanidines from the Carboniferous Fire Clay Tonstein of the Appalachian Basin of the southern United States are homogeneous at the single crystal scale, at least as measurable with single collector approaches, and reasonably reproducible among laboratories.

The reproducibility of the Fire Clay populations for the 8 iterations in the LDEO experiment (including 304 individual grains of Fire Clay sanidine and 137 of Fish Canyon) is 0.03% (1σ, analytical only). Encouraged by these results we distributed aliquots to four other labs for inter-laboratory comparisons.

Preliminary results are promising. All labs find a small range of ages, although the reported estimates are not all overlapping with estimated analytical errors. The agreement in terms of *R*-values, defined as the $^{40}Ar^*/^{39}Ar_K$ of the Fire Clay sanidine relative to the Fish Canyon sanidine standard, is quite reasonable with an interlaboratory average of 12.0799 ± 0.0296 (0.24%), and the small variability of ages suggests the potential for probing interlaboratory biases. This *R*-value translates to 315.3 ± 0.7 Ma and 314.6 ± 1.1 Ma using the calibrations of [2] and [3,4], respectively, including full systematic uncertainties. The Fire Clay tonstein is a promising natural sample for inter-laboratory comparisons and is a good candidate for producing a Carboniferous sanidine monitor standard.

The geochemical signal of the provenance of ice-rafted deposits and ice sheet dynamics

S.R. HEMMING[1,2]

[1]Columbia University, New York, USA, epierce@ldeo.columbia.edu
[2]Lamont-Doherty Earth Observatory, Palisades, USA

Ice sheets are important components of the climate system. Their high albedo leads to a positive cooling feedback, and their presence affects atmospheric and oceanic circulation. Understanding the temporal record of ice sheets in the past and how they correlate to other climate-sensitive processes are important to understanding the vulnerability of ice sheets in a warming world. The distribution of ice-rafted detritus in marine sediments has been used in the polar oceans to provide significant insights into ice sheet behavior and processes that control climate conditions. A key element for understanding ice sheet interactions in the climate system is identifying the major sources of ice-rafted detritus. I will review some examples of the application of radiogenic isotope provenance studies of glaciogenic marine sediments. Because of the fortuitous patchwork distribution of continental terranes with variable geologic age and history, radiogenic isotopes are powerful tracers of sediment provenance that can provide important clues about past ice sheet behavior. In favorable cases application to marine sediments allows developing a precise time line of ice sheet behavior that can be integrated with evidence for paleoclimate and paleoceanography changes. Additionally ocean sediment archives tend to have relatively continuous sediment accumulation, so although they are separated from the more direct continental evidence, they provide an important complement to the study of land-based glacial features.

There is a wide array of fruitful approaches to geochemical provenance of glaciogenic marine sediments. Because sediments produced from glaciers tend to be dominantly from strongly mechanical weathering regimes, the degree of chemical alteration is a good indication of the abundance of recycled sedimentary sources. Approaches that use bulk sediments have the advantage of providing an average of the contributing sources and the disadvantage of providing a mixed signal. Approaches that use measurements of individual grains have the advantage of separating multiple source contributions and the disadvantage of being much more costly and time-consuming. The combination of bulk-sediment and individual grain approaches is preferred. A combination of petrographic and geochemical approaches helps to mitigate the inevitable biases of each individual approach, although most geochemical approaches are biased against detecting mafic contributions.

^{236}U in seawater – contaminant and tracer

GIDEON M. HENDERSON[1*], NICK S. BELSHAW[1], REBECCA NEELY[1], ALEX L. THOMAS[1], PHILIP F. HOLDSHIP[1], KEN O. BUESSELER [2]

[1] University of Oxford, Department of Earth Sciences, South Parks Road, Oxford, OX13AN, UK, gideonh@earth.ox.ac.uk
[2] Woods Hole Oceanographic Institution, USA.

U-236 is generated from ^{235}U by the neutron flux of a nuclear explosion or power plant. Resulting ^{236}U/^{238}U ratios from such processes can be as high as $5x10^{-3}$ [1] and up to 8 orders of magnitude higher than expected theoretically for the natural environment. In contrast, ^{238}U/^{235}U ratios vary by only 4 orders of magnitude between weapons grade and residual depleted uranium. U-236 is therefore a more sensitive tracer of the presence of nuclear contamination. In seawater, the conservative behaviour of uranium means that this tracer may provide information not only about contamination, but about ocean mixing and advection away from point sources of such contamination.

U-236 has not frequently been measured in the natural environment, but most studies to have done so rely on accelerator mass spectrometry (AMS) to achieve the high abundance sensitivity required to accurately assess the ^{236}U/^{238}U ratio. In this study, we demonstrate the use of ICP mass spectrometry (with a large-geometry Nu-Instruments 1700 MC-ICP-MS) to measure ^{236}U/^{238}U ratios as low as 10^{-8}. Although this detection limit is not as low as that of AMS, the ICP approach allows measurement on significantly smaller samples (≈200mL of seawater) and for more routine sampling and analysis.

We present measurements on a suite of 30 seawater samples collected from the upper 50 m of the water column offshore the Fukushima power-plant in the months immediately following the disaster at that plant. The samples were collected from the RV KOK during a cruise (June 4-19 2011) sponsored by the Gordon and Betty Moore Foundation, and are set in the context of Cs isotope results. A wide range of other contaminant radionuclides will also be measured on seawater samples from this cruise, enabling the release of ^{236}U from the Fukushima plant into the marine environment to be well constrained, and the relative impact of atmospheric versus hydrographic routes to the ocean to be assessed. This case study will also provide an assessment of the future use of ^{236}U as a tracer of ocean contamination and transport.

Uranium series rate meters for ocean processes

GIDEON M. HENDERSON[1*], YU-TE HSIEH[1], MARK D. BOURNE[1], WALTER GEIBERT[2], FEIFEI DENG[1], ALEX L. THOMAS[1]

[1] University of Oxford, Department of Earth Sciences, South Parks Road, Oxford, OX13AN, UK, gideonh@earth.ox.ac.uk
[2] University of Edinburgh, School of Geosciences, Edinburgh, UK

Uranium-series nuclides have a range of solubility in seawater which, coupled to their diverse half-lives, make them excellent timekeepers for a wide variety of ocean processes. Not only do they record the timing of growth of marine precipitates (most notably corals) but they provide information about the rates of ocean processes such as mixing and circulation, and about chemical fluxes into and out of seawater and sediments. Recent analytical advances are reinvigorating the use of U-series approaches to assess ocean processes. This presentation will illustrate the power of these new measurement techniques to assess three critical ocean processes.

Development of new mass-spectrometric approaches to measurement of ^{228}Ra in seawater [1] allow lower detection limits and higher precision. This precision allows use of ^{228}Ra to quantify ocean mixing and chemical inputs more accurately than before, and in settings not previously investigated, as we will demonstrate with results from the Cape Basin (South Atlantic) and Loch Etive (Scotland).

Measurement of Th isotopes in dissolved form and settling particles enables assessment of downward fluxes of material in the oceans. Th-234 has been widely used to assess downward carbon fluxes, for instance. But increasing precision of ^{230}Th and ^{228}Th measurements in seawater now allow these nuclides to be used to provide complementary information about downward fluxes on other timescales. These tools have huge potential for assessment of other ocean fluxes, including those of micronutrients critical for ocean life and, via measurement of a fourth Th isotope – ^{232}Th – of detrital inputs to seawater such as mineral dust [2].

Th-230 is also frequently used as a constant flux proxy to assess variations in sedimentation rate. We will illustrate how this approach can be used to assess the duration of past events [3] with well-constrained uncertainties, and to assess chemical fluxes both into and out of marine sediments.

Silicon isotopes in glassy sponges as a tracer of silicic acid in seawater

KATHARINE R. HENDRY[1,2]
LAURA F. ROBINSON[2,3]

[1]School of Earth and Ocean Sciences, University of Cardiff, Main Building, Park Place, Cardiff, CF10 3AT, UK, HendryKR@cardiff.ac.uk

[3]Department of Earth Sciences, Bristol University, Wills Memorial Building, Queen's Road, Bristol, BS8 1RJ, UK.

Dissolved silicon, or silicic acid, is an essential nutrient that feeds the growth of opaline diatoms, which are a photosynthetic organism responsible for a significant proportion of carbon export production in the oceans. Deep-sea glassy sponges also produce their skeletal elements, spicules, out of opal and, while they most likely play a less important part in carbon cycling, they can provide valuable information about seawater composition. Recent work has shown that the silicon isotope composition of spicules reflects the concentration of silicic acid in the ambient seawater in which the sponge grew. Here, we present a global dataset of silicon isotopes in modern and core top spicules, which shows that the relationship between silicic acid concentration and silicon isotopes in sponges is universal. A biological mechanism, linking uptake kinetics of silicic acid in sponges and fractionation, can explain this relationship. This theoretical framework, together with the modern and core top calibration work, supports the view that the isotopic composition of sponge spicules is a robust geochemical proxy, and downcore records can be interpreted in terms of past ocean silicic acid concentration.

[6] Eberhard-Karls-Universität, Tübingen, Germany, Michal.Kucera@uni-tuebingen.de

The boron isotopic compositions of foraminiferal and coral carbonate provide invaluable tools for the reconstruction of past CO_2 levels [e.g.1, 2]. However, calibration studies in both foraminifera and corals have illustrated that many organisms do not conform fully to our theorectical understanding of the proxy and there is often (but not always) a biological imprint upon recorded values. In order to construct reliable palaeo-pH and CO_2 records, it is crucial that we understand, quantify and correct for biological influence or 'vital effects' when applying the proxy to any given organism[3].

Here we present the results of efforts to quantify the biological influence on the boron isotopic signatures of planktic foraminiferal and coral carbonates. Calibration (via MC-ICPMS) of both symbiont-bearing and non-symbiont-bearing foraminifera (from cultures, tows and sediments) provides insight into the influence of symbiont photosynthesis, symbiont-host respiration and host calcification on the microenvironment pH around the foraminifera and thus the recorded boron isotopic signature of calcite. In this way, biological and environmental signals can be disentangled and proxy records extended.

In addition, analyses of coral carbonate (*Siderastrea siderea*) cultured under controlled pH not only constitute a new species-specific $\delta^{11}B$ calibration for palaeo-application, but shed light on the calcifying fluid pH of scleractinian corals when viewed in the context of recent pH micro-electrode measurements[4].

[4]POSIVA, Finland, anne.lehtinen@posiva.fi

The Greenland Analogue Project (GAP) aims to further the understanding of groundwater evolution due to the influence of a continental ice sheet and continuous permafrost. Geochemical and hydrogeological processes are being studied in the area around Kangerlussuaq, Greenland. Geochemical and isotopic (^{18}O, ^{2}H, ^{3}H, ^{37}Cl, ^{87}Sr and ^{34}S and ^{18}O of SO_4) tracers are used to interpret the flow and geochemical evolution of groundwater in this crystalline environment.

Three boreholes have been drilled since 2009. Two boreholes are equipped with groundwater sampling devices: DH-GAP01 intersects a talik beneath a large lake and DH-GAP04 provides 3 sampling sections beneath and adjacent to the ice.

Talik waters from DH-GAP01 and the first groundwaters sampled at DH-GAP04 appear to be geochemically similar in many ways, such as high concentrations of sulphate. High sulphate groundwaters are also found in other permafrost impacted crystalline environments in Northern Canada [1],[2]. GAP borehole waters are depleted in $\delta^{18}O$ and $\delta^{2}H$ compared to modern precipitation when a simple linear mixing model is used to calculate final compositions of DH-GAP04 based on the concentration of tracer in the samples (Fig. 1). Further sampling of DH-GAP04 is planned for 2012.

A spring located directly infront of Leverett Glacier, about 10 km south of DH-GAP01, yields groundwaters that are geochemically distinct from the waters sampled from the boreholes with elevated iron concentrations up to 14.8 mg/L.

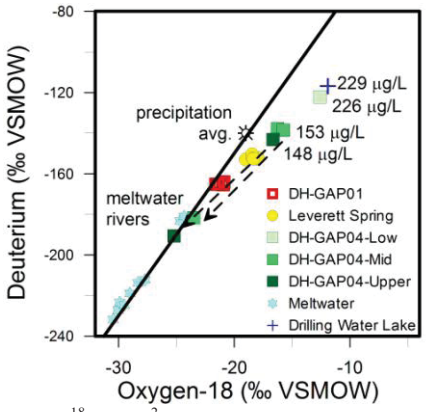

Figure 1: $\delta^{18}O$ vs $\delta^{2}H$ for groundwaters and glacial meltwaters. Concentrations are the sodium fluorescein tracer used in drilling.

Clumped isotope thermometry of Carboniferous brachiopods and the effects of burial heating

GREGORY A. HENKES[1*], ETHAN L. GROSSMAN[2], THOMAS E. YANCEY[2] AND BENJAMIN H. PASSEY[1]

[1]Department of Earth and Planetary Sciences, The Johns Hopkins University, Baltimore, MD, USA 21211 (*ghenkes1@jhu.edu)
[2]Department of Geology and Geophysics, Texas A&M University, College Station, TX, USA 77843

Clumped isotope thermometry of well-preserved carbonate fossils holds great promise for detangling the effects of paleotemperature and seawater oxygen isotope composition on the oxygen isotope composition of fossils. Meaningful application of this paleothermometer requires accurate calibration curves, as well as an understanding of the burial temperatures where solid-state reordering of C-O bonds becomes significant. We describe the results of a clumped isotope calibration for modern brachiopods and mollusks, then use this calibration to determine paleotemperatures from a suite of nominally pristine Carboniferous brachiopod fossils. Apparent paleotemperatures of the brachiopods range from 15 to 197 °C. Thus, while the Δ_{47}-derived temperatures of many of the fossils are consistent with formation at Earth's surface, some shells give paleotemperatures that are clearly inconsistent with biological mineralization. We have conducted laboratory heating experiments on natural calcites to determine Arrhenius parameters for solid-state C-O reordering. These parameters are used in numerical models to predict the Δ_{47} evolution of the Carboniferous brachiopods, where the T-t paths are constrained by independent geological data. We observe a reasonably close correspondence between predicted and observed Δ_{47} values, and the models predict that reordering becomes important at temperatures above ~100-125°C for dwell timescales of 10^8 years.

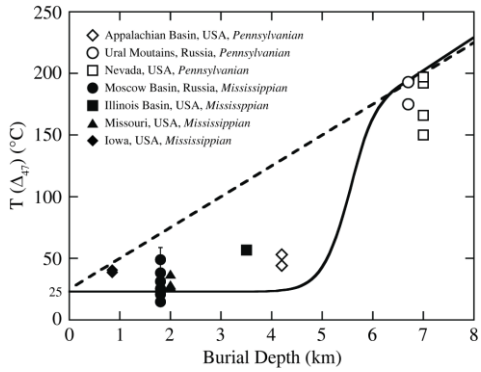

Figure 1: Clumped isotope temperatures and estimated burial depths (based on independent geological information) for pristine Carboniferous brachiopods from several Paleozoic sedimentary basins. The solid line is a modeled solid-state reordering pathway showing the clumped isotope temperature evolution of a shell buried at a rate of 0.25 km/Ma under a geothermal gradient of 25 °C/km (dashed line). Samples undergoing solution-precipitation should plot in the area bounded by the solid and dashed lines.

Monopolar and highly asymmetric nucleation at low temperatures: Insights from tourmaline

D.J. HENRY[1*], B.L. DUTROW[1]

[1]Louisiana State University, Dept. Geology & Geophysics, Baton Rouge, LA, USA, dutrow@lsu.edu

Minerals overcome the nucleation barrier to growth by numerous methods. Epitaxial growth can be found between different minerals that share structural features e.g. kyanite and staurolite. Alternatively, new growth can nucelate on substrates of the same mineral. In low-temperature systems, crystallographically congruent overgrowths are common such as the often observed quartz overgrowths on quartz. Here, composition of the substrate is nearly identical, except for trace element compositions. In contrast, at diagenetic and low grade metamorphic conditions, tourmaline supergroup minerals commonly nucleate on substrates of pre-existing tourmaline, even when their compositions are substantially dissimilar.

In these environments, the substrate, a detrital core, is distinctly different in composition such that it may be classified as a different species that may manifest as a contrasting color (Fig. 1). These interfaces appear sharp with little-to-no diffusion across the interface. In addition, these oriented overgrowths are in optical continuity with the detrital grain and are more pronounced at the $+c$ axis of the crystal providing a crystallographic identifier. Such overgrowths suggest distinct and major differences in surface energy at different poles of the crystal. At diagenetic conditions the tourmaline overgrowth is monopolar – only at the $+c$ axis. At low grades of metamorphism the overgrowths are highly asymmetric along the c axis with significant differences in composition at the opposite poles. With increasing metamorphic grade the asymmetric differences in overgrowth dimensions and compositions diminish and converge at roughly 550°C. Tourmaline is one of the few minerals to exhibit such features at low temperatures and supports the fact that preferred nucleation reduces the nucleation barrier. Because of the temperature dependence of the asymmetric development of tourmaline, it is likely that differential surface energy plays a very significant role in tourmaline nucleation.

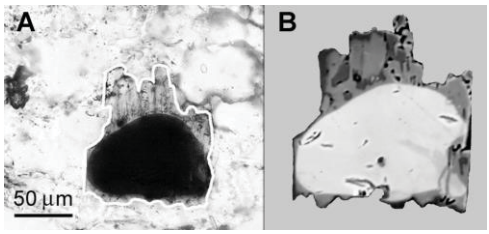

Figure 1: Detrital tourmaline grain with asymmetric overgrowth developed in chlorite zone metawacke. (A) Optical photomicrograph with dark detrital core and lighter overgrowth highlighted by white outline. (B) Backscattered electron image showing some of the textural and chemical variability of the overgrowths. [1]

Iron Oxides Chemistry from High-grade Iron Ore, Iron Quadrangle

ANA-SOPHIE HENSLER[1*], STEFFEN HAGEMANN[1], CARLOS ALBERTO ROSIERE[2], THOMAS ANGERER[1] AND SARAH GILBERT[3]

[1]Center for Exploration Targeting, University of Western Australia, hensla01@student.uwa.edu.au (*presenting author)
[2]Universidade Federal de Minas Gerais, Brazil, crosiere@gmail.com
[3]University of Tasmania, Australia, sgilbert@utas.edu.au

Abstract

Most of the high-grade iron ore deposits in the Iron Quadrangle (IQ), Brazil are hosted by itabirites of the Caue Formation, a Paleoproterozoic Lake-Superior type Banded Iron Formation. The IQ was affected by two main orogenies, the Transamazonian (2.6 – 2.0 Ga) and the Brasiliano (0.7 – 0.45 Ga) resulting in a western low-strain and an eastern high-strain domain. Iron ore bodies in the western domain are dominated by early-stage martite and granoblastic hematite, whereas ore bodies of the eastern domain contain mainly late-stage microplaty hematite and specularite.

Minor and trace element contents (Mg, Mn, Al, Cr, V, Ti, Ga, Ni, Co, Zn, As, Bi and REE) of selected iron ore deposits in the IQ, such as Aguas Claras, Pau Branco, Casa de Pedra, Bau and Conceicao were analysed using Laser Ablation ICPMS. At a deposit-scale, the minor and trace element patterns of specific iron oxide phases (e.g., martite) are consistent within an ore body, but show significant variations, when compared to another iron oxide phase of the same ore body (e.g., to microplaty hematite). A progressive depletion of elements, (most significantly Mg, Al, Cr, Ti, and Ni) is recorded when comparing paragenetically older (i.e., granoblastic hematite) with younger (i.e., microplaty hematite, specularite) oxides (Figure 1). At a scale of the IQ, chemistry of iron oxides that formed during the early Transamazonian event (i.e., martite after magnetite and granular hematite) shows consistent Mn, Al, Ti, Ga, Co, Zn, As, and Bi contents. This is distinct from late crystallised oxides (i.e., microplaty hematite, specularite), which display also consistent but different chemical patterns (e.g., Mn, Cr, Ti, Ga, and As) when compared to the "early" oxides. Therefore, different tectonometamorphic stages may have a major influence on the mineral chemistry of the iron oxide generations. The actual factors, that may control the mineral chemistry patterns of iron oxides and are currently under investigation, are the host and country rock petrology, fluid source type(s) and/or the mineral-specific preference of cation substitution.

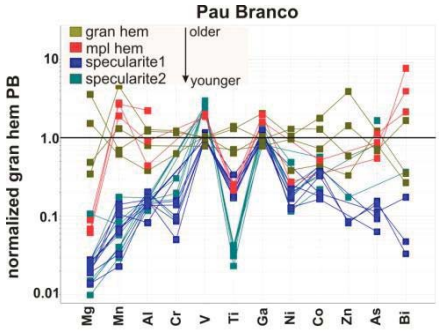

Figure 1: Chemical signature of iron oxide species from Pau Branco (PB) iron ore deposit, normalized to granoblastic hematite. Abbreviations: Gran hem = granoblastic hematite; mpl hem = microplaty hematite

Pilot-scale barrier system for removal of nitrate in mine drainage

ROGER HERBERT[1*] AND HARRY WINBJÖRK[2]

[1] Department of Earth Sciences, Uppsala University, Uppsala, Sweden, roger.herbert@geo.uu.se (* presenting author)
[2] LKAB, Malmberget, Sweden, harry.winbjork@lkab.com

Introduction

Undetonated ammonium nitrate - based explosives are readily soluble in water and quickly enter into the mine water and process water at a mine site. Process water is eventually discharged to a surface water body and, without treatment, can lead to eutrophication in the recipient. In order to investigate the application of nitrate removal by denitrification in the cold climate of northern Sweden, laboratory and field experiments have been conducted. Laboratory column experiments were designed to determine denitrification rates at relevant temperatures for northern Sweden. Based on the column experiments at low temperature, a hydraulic residence time of ca. 24 hours was one of the design criteria used for dimensioning a barrier system in the field. In autumn 2009, a pilot-scale barrier system was constructed of sheet metal at the Malmberget iron ore mine. The barrier (9m x 2m x 1.5m) appears as an open basin with three inner dividing walls, and is filled with a reactive mixture consisting of crushed rock, sawdust, and sewage sludge. A small fraction of the water discharging from the Malmberget clarification pond was fed by pump to the barrier at a rate of ca. 5 m^3 day^{-1}.

Results

In the pilot-scale barrier system, analytical results from 2010 indicated that nitrate (NO_3^-) removal generally lay in the range between 11 and 77% of influent nitrate concentrations. In order to achieve a higher removal rate, the barrier system needed to be supplemented with an additional carbon and energy source for denitrifying bacteria. In 2011, a sodium acetate solution as an external electron donor was continuously added to the barrier system along with the influent water. Analytical results from 2011 indicate that the barrier system in Malmberget removes >95% of the incoming nitrate during summer months (average daily temperature 14°C for 2011) with the addition of acetate. The barrier did exhibit decreases in performance toward the end of the study period in 2011, but this is likely the result of a lower hydraulic residence time in the barrier at this time.

Nitrite (NO_2^-) concentrations in effluent waters were initially in excess of influent values, indicating the production of nitrite in the barrier. However, both nitrite and ammonium (NH_4^+) concentrations decreased to below detection limits after the addition of acetate (CH_3COO^-), suggestion the occurrence of anaerobic ammonium oxidation (anommox) in the barrier substrate. During this period, alkalinity values peaked at 500 mg HCO_3^- L^{-1} in effluent waters, indicative of organic carbon (acetate) oxidation through denitrification:

$$5CH_3COO^- + 8NO_3^- + 3H^+ \rightarrow 4N_2(g) + 10HCO_3^- + 4H_2O$$

Stable isotope analyses of $\delta^{15}N$ and $\delta^{18}O$ in nitrate demonstrate an enrichment in ^{15}N and ^{18}O along the flowpath, supporting the conclusion that denitrification is responsible for nitrate removal.

Abstract

Generally, coal-deposits and associated organic-rich horizons in continental successions in North-America have been interpreted to represent swamp deposits, which accumulated on the floodplain as a consequence of autocyclic or tectonic processes. However, spectral-based analyses of geochemical proxies have shown precession-eccentricity controlled stacking patterns in the Tongue River Member of the Fort Union Formation in the US. Similarly, Upper Cretaceous alternations of sand-silt-organic-rich horizons likely represent precession-controlled cycles in the Horseshoe Canyon Formation in the Western Canada Sedimentary Basin. To support the lithological proxy-data, mainly represented by the color, geochemical data has been generated for each single layer that include some of the soluble, moderately soluble and insoluble elements, and compared them with seawater and upper crustal partition abundances. All different lithologies show the same characteristics: increased abundances of Mg, Ba, Cr, Zn and lower abundances of Ca relative to the very homogeneous Coal 13 or Nevis Coal. Although the chemical index of alteration (CAI) is the most widely accepted weathering index applied to siliciclastic sedimentary rocks and it has been successfully applied to evaluate various climatic conditions in the Precambrian, in the Horsehoe Canyon Formation the CAI does not yield any clear paleoclimatic information, most probably due to mobilisation of Na^{+}, K^{+} and Ca^{2+} during diagenesis or the presence of apatite. In addition a combination of grain-size effects and the possible incorporation of older weathered material may have affected the CAI-values for the deposits. For some of the elemental ratios, the redox sensitive (Cr/V)-proxy, and the Mg#, the data show trends that mirror those observed in the color proxy when normalized to the reference layer coal. Furthermore, when applying wavelet analysis to the records, periodicities appear to be more evident. This, in combination with new paleomagnetic, Ar-Ar and U-Pb (CA-TIMS) data, will enable us to link our records to the Maastrichtian, including the C29R and the K-Pg boundary. This research is funded by the European Community's Seventh Framework Program (FP7/2007-2013) under grant agreement no. 215458.

Micro- to macro-scale investigations of manganese in soil-plant systems

ELIZABETH M. HERNDON[1*], JAMES KUBICKI[2], AND SUSAN L. BRANTLEY[3]

[1]Dept. of Geosciences, Penn State University, University Park, PA, United States, eherndon@psu.edu (* presenting author)
[2]Dept. of Geosciences, Penn State University, University Park, PA, United States, jdk7@psu.edu
[3]Earth and Environmental Systems Institute, Dept. of Geosciences, Penn State University, University Park, PA, United States, sxb7@psu.edu

Industrial processes have emitted large quantities of metals into the atmosphere which have been subsequently redistributed across the Earth's surface. As a result, we can observe enrichment of many metals in air, water, soil, and biota. Vegetation can impact the residence time of these metals in soils and their rate of transfer from soils to river systems. In particular, biotic uptake into vegetation can slow leaching and outflux of manganese contaminants from soils. Mn that is taken up by vegetation can be stored in standing biomass or returned to the soil through litterfall. In order to better predict Mn mobility in the environment, it is necessary to characterize the abundance and chemical forms of Mn-compounds in mineral soil, soil organic matter, and vegetation. Here, we combine spectroscopic techniques with molecular modeling and mass balance models to develop better ecosystem-scale understanding of Mn transport through vegetation and soils.

Spectroscopic techniques (XRF and XANES) reveal the chemical transformations of Mn that occur during its movement through the plant-soil system. Mn(II) is complexed to organic matter in roots, branches, and foliar tissue. Mn is concentrated in the foliage, where Mn(II)-organic complexes dominate, but where we have also observed a distinct chemical form of Mn localized in Mn-rich black spots. Foliar Mn is oxidized and immobilized as mixed-valence Mn-oxides in the soil during decomposition of litterfall.

To complement the spectroscopic data, molecular modeling is being used to calculate ligand-dependent shifts in the Mn K-edge energy and provides insight into the Mn oxidation state and coordination environment. Furthermore, bulk chemistry data is combined with the spectroscopic data to create mass balance models and estimate Mn fluxes between reservoirs in the soil-plant system. While bulk chemistry itself alone yields important information about Mn dynamics, techniques such as μXRF and μXANES can deliver further insight into the spatial distribution, oxidation state, and chemical form of Mn in soils and vegetation. As demonstrated here, integration of microscale techniques with ecosystem analysis can prove valuable to understanding ecosystem metal dynamics.

Input and transport of ^{129}I in the Canadian Arctic: evidence of a Fukushima pulse

MATT N. HEROD[1]*, IAN D. CLARK[1], W.E. KIESER[2], XIAO-LEI ZHAO[3]

[1]University of Ottawa, Earth Sciences, Ottawa ON, Canada mhero065@uottawa.ca (*presenting author)
[1]University of Ottawa, Earth Sciences, Ottawa ON, Canada idclark@uottawa.ca
[2]University of Ottawa, Physics, Ottawa ON, Canada liam.kieser@utoronto.ca
[3]University of Toronto, Physics, Toronto ON, Canada xiaolei.zhao@utoronto.ca

Since the 1950s, nuclear fuel reprocessing and nuclear accidents have released large amounts of anthropogenic ^{129}I into the atmosphere. This ^{129}I has spread throughout the northern hemisphere, increasing concentrations above natural fallout and geogenic levels in these regions. Because it is very mobile and readily absorbed by living organisms, ^{129}I is considered a contaminant of concern, especially in terms of the long term disposal of radioactive waste.

The Arctic has been identified as a location that may be affected by ^{129}I fallout from nuclear activities in Europe and Asia. A multi-year comparison of ^{129}I concentrations, ratios and fluxes between Arctic watersheds is a valuable tool to assess the origin and extent of contamination, and to understand ^{129}I transport dynamics. Water samples from a number of watersheds were collected in the Yukon Territory, Canada in 2010 and 2011. Sampling was conducted in Whitehorse (60°43′00″N) and continued north along the Dempster Highway as far as Tsiigehtchic, Northwest Territory (67°26′26″N). ^{129}I was extracted from water samples by redox separation, precipitated as AgI, and analyzed using accelerator mass spectrometry (AMS). Total iodine was determined using ICP-MS. Mean concentrations for ^{129}I northwest Canadian rivers were 16.1x10^{6} atoms/L in 2010 and 66.8 x10^{6} atoms/L for 2011. These values significantly exceed previously published values for waters containing only geogenic or cosmogenic ^{129}I. A comparison of ^{129}I flux over the two years for a subsection of the sampling area also shows a 10-fold increase in the fallout of ^{129}I (atoms/m^2/yr) in the watersheds between 2010 and 2011. The source of ^{129}I in the Arctic is mainly from nuclear fuel reprocessing releases which are transported atmospherically through a cycle of deposition and revolatilization to remote regions throughout the northern hemisphere. The substantial increase in ^{129}I fallout in these watersheds from 2010 to 2011 is consistent with elevated levels of ^{131}I measured on the western coast of North America in the days following releases from the Fukushima Daiichi nuclear power plant in March 2011.

U isotopes in marine calcareous algae: a paleo-redox proxy?

ACHIM D. HERRMANN[1*], STEPHEN J. ROMANIELLO[1], R. PAMELA REID[2], ARIEL D. ANBAR[1,3]

[1] School of Earth and Space Exploration, Arizona State University, Tempe, AZ, USA, achim@asu.edu (* presenting author)
[2] Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL, USA
[3] Department of Chemistry & Biochemistry, Arizona State University, Tempe, AZ, USA

Significant variability in the uranium isotopic composition of natural samples [1] is largely due to isotope fractionation during redox transformations associated with uranium deposition in reducing sediments. This suggests that the uranium isotopic composition of seawater may be determined by the redox state of the global ocean. Limited evidence indicates that scleractinian corals record the uranium isotopic composition of seawater [1]. Thus, changes in the uranium isotopic composition of carbonates through time may reflect changes in the redox conditions of the global oceans. More work is needed, however, to confirm that uranium values of biogenic carbonate sediments in general reflect seawater values, irrespective of the biomineralization pathways that led to the formation of the calcium carbonate. In particular, it will be critical to establish that carbonates faithfully record uranium values of seawater without fractionation. Here, we report uranium isotope values from a range of different marine algae from the Bahamas to further test the potential of calcium carbonates as a paleo redox proxy.

It has long been known that calcareous algae incorporate different amounts of uranium [2] and have different biomineralization pathways that affect the δ^{13}C and δ^{18}O of the precipitated carbonate [3]. These difference might also lead to a fractionation of uranium isotopes during the formation of calcium carbonate in different algae. However, our results indicate that fractionation of uranium during biomineralization of algae does in fact not take place. Despite difference in uranium concentrations (ranging from ~1ppm to ~2.5ppm) and different biomineralization pathways (*Acetabularia* sp., *Rhipocephalus* sp., *Halimeda incrassata*, and *Penicillus capitatus*), the uranium isotopic compositions in these various algae are the same and reflect seawater values (δ^{238}U ~-0.40‰). The δ^{238}U values of the calcareous green algae are indistinguishable from δ^{238}U values of scleractinian corals (*Diploria* sp, *Siderastrea* sp., and *Porites* sp.) collected in the same area. Futhermore, δ^{234}U values of all samples are indistinguishable from seawater values.

Our results show that biominearlization pathways do not lead to fractionation during the uptake of uranium isotopes and calcareous algae are thus excellent candidates to serve as paleo-redox proxies. Since calcareous algae are important producers of fine sediment in carbonate settings, the lack of fractionation within the algal material further implies that bulk sediment analyses of carbonate rocks dominated by algal material as a tracer of paleo-redox are possible.

Origin of spherulitic concretions in Cambro-Ordovician black shales, St. Lawrence Estuary, Quebec, Canada

REINHARD HESSE[1*], CHRISTOPHER FONG[2]

[1]Earth & Planetary Sciences (McGill), Montreal, Canada, Reinhard.Hesse@mcgill.ca*
[2] Apt. 102, No.16, Lane 3292, Hongmei Road, Shanghai, 201103 China, Fongchristopher@hotmail.com

Introduction and Results

Spherulitic concretions are very rare among carbonate concretions which are a trademark of organic-matter rich sediments and normally consist of micritic carbonate. The occurrence in Cambro-Ordovician black shales of unknown stratigraphic age on mid-channel islands in the St. Lawrence Estuary in Quebec is among four hitherto known examples [1,2,3] of spherulitic concretions and their origin is still poorly understood. These concretions occur in close association with and show various transitions to cone-in-cone structure. The spherules are 0.5 to 12 mm in diameter. They consist of intergrown fine fibers of ferroan calcite and quartzine, pointing to the formation of the concretions below the sulfate reduction zone. A phenomenological theory of spherulitic crystallization [4] relates the thickness δ of an impurity-rich layer in front of impurity-rejecting growing crystals to the impurity-diffusion coefficient D and the growth velocity G of the crystal by δ=D/G. In spherulite-forming environments, extremely small values of δ (on the order of $<10^{-4}$cm) in conjunction with cellulation lead to spherulitic fibre growth. The intimate association of calcite and quartzine in the concretions seems hard to understand. Most spherules precipitated experimentally in the laboratory crystallized in a gelatinous medium in the presence of impurities. Silica gel is the most common medium used. The occurrence of silica gel has not been reported from clastic or biogenic siliceous pelagic deep-sea sediments, not even in hydrothermally sourced ponds of mid-oceanic ridges. However, experimental spherulite precipitation has also been achieved from alkaline aqueous solutions. Alkaline conditions are established during early diagenesis in the lower sulfate reduction zone so that fibrous calcium carbonate precipitation in the presence of impurities may easily start in the carbonate-reduction (methane-generation) zone. The switch from carbonate precipitation to silica precipitation into the pore spaces of coarse, open-texture fibrous carbonate spherulite may be achieved by the dissolution of sponge spicules or radiolarians which would lead to low supersaturation allowing the direct precipitation of quartzine.

Conclusion

Intergrown spherulitic carbonate/quartzine concretions seem to require special chemical conditions of pore-water composition and burial-diagenetic evolution that may shed important light on unusual early diagenetic chemical environments. Sperulitic concretion growth can be explained in view of a phenomenological crystallization theory [4] and experimental results.

New insights into the origin of the Shatsky Rise from Sr-Nd-Pb-Hf isotopes of volcanic rocks from IODP Exp. 324

KEN HEYDOLPH[1*], JOERG GELDMACHER[1], KAJ HOERNLE[1]

[1]GEOMAR | Helmholtz Centre for Ocean Research, Kiel, Germany, kheydolph@geomar.de (* presenting author)
jgeldmacher@geomar.de
khoernle@geomar.de

Shatsky Rise: a unique large igneous province

The submarine Shatsky Rise plateau, situated in the northwest Pacific Ocean ca. 1500 km east of Japan, is the only large intraoceanic plateau, which formed during the Late Jurassic to Early Cretaceous at a time period with numerous reversals of the Earth's magnetic field. Combined with bathymetric data, the magnetic reversals allow a detailed reconstruction of the original tectonic setting, spatial evolution and approximate seafloor age from the magnetic record [1]. Accordingly, the three main volcanic edifices Tamu, Ori, and Shirshov massifs formed by massive volcanism during a short time span along a southwest - northeast trending, rapidly spreading triple junction. After the initially voluminous stage, which created the large Tamu massif, the volcanism waned to less voluminous phases, creating Ori and eventually the smallest Shirshov massif.

We present here Sr-Nd-Pb and Hf isotope data from relatively fresh basaltic lava flows from Site U1347A drilled during IODP Expedition 324 and Site 1213B (ODP Leg 198) both located on the southernmost (oldest) volcanic edifice of Shatsky Rise. Initial $^{143}Nd/^{144}Nd$: 0.512903 to 0.512981 and $^{176}Hf/^{177}Hf$: 0.283076 to 0.283100 isotopic compositions from Site U1347A samples are quite uniform throughout the entire hole and show neither distinct MORB nor intraplate (Ocean Island Basalt) affinity. Site 1213 samples are slightly less radiogenic in Nd and Hf isotopic compositions. In a Nd vs. Hf isotope plot Site U1347 form a tight cluster at the edge of the Pacific MORB field below the present-day Hf-Nd mantle array. Site 1213 samples have less radiogenic Nd and Hf isotopic compositions. Although initial Pb double spike $^{206}Pb/^{204}Pb$ and $^{208}Pb/^{204}Pb$ isotopic compositions for Site U1347 range from 18.13 to 18.46 and 37.71 to 37.96 respectively and overlap with MORB-like compositions, they trend towards more radiogenic, intraplate-like values.

In general, our isotopic data from Tamu massif show a very homogeneous and relatively depleted isotopic composition. Such composition could reflect a large degree of melting, consistent with an origin of the initial (oldest) phase of Shatsky volcanism from an arriving hot plume head [2].

Large and heterogeneous isotopic anomalies of Sm and Gd in the Norton County meteorite

HIROSHI HIDAKA[1*] AND SHIGEKAZU YONEDA[2]

[1]Hiroshima University, Earth and Planetary Systems Science, Higashi-Hiroshima 739-8526, Japan, hidaka@hiroshima-u.ac.jp
[2]National Museum of Nature and Science, Science and Engineering, Tsukuba 305-0005, Japan, s-yoneda@kahaku.go.jp

Introduction

Cosmic rays in space penetrate a few meters into the surface of planetary materials, and produce cosmogenic nuclides in the materials. The exposure history of meteorites has been characterized by several cosmogenic nuclides. Sm and Gd isotopic shifts by neutron capture reactions also provide useful information for understanding the exposure records of meteorites, because ^{149}Sm and ^{157}Gd have very large thermal neutron capture cross sections and shift to ^{150}Sm and ^{158}Gd, respectively.

Enstatite achondrites (aubrites) are highly reduced achondrite meteorites, and must have formed in a very unique part of the solar nebular. The Norton County aubrite is known as one of the longest cosmic-ray exposure ages (111 Ma [1]), and its recovery of the main mass over 1000 kg is large enough to accumulate many kinds of cosmogenic nuclides. Therefore, Norton County is one of the best examples to study cosmic-ray irradiation effects [2-5]. We found very large and heterogeneous isotopic shifts of Sm and Gd in specific phases of Norton County, and would like to discuss the possible existence of preirradiation materials migrating into the meteorite body.

Experiments

In this study, whole rock, handpicked material of the light-colored phase (consisting mainly of enstatite), and chemical separates obtained by a sequential acid-leaching method (acetic acid-ammonium acetate, 0.1 M HCl, 2 M HCl, aqua regia, and the residue) were prepared from the same single fragment of Norton County. Sm and Gd were separated from the individual samples by a conventional method using cation exchange methods [6]. A thermal ionization mass spectrometer was used for the isotopic measurements of Sm and Gd.

Results and Conclusions

Large and heterogeneous isotopic variations of ^{150}Sm/^{149}Sm and ^{158}Gd/^{157}Gd due to neutron capture reactions caused by cosmic-ray irradiation were found in chemical and mineral separates from the Norton County meteorite. The light-colored separates have a very large neutron fluence of 1.98×10^{17} n cm^{-2}, which is 10 times higher than that of the whole rock. Furthermore, four chemical separates showed a large variation in neutron fluences, ranging from 1.82×10^{16} to 1.87×10^{17} n cm^{-2}. The variable amounts of neutron fluences from a small single fragment of the Norton County meteorite cannot be simply explained by single-stage cosmic-ray irradiation in space.

Microscopic Structure of Interfaces of Minerals in Relation to Macroscopic Ion Adsorption Phenomena

TJISSE HIEMSTRA[1] AND WILLEM VAN RIEMSDIJK[1]

[1]Wageningen University, Wageningen, The Netherlands

Mineral-water interfaces are important in regulating the free ion concentration of many minor elements in nature. In the interface, a bulk mineral meets the water network, forming a reactive structure for ion adsorption in which surface groups are a key for understanding reactivity. Surface groups and surface complexes can be characterized with modern spectroscopy (e.g. X-ray techniques, FTIR) and computational approaches (MO/DFT and MD simulations). Microscopic surface complexation is usually conditional, i.e. it will depend on pH, ionic strength, the concentration of the ion involved as well as the presence of cooperative and competitive ions. Surface complexation models (SCM) can be used to generalize experimental microscopic information and to rationalize macroscopic adsorption behavior as a function of environmental conditions. Microscopic data and tools are also highly valuable for parameterization and development of mechanistic adsorption frameworks, such as the CD and MUSIC model. Achievements and challenges will be discussed.

The variable surface speciation of a particular ion is largely regulated by the joint electrostatic interactions of all ions in the interface and there is a feedback from the water network. The structure of interfacial water and location of interfacial charge are essential. Interfacial structure and mechanisms of charging of minerals are very different. This will be illustrated, comparing metal oxides, silver halides, and ice, using experimental information as well as computational data.

Chlorine-rich fluid in granulite facies continental collision zone

FUMIKO HIGASHINO[1*], TETSUO KAWAKAMI[1], M. SATISH-KUMAR[2], MASAHIRO ISHIKAWA[3], KENSHI MAKI[1], NORIYOSHI TSUCHIYA[4], GEOFF GRANTHAM[5], AND TAKAFUMI HIRATA[1]

[1]Department of Geology and Mineralogy, Kyoto University, Kyoto, Japan, fumitan@kueps.kyoto-u.ac.jp (* presenting author).
[2]Shizuoka University, Shizuoka, Japan
[3]Yokohama National University, Yokohama, Japan
[4]Tohoku University, Sendai, Japan
[5]Council for Geoscience, Pretoria, South Africa

In the granulite facies rocks, CO_2-rich fluid has been considered important and studies on Cl-rich fluid are not sufficiently available, because Cl-rich fluid inclusions are less observed than CO_2-rich ones. However, Cl-bearing brines are increasingly recognized as playing an important role in high-*T* metamorphic rocks [1]. Using Cl concentration of minerals, it is possible to decipher the Cl-rich fluid activity and its role during metamorphism.

We have investigated the field distribution of Cl-rich Bt in the pelitic gneisses of the Sør Rondane Mountains, East Antarctica where Late Proterozoic to Cambrian granulites are widely exposed [2]. Among more than 20 samples studied, a Grt-Bt-Sil gneiss from Balchenfjella was selected as best suited sample to constrain the *P-T-t* condition of Cl-rich fluid activity. This gneiss contains Grt porphyroblasts (5-10 mm) that have P-rich core with oscillatory zoning in P. The Grt core includes Cl-poor Bt and Ap. This core is once resorbed and discontinuously overgrown by the P-poor rim, in which Cl-rich Bt and Ap are included. Coarse-grained (ca. 100 μm), round Zrn grains are exclusively included in the rim of the Grt porphyroblast and present in the matrix. This mode of occurrence suggests that Cl-rich Bt and Ap, and coarse Zrn were formed almost simultaneously. The *P-T* conditions of the Cl-rich Bt entrapment in the Grt rim were estimated to be ca. 800 ºC and 8 kbar, and those of the peak metamorphic condition were ca. 850 ºC and 11 kbar, using Grt-Bt geothermometer and GASP geobarometer [3]. The f_{HCl}/f_{H2O} ratio of the fluid in equilibrium with Cl-rich Bt [4] and Ap [5] in the Grt rim are ten times larger than that in equilibrium with Cl-poor Bt and Ap in the matrix and the Grt core. The LA-ICPMS U-Pb dating of the coarse Zrn gave $^{206}Pb/^{238}U$ age of ca. 600 Ma. Therefore, the Cl-rich fluid infiltration took place at near metamorphic peak condition of ca. 800 ºC and 8 kbar at ca. 600 Ma.

The field distribution of Cl-rich fluid activity is somewhat linear. Some of them are located near the ductile shear zones [6], and suggesting its relation to high-strain zones [e.g. 7]. Regional distribution of near-peak metamorphic Cl-rich fluid activity in the Sør Rondane Mountains implies that it is one of the major phenomenon in the continental collision processes.

Cenozoic seawater chemistry – insights from Mg isotopes in pelagic carbonate sediments and pore-fluids

JOHN A HIGGINS[1] AND DANIEL P SCHRAG[2]

[1]Princeton University, Princeton, NJ, jahiggin@princeton.edu*
[2]Harvard University, Cambridge, MA

10b. Seawater chemistry changes through time

Large changes in seawater chemistry accompanied a decline in atmospheric CO_2 and cooling of Earth's climate over the Cenozoic. Sources and sinks of magnesium in seawater have distinct isotopic compositions, making the magnesium isotopic composition of seawater a tracer of the processes that control seawater chemistry [1]. Here we present Mg isotope data from both pore-fluids and pelagic carbonate sediments from ODP sites 1265 and 807A in the Atlantic and Pacific ocean basins, resepecitvely. Pore-fluid profiles of Mg and Ca in deep-sea carbonate sediments can be explained to first order by the recrystallization of biogenic carbonate and changes in Cenozoic seawater Mg and Ca. Our results are consistent with a substantial (>10 mmol) increase in seawater Mg over the Neogene, approximately balanced by a similar decline in seawater Ca. Magnesium isotope ratios measured in pelagic carbonates and corrected for re-crystallization vary systematically: peaking in the Paleogene, declining by ~0.4‰ to the Oligocene-Miocene boundary and remaining approximately constant from the Miocene to the present. Using a numerical model of global geochemical cycles (C, Mg, Ca, alkalinity), we explore mechanisms for changing seawater Mg and Ca and discuss implications for carbon cycling during the Neogene.

Arsenic speciation and stable isotope chemistry in an arsenic contaminant plume at a landfill site

BRENDAN HILDUM[1*], RUDOLPH HON[1], SHAKIB AHMED[1]

[1]Department of Earth and Environmental Sciences, Boston College, Chestnut Hill, MA, USA, Hildum@bc.edu ([*]presenting author)

A groundwater plume beneath a capped landfill in North-Central Massachusetts contains dissolved arsenic concentrations exceeding 15,000 ppb in some locations. Disposal of solid wastes at the landfill spanned nearly a century with little documentation of the material disposed. The source(s), fate, and transport of arsenic in the landfill aquifer have been studied extensively; however site characterization has yet to be fully defined. The primary source of the arsenic is not believed to be directly from the landfill based on several lines of evidence, including naturally derived arsenic mobilization due to reducing conditions created by in-situ bioremediation at a nearby airfield (less than 0.5 miles), the existence of extremely high arsenic concentrations in sediment (8,500 ppm) in the bordering marshland, and prior studies performed at the site including arsenic leachate potential from landfill and aquifer materials [1]. Potential natural sources include a layer of peat located beneath the landfill believed to be a part of a historic marshland, previously insoluble iron hydroxides within the glacial sands, and/or bedrock due to oxidation of sulfides containing arsenic.

Arsenic species, including inorganic As(III) and As(V) as well as organic monomethyl arsenic acid (MMA) and dimethyl arsenic acid (DMA), along with groundwater parameters such as pH and redox conditions may provide information as to where the arsenic is primarily originating from and how it is transported through the aquifer. Furthermore, the analysis of stable isotopic ratios of groundwater from different zones of the landfill with varying arsenic concentrations will aid in the delineation of probable arsenic sources, the mobilization processes, and arsenic transport modes within the aquifer. The role of strong redox gradients and the various redox ladder reactions involving water are likely to create characteristic isotopic signatures which might lead to a better understanding of biogeochemical processes within and beneath the landfill waste pile and also assist with future remidiation of the aquifer.

FORAMINIFERAL ISOTOPES IN THE SEA-ICE ENVIRONMENT

CLAUDE HILLAIRE-MARCEL[1]* AND ANNE DE VERNAL[2]

[1] GEOTOP-UQAM, Montréal, Canada, chm@uqam.ca

[2]GEOTOP-UQAM, Montréal, Canada, devernal.anne@uqam.ca

The only abundant planktic foraminifer in cold environments, *Neogloboquadrina pachyderma* left coiled (Np), is generally seen as a deep dwelling species forming its shell along the pycnocline. This may be true in the North Atlantic Ocean but can be challenged in the Arctic Ocean and sea-ice environment in general. Np occurs in sea-ice brine bubbles, especially near the base of the ice characterized by higher temperature and food availability [1]. It also occurs in cold and shallow waters where salinity is ≥34 and/or potential density ≥27.25 [2]. In sea-ice environment, Np-$\delta^{18}O$ often shows negative offset vs. isotopic equilibrium for calcite precipitated at mid-pycnocline depth. In the Arctic Ocean, the offset ranges –1 to –3‰ in the Western Arctic and there is a negative size-dependent isotopic gradient between light/small and heavy/large shells, which is opposite to what is observed in subarctic seas [3-5]. In sea ice, freezing of low $\delta^{18}O$ sea-surface waters produces isotopically-light brines that either concentrate in the sea-ice itself or sink deeper in the water column. *In vitro* experiments by Spindler [1] have shown that formation of new Np-shell chambers still occur in salinities of up to 58. A simple Rayleigh distillation equation governs the ^{18}O-content of brines. From a mean Arctic surface water (S ~ 30; $\delta^{18}O_{WATER}$ ~ -1‰ vs. VSMOW), brines with salinity of 34-58 and temperature of -2 to -3.5°C [6] have $\delta^{18}O$ ranging - 0.2 to -1.5‰, which may thus account for large Np isotopic offset. The brines sinking in the water column may partly accumulate along the pycnocline with the underlying saltier and warmer North Atlantic water carrying Np-tests and alive specimens. When dominant, Np is by itself a good indicator of polar water and sea-ice. When isotopic offsets vs. equilibrium increase, a longer seasonal duration of sea-ice cover may be inferred. A proxy calibration is not totally out of reach, but remains difficult because of highly variable conditions within sea-ice environment. In any case, the specific adaptation of Np to sea-ice has to be taken into account for the interpretations of paleo-records. It results in unreliable stratigraphy of $\delta^{18}O_{Np}$ -records from deep-Arctic cores [7] whereas the large amplitude shifts towards exceptionally light $\delta^{18}O_{Np}$-values, which accompanied Np abundance peaks in the glacial North Atlantic, are more likely a response to the spreading of sea-ice rather than the direct impact of glacial ice meltwater on salinity [8].

He-CO_2-N_2 systematics of the Tengchong Geothermal Province, SW China: Degassing along a plate boundary

DAVID R. HILTON[1*], ZHENGFU GUO[2], PETER H. BARRY[1], M. ZHANG[2], Z. CHENG[2]

[1]Scripps Institution of Oceanography, La Jolla, California, USA 92093-0244, drhilton@ucsd.edu (* presenting author).
[2] Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences (CAS), 100029, Beijing, China.

The Tengchong Geothermal Province (TGP) is located on the northeast edge of the Indian-Eurasian plate collision zone, immediately east of the region of low-angle subduction of the Indian plate beneath the Burma microplate. It lies within the Gaoligong fold belt of the Tibetan-Yunnan fold system, between Myitkyina and the Nujiang suture. The TGP is characterized by recent volcanism, geothermal activity, and frequent earthquakes. Seismic evidence suggests that (a) faults in the region extend to the lower crust, with the Tengchong fault penetrating the Moho, and (b) melt in the region is generated in the upper mantle [1]. We aim to determine the volatile systematics of this shear zone by sampling thermal waters and geothermal gases along the Tengchong fault zone and in the nearby Kunming Province. Through analysis of He, C, and N (relative abundances and isotopic compositions) we consider the distribution of magmatic inputs to the volatile inventory, spatial controls on the degassing fluxes, and provenance characteristics of the volatiles.

We report new results from 16 geothermal gas and thermal water locations: 12 along a N-S transect within the Tengchong Block and 4 on the Eurasian plate in the Dali and Kunming areas. In the Tengchong Block, He isotope ($^3He/^4He$) ratios vary between 0.2 and 5 R_A (where R_A is the $^3He/^4He$ value of air), indicating a mixture between mantle (8 ± 1 R_A) and crustal (0.1–0.01 R_A) sources. Carbon isotope ($\delta^{13}C$) values of CO_2 range from -12.2 to -2.8 ‰ (vs. VPDB). $CO_2/^3He$ ratios range from 1.2×10^9 to 5.4×10^{12} with the majority of values falling between 10-100 times greater than the MORB value ($\sim2\times10^9$). Nitrogen isotope ($\delta^{15}N$) values of N_2 range from -2.1 to +5.8 ‰ (vs. air), but the majority are > 0 ‰, consistent with a crustal source. In contrast, Eurasian plate samples are dominated by radiogenic helium and $^3He/^4He$ does not exceed 0.6 R_A. In addition, $\delta^{15}N$ varies from +0.7 to +8.2 ‰, $CO_2/^3He$ ranges from 8×10^8 to 5.4×10^{12}, and $\delta^{13}C$ values range from +0.52 to -14.5 ‰.

The contrast in $^3He/^4He$ ratios between Tengchong and the Eurasian plate indicates that regional mantle degassing is narrowly focused on the Tengchong shear zone. Based on a ternary mixing model, CO_2 provenance is highly variable within the Tengchong Block, with contributions from mantle-derived CO_2, and crustal limestone and organic matter. Most samples have less than 10% mantle contribution, but mantle CO_2 exceeds 60% at two localities. The results are consistent with magma in the crust being derived from the upper mantle - in agreement with seismic evidence - we find no evidence for the presence of a slab-influenced mantle wedge. Thus, deep faulting in the Tibetan-Yunnan fold system must sustain sufficiently high crustal permeability to allow mantle volatiles to degas via the TGP. The results add to a growing body of evidence that strike-slip plate boundaries (e.g., San Andreas Fault and the North Anatolian Fault) represent important pathways for mantle volatile loss although, to date, their relative contributions to the total degassing budget remains unknown.

Climatic and geomorphic controls on the erosion of carbon from mountain forest: Implications for Earth's thermostat

ROBERT. G. HILTON[1*], ALBERT GALY[2], NIELS HOVIUS[2], SHUH-JI KAO[3], MING-JAME HORNG[4], HONGEY CHEN[5]

[1]Department of Geography, Durham University, Durham, UK, r.g.hilton@durham.ac.uk (* presenting author)

[5]Department of Geoscience, National Taiwan University, Taipei, Taiwan, hchen@ntu.edu.tw

Erosion of particulate organic carbon (POC) occurs at very high rates in mountain river catchments, yet the proportion derived recently from atmospheric CO_2 in the terrestrial biosphere ($POC_{biomass}$) remains poorly constrained. In these settings, export of $POC_{biomass}$ with large amounts of clastic sediment can drive geological CO_2 sequestration [1]. However, erosion can also mobilise fossil POC from bedrocks (POC_{fossil}) and this needs to be quantified. Here we examine the fluvial transport of $POC_{biomass}$ in suspended sediments of mountain rivers in Taiwan and assess the extent to which climatic and tectonic boundary conditions drive carbon transfer from atmosphere to lithosphere.

In 11 major river catchments in Taiwan, we have previously corrected for POC_{fossil} input using N/C, $\delta^{13}C$ and $\Delta^{14}C$ [2]. Here, $POC_{biomass}$ measurements are combined with water discharge (Q_w, $m^3\ s^{-1}$) and suspended sediment concentration (mg L^{-1}) over 2 years, with samples from flows between 0.1 and 20 times the long-term mean Q_w. In these catchments, $POC_{biomass}$ concentration (mg L^{-1}) was positively correlated with Q_w, with enhanced loads at high flow attributed to rainfall driven supply of $POC_{biomass}$ from forested hillslopes. This climatic control on $POC_{biomass}$ transport was moderated by catchment geomorphology: the gradient of a linear relation of $POC_{biomass}$ concentration and Q_w increased as the proportion of steep hillslopes (> 35°) in the catchment increased. The data suggest enhanced supply of $POC_{biomass}$ by erosion processes which act most efficiently on the steepest sections of forest.

Across Taiwan, $POC_{biomass}$ yield was correlated with suspended sediment yield, and did not limit at high physical erosion rates. Our data demonstrate that, for a constant set of geomorphic conditions, the fluvial transfer of $POC_{biomass}$ from mountain catchments is driven by climate through the activation of erosion and transport processes during heavy rainfall. A move to a wetter, stormier climate should enhance the erosional export of $POC_{biomass}$. In settings with strong coupling between depositional sinks and terrestrial inputs this offers a feedback in the Earth System, whereby climate can modify rates of CO_2 sequestration through erosion and burial of $POC_{biomass}$ [1,3].

Stable calcium isotope fractionation in basaltic catchments (Iceland)

R. S. HINDSHAW[1,2*], B. C. REYNOLDS[1], K. W. BURTON[3] AND B. BOURDON[4]

[1]IGP, ETH Zurich, Zurich, Switzerland, ruth.hindshaw@ngu.no (* presenting author)
[2]NGU, Trondheim, Norway
[3]Durham University, Durham, UK
[4]LGL, ENS Lyon, CNRS and UCBL, Lyon, France

Calcium (Ca) isotope studies of river water have potential to reveal information about biogeochemical processes affecting calcium, one of the most abundant elements in the Earth's crust. In this study, river water samples were taken from twenty-five different rivers draining basaltic lithology in Iceland. Previous studies in this region have shown that 1) calcium containing secondary phases are prevalent in these catchments [1] and 2) there are clear differences in weathering regime between different parts of the island [e.g. 2]. The aim of this study was to investigate whether the aforementioned factors would impact on the calcium isotopic composition of river water, and thus help develop the use of Ca isotopes as a viable tracer of catchment scale biogeochemical processes.

Calcium isotopic compositions were measured by TIMS, after chemical purification, using a ^{43}Ca-^{46}Ca double-spike. The measured water samples span a range of 0.22‰ in $\delta^{44/42}$Ca (0.45‰ – 0.67 ‰), with rivers draining glaciated catchments tending to have higher $\delta^{44/42}$Ca values than rivers unaffected by present-day glaciation. An ice-melt sample, representing precipitation inputs, and a hydrothermal sample were also measured.

The Ca isotopic composition of river water samples draining un-glaciated catchments was consistent with a mixture of the basaltic rock isotopic composition ($\delta^{44/42}$Ca = 0.41‰) and precipitation, which is characterised by a seawater Ca isotopic composition ($\delta^{44/42}$Ca = 0.95‰). Mixing between rock and precipitation sources for divalent cations was corroborated by radiogenic strontium measurements.

Calcium isotopic compositions from rivers draining glaciated catchments could not be explained by mixing of known sources and it is probable that isotope fractionation processes affect the Ca isotopic compositions of these rivers. The water samples from the presently glaciated samples fitted a simple Rayleigh distillation model, consistent with isotope fractionation during the removal of Ca from the dissolved phase by the formation of secondary minerals.

This study demonstrates that in Iceland 1) differences in riverine Ca isotopic values may simply reflect differences in precipitation volume and 2) glaciation significantly affects the weathering regime, resulting in different controls on Ca isotopic compositions, as compared to unglaciated terrain.

Interaction of Fe(II) with phosphate and sulfate on iron oxide surfaces: Implications for interfacial electron transfer

MARGARET ANNE G. HINKLE[1*] AND JEFFREY G. CATALANO[1]

[1]Washington University in St. Louis, Earth and Planetary Sciences, St. Louis, USA, (*correspondence: mhinkle@eps.wustl.edu)

Adsorption and coprecipitation reactions on iron oxide surfaces exert considerable controls on trace element and oxoanion concentrations in soil and aquatic environments [1]. Biogeochemical cycling of iron by microorganisms, involving the reductive dissolution and oxidative precipitation of iron oxides, activates interfacial electron transfer and atom exchange (ET-AE) reactions between aqueous Fe(II) and solid Fe(III) oxide minerals, causing mineral recrystallization [2,3]. This dynamic recrystallization of iron oxide minerals causes the incorporation of divalent metal adsorbates into the mineral and the release of preincorporated divalent metal ions to solution [4,5]. However, the effect of ET-AE reactions on the behavior of structurally incompatible oxoanions is not well understood. Recent research has shown that Fe(II) does not signficantly affect arsenate adsorption mechanisms, yet Fe(II) adsorption is suppressed in the presence of arsenate through competative adsorption processes [6]. This indicates that oxoanion adsorption can affect as well as be affected by ET-AE interactions between aqueous Fe(II) and Fe(III) oxides.

Here we consider the effect of aqueous Fe(II) on phosphate and sulfate adsorption onto hematite and goethite, and the effect of phosphate and sulfate on Fe(II) adsorption. We observe that the pH dependent adsorption of Fe(II) onto hematite and goethite slightly increases in the presence of phosphate and sulfate. The effect of phosphate and sulfate on Fe(II) adsorption, probed by metal release from doped iron oxides reacted with Fe(II) and oxoanions, will also be presented. We find that sulfate and phosphate adsorption also increases with the addition of Fe(II). If the observed adsorption behavior is the result of electrostatic effects, ET-AE reactions may be promoted. However, if the behavior is due to ternary complexation then ET-AE reactions may be suppressed because such complexes may stabilize adsorbed Fe(II) or inhibit electron transfer to the surface. The effect of Fe(II) on oxoanion adsorption mechanisms, determined by ATR-FTIR spectroscopy, will also be discussed. This work will further clarify the interactions between iron oxide minerals and common aqueous species in regions with active biogeochemical iron cycling.

New results from metamorphic nucleation experiments

DAVID M. HIRSCH[1*], CRAIG E. MANNING[2]

[1]Western Washington University, Bellingham, WA USA, hirschd@geol.wwu.edu (* presenting author)

[2]University of California Los Angeles, Los Angeles, CA USA, manning@ess.ucla.edu

Introduction

The rates and mechanisms of metamorphic crystallization remain poorly understood despite decades of study. In particular, nucleation processes such as the relationship of nucleation rate to driving force have proven difficult to quantify. Nucleation theory predicts that the nucleation rate can be expressed as:

$$\frac{dN}{dt} = C_1 \exp\left(\frac{-C_2}{T\Delta G_{rxn}^2}\right) \quad (1)$$

where N is the number of nuclei per unit volume, T is the absolute temperature, ΔG_{rxn} is the Gibbs free energy of the chemical reaction, and C_1 and C_2 are constants, which can be related to other, less well-constrained properties of the system [1]. However, this theory has not been adquately tested against geological data.

Experimental Method

We have undertaken a experimental pilot project to model nucleation, focusing on the reaction An + Wo = Grs + Qtz from an initial assemblage An+Wo+Qtz. This reaction is simple enough to make the experiments tractable, yet retains key basic features of reactions studied by others working on crystallization kinetics: aluminous garnet is the nucleating phase and the reaction involves multiple reactants and products. In order to remove temperature as a variable, all experiments are performed at constant temperature (1100 °C), and nucleation is initiated by a change in pressure only (1.41-1.90 GPa). Stereological methods were used to determine 3D nucleation counts.

Results

The experiments successfully nucleated grossular in runs within its stability field. Nucleation rates are generally replicable from run to run. Our preliminary results show that there is a systematic relationship between nucleation rate and driving force. By fitting equation (1) to the data, values for the constants are estimated at C_1=8.9 x 10^6 and C_2=2.0 x 10^4 (Fig. 1). The results support the theoretical prediction of a sharp increase in nucleation rate with driving force.

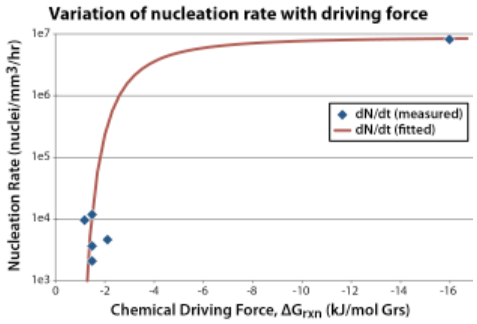

Figure 1: Nucleation rate as a function of thermodynamic driving force.

Magma ocean influence on early atmosphere composition and mass

MARC M. HIRSCHMANN[1*] , HONGLUO ZHANG[1]

[1]Dept. Earth Sci. U. Minneosta Minneapolis, MN USA mmh@umn.edu (*presenting author)

The composition and mass of the atmosphere overlying early terrestrial magma oceans (MOs) likely had a key influence on Earth's early thermal and dynamical evolution, its geochemical differentiation, its path to an equable climate, and development of prebiotic chemistry. It also set the initial conditions for development of deep Earth volatile cycles. Key questions are how MO processes partitions volatiles between the atmosphere, mantle, and core and how reaction between the the MO and overlying vapor influences the composition of the nascent atmosphere.

The availability of Fe alloy in a MO creates reducing conditions, and the expectation that overlying atmospheres consist chiefly of H_2 and CO, but this may be incorrect if the mean depth of alloy-silicate equilibration is deep, if convection in the MO homogenizes Fe^{3+}/Fe^T throughout the magma column, and if the effect of decreased pressure on the chemical potentials of Fe^{2+} and Fe^{3+} in the magma increases relative f_{O2}. Low pressure data [1,2] suggest the opposite – decreases in Δf_{O2} on isochemical decompression – but Mössbauer spectroscopy of andesite glasses quenched from 1-6 GPa provisionally indicate that this relationship reverses at high pressure. Consequently, it is likely that the overlying atmosphere consisted chiefly of H_2O+CO_2, whilst reducing (~IW-1.5) conditions prevailed deep in the MO.

Owing to low solubility of C-species in reduced magma, virtually all of the available C in the MO and the atmosphere may be partitioned into alloy, leaving a virtually C- free mantle and exosphere. However, it is likely that the MO equilibrates with only a small fraction of metal (<5% **[3]** and possibly <1%). As the alloy cannot absorb ~ 8 wt.% C, excess reduced C may saturate as diamond. This too will greatly limit the partial pressure of CO_2 in the overlying atmosphere. Floatation of diamond in the MO **[4]** and could create the principle initial reservoir of C in the BSE.

Following or coinciding with segregation of metal (but not diamond) to the core, the Moon-forming impact resets the volatile distribution in the BSE: virtually all that did not escape ends up in a superheated atmosphere. On cooling, much of the remaining H_2O and some of the CO_2 redissolves in the MO. Upon MO crystallization, much of the H_2O and possibly nearly all the the C returns atmosphere. However, homogenization of Fe^{3+}/Fe^T in the MO should again produce a vertical f_{O2} gradient in the MO and the solubility of CO_2 diminishes by >10X on cooling from a MO adiabat to the peridotite solidus. Thus, precipitation of a C-rich phase (diamond, carbide, or alloy) during crystallization of this final MO is likely, setting up conditions for a MO carbon pump [5] that draws down much of the CO_2 in the atmosphere and deposits much of the BSE C in the mantle rather than the exosphere. This speculative, but plausible, scenario may produce a mantle with a high H/C ratio compared to the exposphere, as remains true at present [6].

Diffusion in the deep Earth: Is it all about grain boundaries?

MATT HISCOCK[1]*, GEOFFREY BROMILEY[1] AND EIMF[2]

[1]Grant Institute of GeoSciences, University of Edinburgh, Edinburgh, UK, Matt.Hiscock@ed.ac.uk (* presenting author)
[2]Edinburgh Ion Microprobe Facility, University of Edinburgh, Edinburgh, UK, ionprobe@ed.ac.uk

We can consider two mechanisms by which diffusion can occur in Earth's deep interior: 1) through mineral lattices: lattice diffusion or 2) along the boundaries between grains: grain boundary diffusion. To date very little work has been conducted on grain boundary diffusion of volatiles under mantle conditions. Here we present recently acquired experimental data obtained using a novel method to determine grain boundary diffusion rates under mantle conditions, initially looking at hydrogen. The data is considered in terms of the mobility of hydrogen in the mantle and how an understanding of this can help to constrain the influence it has on bulk mantle properties. Preliminary results suggest that grain boundary diffusion rates may be of similar magnitude to diffusion through crystal structures, suggesting that very small diffusing species are indiscriminate towards their surroundings/host (mineral lattice versus grain boundary).

Further data is presented on a complimentary study of diffusion of titanium in quartz. Single crystal diffusion rates for Ti in quartz are very slow, potentially acting as a limiting factor for Ti abundance in crystallising quartz – with implications for the applicability of Ti in quartz thermometry.

Tuning the interactions of PNIPAM Gel Nanoparticles

REX P. HJELM*[1], LISE ARLETH[2], ZHIBING HU[3], JIANZHONG WU.[4]

[1]Los Alamos Neutron Science Center, Los Alamos National Laboratory, Los Alamos, New Mexico, 87544 USA, hjelm@lanl.gov.

[4]Department of Chemical and Envronmental Engineering, University of California, Riverside, California, 92521, USA. Jianzhong.wu@ucr.edu

The presence of a lower critical solution temperature (LCST) at 33C in PNIPAM gels is well known. Above the LCST the gel in water collapses from a solvent swollen state. Previously, we syntesized and studied the properties of 5 nm PNIPAM gel nanoparticles [1]. The size of these particles allowed us to characterizae the ttemperature-dependent changes in the particle interactons using light scattering and small-angle neutron scattering (SANS) with the unanticipated result that the interactions go from highly repulsive to attractive as the temperature is increased above the LCST. The magnitude of the repulsive interaction was larger than that anticipated for hard sphere excluded volume effects.

With the aim of understanding the interaction potential of these PNIPAM gel nanoparticles and the relation to the LCST, we studied the concentration and temperature-dependent phase map, using SANS to probe the structures of the fluid, crystalline and glassy phases. Concentration is used to explore the distance dependency of the interaction potential, while temperature is used to tune this potential through the repulsive to attractive states. The overall goal of this work is to understand the underlying phaysics of these and like materials for the development of environmentally responsive systems.

Stable carbon and nitrogen isotopic variations in latest Pleistocene to Holocene organic matter from Lake Ontario, Canada

RYAN HLADYNIUK[1*] AND FRED J. LONGSTAFFE[1]

[1]The University of Western Ontario, London, Canada, rhladyni@uwo.ca (* presenting author), flongsta@uwo.ca

We have examined the variations in organic carbon (OC) and nitrogen (TN) contents, C/N ratios (7-10) and stable carbon and nitrogen isotopic compositions of bulk organic matter (OM) from Lake Ontario (the easternmost Great Lake) since 12.3 ka BP. Samples were obtained from three piston cores that contain sediments from each of Lake Ontario's major sub-basins. These data indicate low primary productivity during glacial times (12.3-10.8 ka BP), consistent with the cold and dry period proposed for this region by Lewis et al. (2008) [1]. That said, the carbon isotopic compositions of OM in glacial sediments display different upward variations in cores from west to east across the Lake Ontario sub-basins: Niagara sub-basin (west), an increase from -29 to -27 per mil (VPDB); Mississauga sub-basin (central), a decrease from -27 to -28.5 per mil (VPDB); Rochester sub-basin (east), an increase from -28 to -27 per mil (VPDB). These differences likely arise from greater contributions of terrestrial OM both in the west and the east as glacial meltwater entered the lake via the Niagara River (west) and directly from the Laurentide Ice Sheet (east). A short-lived influx of glacial meltwater from 10.8-10.5 ka BP is indicated by increased mass accumulation rates (MARs) during this interval of time. Upon cessation of glacial meltwater supply at 10.5 ka BP, the carbon-isotope composition of Lake Ontario OM decreased to -29.5 per mil across the basin. With hydraulic closure of Lake Ontario during the early Holocene, rising lacustrine productivity is indicated by progressively increasing OC and TN concentrations and OM carbon- and nitrogen-isotope compositions. Return of upper Great Lakes water to Lake Ontario during the region's Nipissing Rise at 5.0 ka BP correlates well with a temporary lowering of primary productivity in Lake Ontario. This decrease is followed shortly thereafter by a return to increasing OC, TN and OM carbon- and nitrogen-isotope compositions as modern Lake Ontario emerged. This history of lacustrine productivity for Lake Ontario is similar to that reported for Lake Superior [2], the deepest and largest of the Laurentian Great Lakes. Such comparisons may facilitate future regional synthesis of primary productivity in the Great Lakes during their changing histories from the latest Pleistocene to the present.

W is one of the most widely used and poorly understood elements today [1][2]. A lack of knowledge about its biogeochemistry coupled with its unique and advantageous properties have led to an explosion of W based products for domestic, military, and ind ustrial applications [1]. Recently W has come under scrutiny following a CDC investigation of a leukemia cluster in Fallon, Nevada which implicated high levels of W in the drinking water as a probable cause [1][2]. Besides W's potential health hazards, recent studies have shown that the WO_4^{2-} oxyanion is soluble in water, capable of moving through soils. Also, dissolution of W metal leads to decreases in bacterial biomass in soils and increases in fungal biomass, also having adverse effects on plant life [2][3][4].

The hypothesis to be tested is that the physical and chemical changes from chemical weathering, mineral dissolution and precipitation, and/or redox reactions catalyzed by microbial activity control W transport and sequestration. These parameters control W by means of adsorptive/desorptive reactions, reductive/oxidative mineral dissolution or aqueous complexation with sulfide. Three sites have been chosen for geochemical and mineralogical analysis; two sites of high W concentrations (Fallon and Hoisington, KS) and one site of low concentration (Carrizo aquifer, Texas). Surface samples from within the town of Fallon and in-lake sediments from Cheyenne Bottoms Refuge in Hoisington have both shown high levels of W. The first step used in understanding the W-sediment association is x-ray microprobe aided speciation and bulk XANES, utilizing synchrotron radiation. This is done with μXRF mapping accompanied by μXANES and μXRD on mineral/sediment grains and also elucidates the association of W with other elements (Ca, Fe, Mn, Fe, As, Cu, Mo, Ti, Zn). Sediment samples from Fallon were analyzed for bulk W speciation, and the data showed predominately W-VI, though the presence of minor shoulders in the spectra may indicate the presence of other species. The μXRF map revealed that the highest density of W hotspots was in samples nearest the hard-metal facility, and good correlations were found with Fe. Sequential extractions are also being done to understand the partitioning of sediment fractions and preference of W to bind with variuos fractions.

Weathering phenomena involving mineral nanoparticles, one of the last unexplored geochemical components in soils and sediments: A tribute to Art White

MICHAEL F. HOCHELLA, JR.

Department of Geosciences, Virginia Tech, Blacksburg, VA, USA, hochella@vt.edu.

Art White has made a difference in how we understand Earth. He has been a geochemist in the mold of Victor Goldschmidt in terms of a lifetime of deeply insightful thinking, and in Art's case, he has been a masterful unraveler of the critical zone. Remarkably, some of his experiments have lasted more than a decade. He is one of the best in the world at interpreting soil chronosequences, and is also a world authority on linking field- vs. laboratory-based weathering rates. In my career, he was the first to convince me that seemingly hopelessy complicated Earth systems could be untangled and in fact understood.

Recently, we have realized that the field of nanoscience is important in weathering phenomena. Worldwide, soils blanketing the continents contain an estimated 10^7 to 10^8 terragrams (Tg = one million metric tons) of mineral nanoparticles, with roughly 10^3 to 10^4 Tg being transported to the continental margins annually via rivers. Nanoscience comes into play because experimental and theoretical evidence suggests that dissolution rate is a function of particle size in the nanoscale. Although quite difficult to measure, to date accelerated dissolution rates are associated with smaller nanoparticle sizes for silica, iron oxides/hydroxides, titanium dioxide, zinc oxide, and lead sulfide, and nanothin clay edges dissolve much faster than basel surfaces. However, this is not the case for all minerals. Calcium phosphate minerals, in particular, may experience a dramatic retardation of dissolution rates at the nanoscale relative to larger crystals. This may be because there is a critical particle radius required for the formation of etch pits on these phosphates.

More recently, it has been clearly verified that there are other factors besides size that dramatically affect the dissolution rates of mineral nanoparticles. For example, the exact aggregation state is key: in tightly aggregated clusters, where water is reduced to nanofilms that we can now directly observe, dissolution rates can be reduced by orders of magnitude, essentially quenching the overall reaction per surface area available. In other words, even the fluids in this case are presenting dramatically different properties than in the bulk state, again the hallmark of nanoscience. Examples of mineral nanoparticles where this has been shown include goethtite, lead sulfide, and zinc oxide. In addition, we have recently shown that nanotubular voids that intersect the surface of hematite nanoparticles act as highly reactive sites for reductive dissolution driven by organic acids. So again, acceleation and inhibition of dissolution can be dramatically manifested in different nanofeatures of nanoparticles.

Such minute phenomena can have global consequences. For example, it has recently been realized that phytoplankton (key to CO_2 drawdown from the atmosphere) can acquire one of its vital limiting nutrients, iron, from iron oxide nanoparticles in the oceans that have been shed from the continents. This depends on iron oxide dissolution controlled by some of the factors described above.

Using pore-scale simulations to better quantify mixing and mass transformation in upscaled models

DAVID L. HOCHSTETLER[1*], MASSIMO ROLLE[1,2], PETER K. KITANIDIS[1]

[1]Department of Civil and Environmental Engineering, Stanford University, Stanford, CA , USA

[2]Center for Applied Geosciences, University of Tübingen, Tübingen, Germany

*(presenting author: dhochste@stanford.edu)

We perform pore-scale simulations of different transport scenarios in order to analyze irreversible bimolecular reactive transport with the objectives of: i) finding an empirical relationship that describes the effective kinetic rate constants in upscaled (Darcy scale) models; ii) determining the appropriateness of using intrinsic kinetic rate constants in upscaled models; iii) enhancing understanding of how compound-specific diffusivites affect mass transformation of reactive solutes at the pore-scale; and iv) quantifying the importance of accounting for compound-dependent mixing properties in predicting plume lengths and mass transformation at the Darcy scale. We evaluated transient displacement problems with a range of intrinsic kinetic rates as well as steady-state reactive plumes with a range of flow rates and "fast" and "slow" kinetics.

The results show that an empirical relationship can relate the ratio of the effective rate constant over the intrinsic rate constant to the inverse of the Damköhler; this is similar to what has been found for 1st-order [1] and biofilm [2] reactions. Furthermore, increasing Da does increase the amount of reactant segregation [3] but does not necessarily significantly increase mass overprediction because the reactant transformation may be mostly mixing limited. Thus, using an intrinsic rate constant in an upscaled model resulted in only about 10% overprediction of product mass for our problem set-up [4]. For the steady-state problems, we compare the adequacy of using the traditional linear parameterization for transverse dispersion to using a non-linear compound-specific parameterization [5] to predict reactive transport at the Darcy scale. We quantify the differences for product mass and plume lengths between the pore-scale results and the upscaled predictions using the linear and non-linear transverse dispersion coefficients.

When iron and silver nanoparticles meet natural organic matter: Probing NP-NOM interactions with molecular spectroscopy and quartz crystal microgravimetry

W.C. HOCKADAY[1*] AND B.L.T. LAU[2]

[1*] Baylor Univ., Waco TX 76706 (william_hockaday@baylor.edu)
[2] Baylor Univ., Waco TX 76706 (boris_lau@baylor.edu)

As natural organic matter (NOM) is ubiquitous in natural waters and known to complex with nanoparticle (NP) surfaces, it is important to study NP-NOM dynamics to better understand the fate and transport of NPs. This work combines molecular spectroscopy and quartz crystal microgravimetry (QCM) to determine the mechanisms and kinetics of NOM interaction with the surfaces of NP and silica. Hematite NPs (FeNPs) and silver NPs (AgNPs) were used to represent natural and engineered NPs in this study.

The identity and affinity of NOM on NP surfaces can affect the way NPs behave in aquatic systems. ^{1}H NMR and Raman spectroscopy were used to identify the reactive organic functional groups in Suwanee River NOM and probe the mechanism of covalent and non-covalent bonding. FeNPs was observed to expedite the spin-lattice relaxation time (T_1) of aromatic and heteroatom-substituted aliphatic groups, which suggests a decrease in molecular motion (intra- and inter-molecular) upon interaction with the NPs. Raman spectroscopy was used to probe the interatctions of NOM with AgNPs having a polyvinyl pyrrolidone (PVP) capping agent. Raman spectroscopy suggested that O-substituted alkyl groups in the NOM interacts with both the polyvinyl domain of (PVP) and the oxygen atom of the PVP-capped AgNPs. These spectroscopy results have important implications for the fate of NPs in aqueous suspensions, as NOM may change the stability of NPs.

While NP's interactions with "free" NOM in the bulk solution is critical in predicting their mobility, NP's associations with "immobilized" NOM on mineral or other environmental surfaces are equally important in controlling their transport in natural waters. With high sensitivity (ng/cm^2) to quantify mass deposition on substrate surfaces, QCM was used as a tool in determining the extent and kinetics of NP adsorption in real-time. Preliminary QCM experiments revealed observable differences in the adsorption dynamics of FeNPs and AgNPs on silica substrate when NOM is coated on either the particle surface or substrate surface or both. For example, at pH 6, deposition of FeNPs on silica substrate was found to be at least two order of magnitude slower in the presence of NOM. QCM results also suggested that humic and fulvic fractions of the NOM exert differing degrees of influence on the adsorption of AgNPs.

Mobility of antimony in soils under changing redox conditions

KERSTIN HOCKMANN[1*], SUSAN TANDY[1], MARKUS LENZ[2,3] AND RAINER SCHULIN[1]

[1]Institute of Terrestrial Ecosystems, ETH Zurich, Switzerland, kerstin.hockmann@env.ethz.ch (* presenting author)
[2] University of Applied Sciences and Arts Northwestern Switzerland (FHNW), Institute for Ecopreneurship
[3] Wageningen University, Sub-Department of Environmental Technology, The Netherlands

Human activities have led to highly elevated antimony (Sb) concentrations in many soils and, consequently, to increased exposure of biota to this toxic element. Knowledge about the risks of Sb leaching from such soils is, however, very limited.

A key factor regarding the mobility of Sb in soils is the water regime. Many soils are subject to permanent or periodic water-logging. Under aerobic conditions, Sb is stable as the pentavalent $Sb(OH)_6^-$ in soil solution. Under reducing conditions, the trivalent $Sb(OH)_3$ becomes dominant [1]. Both species strongly differ in their affinity to iron (Fe) and manganese (Mn) (hydr)oxides. The interplay of Sb redox transformations, differential sorption and reductive dissolution of Mn and Fe (hydr)oxides during water-logging and its effect on Sb mobility has received little attention though.

Here, we investigated changes in Sb speciation and solubility over a reduction-reoxidation period in Sb-contaminated shooting range soil (pH 7.8). Lactate was used as carbon source to stimulate microbial activity. Antimony(V) concentrations strongly decreased with the development of reducing conditions (Figure 1), while dissolved Sb(III) concentrations remained low. During further reduction, soluble Sb(III) increased together with dissolved Fe(II) concentrations. Reoxidation of the soil batches caused Sb(III) to decrease and soluble Sb(V) to increase again.

The results indicate that water logging conditions at first led to the immobilization of Sb by reduction of Sb(V) to Sb(III), since the latter has a higher binding affinity to metal hydroxides. When reducing conditions continued, the previously bound Sb(III) was released into the solution again due to reductive dissolution of the (hydr)oxides, resulting in increased mobility.

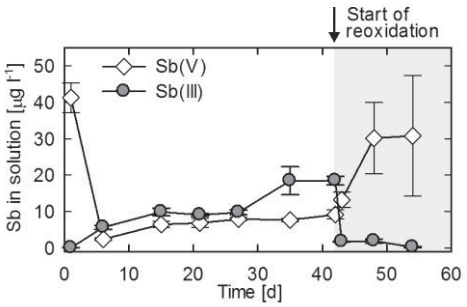

Figure 1: Antimony(III) and Sb(V) concentrations during varying redox conditions. Error bars are the standard deviation of triplicates.

Direct infusion lipidomics: profiling the oil sands microbiome

P. HODGSON*, B. E. MCCARRY

McMaster University, Chemistry and Chemical Biology
hodgspa@mcmaster.ca, (* presenting author),
mccarry@mcmaster.ca

Introduction

Oil sands processing recycles large quantites of water from settling ponds employed to settle out the fine particulate matter end products of bitumen extraction. Settling pond characterization has indicated vibrant microbial communities and thus there is a strong likelihood that at least some portion of this community is present in process water; where their impacts on extraction efficiency and/or settling pond water quality remain unknown. We are applying a comprehensive bacterial lipid profiling method previously developed [1,2] to characterize the bacterial community associated with process water collected prior to discharge into the settling pond in an effort to identify possible microbially linked strategies for improved management and process efficiencies.

Results

Process water samples were treated with organic solvents to extract the non-polar constituents, using a developed method [1,2] capable of detecting profiles of eight lipid classes using direct infusion electrospray mass spectroscopy in a triple quadrupole mass spectrometer. The profiles of individual lipid classes were obtained by infusion of a $CHCl_3$:MeOH solution of the process water extract in the presence of 4mM LiCl; each lipid class is detected using tandem mass spectrometry with a neutral mass loss specific to each phospholipid class. For example, phosphatidylethanolamines (PE) undergo a neutral loss of 147 mass units while phosphatidylcholines lose 189 mass units. The presence of lithium chloride not only affords more intense neutral losses but also simplifies the mass spectrum by affording a single metal ion (Li^+) adduct. By using phospholipid standards it is possible to quantify the intact lipid components in the extracts. This work is being undertaken in concert with phospholipid fatty acid (PLFA) analyses. Results indicate microbial lipids in the process water sample. Phospholipid profiles of this microbial community will be presented.

Overview

Current numerical and analog models predict discrete interactions and feedbacks between tectonic deformation and climate-driven denudation [1]. To test the applicability of these models, we utilize cosmogenic radionuclides (CRN) to quantify basin-scale erosion rates in the Cordillera Blanca Mountain Range (CB) of Northern Peru [2]. The range is an actively deforming, NNW trending massif running from ~8-10°S. The CB is closely associated with pronounced extension along the Cordillera Blanca Detachment Fault (CBDF) that delineates the western margin of the grano-tonalitic batholith. The ~200 km long, NNW trending CBDF accommodates significant crustal scale extension in the heart of the dominantly contractile Andean Orogen [3]. Previous thermochronologic and CRN based studies have outlined the potential for linkages between patterns of long-term (Ma) exhumation/uplift and short-term (ka) rates of fault slip [4,5]. Exhumation data, while sparsely dispributed, suggest elevated rates of uplift from ~4-6 Ma in the central portion of the range relative to the flanks (~0.5 km Ma^{-1} and ~0.2 km Ma^{-1}, respectively). More recent exhumation rates spanning ~2-4 Ma suggest a unform ~0.5 km Ma^{-1} along the entire range. Spatial trends in CRN-based fault slip rates are reminescent of those from 4-6 Ma exhumation rates, and decrease dramatically by an order of magnitude towards the south. Our new CRN dataset fills a crucial gap in the development history of the range, representing landscape modification on the order of 10^3 to 10^5 years in response to both tectonic and climatic variations within the batholith.

Results and Conclusion

Preliminary calculated erosion rates range from 0.0096 to 4.1 mm yr^{-1}. Highest erosion rates are located near the center of the range, correlating with the highest peak elevations and the highest degrees of glacial cover. Spatial patterns follow those of 4-6 Ma exhumation rates and CRN fault slip rates, suggesting a long-lived, tectonic control on range development. Erosion and uplift are likely encanced in basins with higher degrees of glaciation due to isostatic responses to glacial erosion.

Organic matter and Fe oxide coatings reduce the relevance of laboratory rates to mineral dissolution in soil

SAMUEL A. PARRY[1], MARK E. HODSON[1*], SIMON J. KEMP[2], ERIC H. OELKERS[3]

[1]University of Reading, Reading, UK, s.a.parry@pgr.reading.ac.uk, m.e.hodson@reading.ac.uk (* presenting author)
[2]British Geological Survey, Keyworth, UK, sjk@bgs.ac.uk
[3]GET-OMP, Toulouse, France, oelkers@ltmg.obs-mip.fr

The minerals present in a soil and the reactive surface area of those minerals are key factors in determining element release rates from soils due to mineral dissolution. This study examines the contribution and influence of the relatively un-reactive soil organic matter (SOM) and amorphous and free Fe oxide phases to soil surface area and element release from the dissolution of primary silicate minerals within two podzol soil profiles. Soils were sampled systematically with depth (using a coarse-stepped continuous strategy) from granitic podzols directly overlying bedrock in Dartmoor and Glen Dye, UK. The geometric and BET specific surface area and porosity of bulk soil samples were calculated and measured prior to and following the removal of SOM and amorphous and free Fe oxide phases. Batch and flow through dissolution experiments were then performed on the different sample sets.

Bulk soil surface area and porosity decreased overall from the base of the soil profiles to the soil surface, largely due to the loss of relatively reactive primary minerals up the soil profiles and an associated increase in the proportion of residual quartz, the quartz dilution effect [1]. Superimposed over these variations were the contributions and influences of the SOM and amorphous and free Fe oxide phases on soil surface area. SOM aggregated and coated soil mineral grains, increasing the effective diameter of the mineral grains and occluding underlying mineral surfaces and porosity, thus reducing bulk soil surface area. Amorphous and free Fe oxide phases contributed to soil surface area as discrete fine particles and architecturally elaborate and porous surface coatings. They were also present as aggregate binding agents and smooth surface coatings (amorphous only) that occluded mineral surfaces and reduced soil surface area. Podzolisation translocated the SOM, amorphous and free Fe oxide phases down the soil profile and in doing so redistributed un-reactive mineral surface area and porosity between the eluvial and illuvial horizons. This exacerbated the quartz dilution effect between these horizons and resulted in a relative peak in bulk soil surface area in the illuvial horizon.

The presence of SOM, amorphous and free Fe oxide phases typically reduced bulk soil Si release rates through the contribution of unreactive surface area and/or the occlusion of underlying reactive mineral surface area. The exception was the contribution of biogenic silica to reactive soil surface area and Si release rates in the upper soil profile. As a result, pristine mineral laboratory dissolution studies do not account for the influence of SOM, amorphous and free Fe oxide phases reactive surface area in the field environment and thus the derived dissolution rates are not representative of aggregated and coated field grains.

Geochemical Zonation of Mantle Plumes: Lower Mantle Chemical Heterogeneity and Plume Splitting

KAJ HOERNLE [1*], JOANA DEPPE[1], FOLKMAR HAUFF[1], REINHARD WERNER[1], JASON PHIPPS MORGAN[2]

[1] GEOMAR Helmholtz Centre for Ocean Research Kiel, Germany (* presenting author khoernle@geomar.de)
[2] Cornell University, Ithaca, NY, U.S.A.

The geochemistry of basalts from single hotspot tracks contains important clues about the compositional heterogeneity of the Earth's mantle. Increasingly spatial chemical zoning has been recognized as a long-term feature (up to 80 Ma) of hotspot tracks, including the Galapagos [1,2], Hawaii [3,4], Marquesas, Somoa [5] and Tristan-Gough [6] hotspot tracks. It is argued that geochemical zonation of hotspot tracks reflect lateral zonation in the plume stem in the form of stripes or filaments that ultimately reflect tapping of different geochemical reservoirs in the plume source [1,4-9]. An important question is what plume zonation tells us about the plume source in the lower mantle. Seismic tomographic studies show the existence of two large seismic low-velocity anomalies in the lower mantle beneath the southern Pacific and beneath southern and western Africa [e.g.10]. It has been proposed that the zoned plumes are related to the margins of these large-scale low-velocity anomalies and that the orientation of the zoning can provide information about the chemical composition of these lower mantle seismic anomalies [4,5,6]. The talk will discuss problems with this model and how these problems might be resolved. The talk will also explore other implications of zoned plumes, for example, if plume zonation can led to the breakup/splitting of the plume conduit or alternatively if plume-splitting allows us to identify chemical zonation in plumes.

Building Eoarchean crust: the arc tholeiite – TTG connection

J. Elis Hoffmann[1,2*], Carsten Münker[1], Thorsten J. Nagel[2], Tomas Næraa[3,4], Ali Polat[5] and Minik T. Rosing[4]

[1] Institut für Geologie und Mineralogie, Universität zu Köln, Germany (hoffjoel@uni-bonn.de)

[5] University of Windsor, Ontario, Canada

A pertinent issue in Archean research is the genetic relation between the TTG suite and the associated mafic supercrustals. Here we present a coherent model for the geodynamic evolution of the oldest (3.65 to 3.85 Ga) continental crust in southern West Greenland. Within the Isua Supracrustals, tholeiitic and boninite-like metabasalts dominate the sequence, both displaying trace element patterns consistent with a subduction-related origin. This is well demonstrated by correlated trace element variations in Nb/Th, La/Yb, Gd/Yb, Zr/Nb in Isua tholeiites [1]. Boninite-like rocks in Isua are derived from ultradepleted sources with εHf(3720) of up to ca. +12.9 [2], providing for the first time Hf-isotope evidence from the mafic rock record for the preservation of depleted Hadean mantle domains.

Petrological phase equilibria and trace element modeling suggest a close relationship between Isua arc tholeiites and the TTGs [3,4]. Notably, Hf-Nd isotope signatures between the two lithologies overlap in both showing the characteristic decoupling of initial Hf-Nd isotope compositions. Systematically elevated ^{142}Nd anomalies of tholeiites and TTGs [5] are also in agreement with a related origin. The decoupled Hf-Nd signature is likely an inherited feature from melting of the tholeiites. This is also underlined by new Hf and O in zircon data from Eoarchean TTGs [6] that indicate melting of a thickened mafic crust to form the TTGs. We therefore propose an arc-arc collisional setting, where the TTGs formed by polybaric melting of arc tholeiites at 10-20% of partial melting.

The cause for the decoupling of the Hf and Nd isotope systems is most likely a subduction-related mantle source overprint. Cumulate segregation processes in an early magma ocean or an early metamorphic overprint during intrusion of the TTGs might be alternative scenarios, but they cannot account for all trace element characteristics found in mafic rocks from the Isua region [1].

Holocene intermediate water circulation at the Carolina Slope from sedimentary ^{231}Pa/^{230}Th

Sharon S. Hoffmann [1*], Jerry F. McManus[1]

[1]Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, USA, sharonh@ldeo.columbia.edu (* presenting author), jmcmanus@ldeo.columbia.edu

Meridional overturning circulation (MOC) may play a crucial role in global climate change both at Milankovich and abrupt timescales, making it an important target for paleoceanographic study. Measured ratios of ^{231}Pa/^{230}Th in sediment cores are sensitive to deep and intermediate water residence times, and may provide a dynamical tracer of past MOC strength in the waters overlying core sites. We will present a new ^{231}Pa/^{230}Th record from core KN140-2-51GGC on the Carolina continental slope at 1790 m. This core has an expanded Holocene section [1], allowing for detailed examination of circulation during the 8.2 ka event, resumption of Labrador Sea Water Production, mid-Holocene climate optimum, and cooler late Holocene.

Previous records of Holocene ^{231}Pa/^{230}Th at intermediate depths show no net ^{231}Pa transport [2] (sedimentary ratios at the seawater production ratio of 0.093) or a transition from low ratios in the erly Holocene to production-ratio levels in the mid-to-late Holocene [3]. Sedimentary ratios similar to the production ratio may suggest sluggish MOC in intermediate water in the eastern and central Atlantic. Our results indicate that sedimentary ratios at the Carolina slope remained below the ^{231}Pa/^{230}Th production ratio in seawater throughout the Holocene. These ratios, falling between 0.08 and 0.07 in the earliest Holocene and between 0.07 and 0.06 through the remainder of the Holocene, indicate export of ^{231}Pa, possibly through vigorous ventilation at intermediate depths. This discrepancy between our record and published sites may point to influence of Labrador Sea Water, or the influence of the deep western boundary current along the North American continental slope, at our site. Sediment composition analyses, particularly biogenic opal content, will allow for better constraints on the influence of particle type on ^{231}Pa scavenging at this site. ^{231}Pa/^{230}Th results will be compared to predictions from advection/scavenging models to assess the role of MOC vs. water column ingrowth/scavenging in determining sedimentary ratios. This new record will enable improved comparison between intermediate and deep sites, enhanced understanding of existing water mass boundary records through the addition of a dynamical tracer of ventilation strength, and cross-basinal comparison of ventilation at intermediate depths.

Kinetic isotope fractionation of ionic species in D_2O and methanol

AMY E. HOFMANN[1*], IAN C. BOURG[1], JOHN N. CHRISTENSEN[1], & DONALD J. DEPAOLO[1,2]

[1]Lawrence Berkeley National Laboratory, Earth Sciences Division, Berkeley, CA 94720, USA aehofmann@lbl.gov (* presenting author)

[2] University of California–Berkeley, Department of Earth & Planetary Science, Berkeley, CA 94720, USA

Certain kinetic processes, such as the self-diffusion and desolvation of ions in aqueous solution, have been shown via experiments[1,2] and molecular dynamics (MD) simulations[2,3,4] to fractionate Li^+, K^+, and Ca^{2+} isotopes. Both the self-diffusivities and desolvation rates of these isotopes in pure water follow an inverse power-law dependence on isotopic mass. In other words, lighter isotopes diffuse faster and exchange water molecules between their first hydration shell and the bulk liquid more quickly than heavier isotopes of the same species. In order to better elucidate the mechanism(s) responsible for kinetic fractionations associated with these processes, we performed MD simulations of ions in D_2O and diffusion experiments of ions in methanol comparable to previous experiments and simulations of the same ionic species in pure H_2O.

MD simulations involved one cation and 550 D_2O molecules in a periodically replicated cell at 298 K. Heavy water was modeled by altering the mass of SPC/E water but leaving all other model parameters unchanged. Simulation results indicate that both self-diffusion and desolvation of Li^+ and K^+ in D_2O produce larger isotopic fractionations compared to those determined for the same species in pure H_2O. For Ca^{2+}, ion desolvation rates in D_2O had no isotopic mass dependence, whereas data obtained in H_2O showed $^{44/40}Ca$ kinetic fractionations of order 3 ‰[4,5]. Kinetic isotope fractionations associated with self-diffusion of Ca^{2+} isotopes in D_2O are ambiguous at best due to the magnitude of the errors: simulation results predict diffusive fractionations between ^{44}Ca and ^{40}Ca of ca. 0.8 ± 5 ‰; by comparison, $^{44/40}Ca$ kinetic isotope fractionation by diffusion in H_2O is 0.43 ± 0.05 ‰[2]. Experimental corroboration of our D_2O simulation results is forthcoming.

Preliminary experimental results indicate that diffusion of K^+ in methanol produces larger isotopic fractionations than diffusion in pure H_2O. We are currently testing appropriate force field models for MD simulations of Li^+, K^+, and Ca^{2+} in methanol. Together, these observations reveal how properties of the solvent (and, hence, kinetic processes that chemically couple the solute to the solvent) may play a critical role in the isotopic fractionation of cations in solution.

Influence of nitrate on the Eu(III) uptake by calcite: A TRLFS study

SASCHA HOFMANN[1] , THORSTEN STUMPF[2]

[1] Karlsruhe Institute of Technology, Institute for Nuclear Waste Disposal, Karlsruhe, Germany, sascha.hofmann@kit.edu

[2] Karlsruhe Institute of Technology, Institute for Nuclear Waste Disposal, Karlsruhe, Germany, thorsten.stumpf@kit.edu

Introduction

Calcite is present up to high amounts in clay minerals which are being discussed as a host rock formation and is formed by the degradation of cementitious material as a secondary phase. Furthermore, nitrate is very common in the geological environment and can influence the sorption behaviour of radionuclides. Because of the high impact of trivalent actinides (Pu, Am, Cm) on the radiotoxicity on long time scales, we used Europium as a homologue due to its spectroscopical properties and chemically similar behaviour. Earlier studies[1] have shown that Eu forms solid solutions with calcite under moderate conditions (T=25°C, IS=0.01M, ClO_4^- trace concentration). Three different sites were determined by TRLFS (dotted line, fig.1). By measurement of the fluorescence lifetimes after direct on-site excitation, these have been identified as one sorption (site A) and two incorporation species (sites B and C). For charge compensation, sodium must be present:

$$Eu^{3+} + Na^+ \leftrightarrow 2Ca^{2+}$$

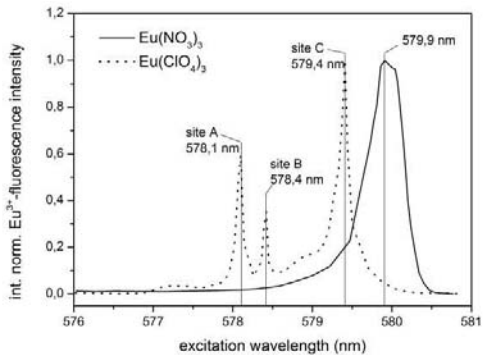

Figure 1: TRLFS excitation spectra of Eu^{3+} doped calcite with nitrate (one site) and perchlorate (three sites) as counterion

Results and Conclusion

By using 2 µM europium nitrate (T=25°C, IS=0.02M) instead of a perchlorate solution, a bathochromic shift of the emission maximum of about 0.5 nm was observed (solid line, fig.1). The long emission lifetime of this species (602 ± 59 µs) indicates that there are no water molecules left in the first coordination sphere of the lanthanaide ion (Horrock's equation[2]). As no other sites could be found, a new mechanism of Eu incorporation in the presence of NO_3^- -ions has to be assumed. Therefore, the uptake of Eu^{3+} by calcite is stongly influenced by the presence of trace amounts of NO_3^-. Considering the ubiquity of nitrate in the geosphere, this will highly affect modelling calculations for long term safety of nuclear waste deposits.

Trace element abundances in Doushantuo cap dolostones from platform and slope settings, Yangtze Platform, South China

S. V. HOHL [1*], H. BECKER[1], D. HIPPLER[2], W. BÄRO[1]

[1] Freie Universität, Berlin, Germany
[2] Technical University, Berlin, Germany
(*correspondence author: shohl@zedat.fu-berlin.de)

Shallow and deep water facies cap carbontes of the Ediacaran Doushantuo Formation (Yangtze Platform, South China) were studied to evaluate the extent of diagenetic alteration and to asses temporal and spatial variations of Ediacaran seawater chemistry. The mineralogical composition and textures of the samples were prescreened using SEM and XRD, and 20 mg sample aliquots were obtained by drilling into presumably unaltered domains of polished rock chips. For analysis of major and trace element concentrations and Sr isotopic composition, sample powders were leached in 10 % acetic acid.

REE+Y patterns of deep water cap dolostones from a slope section (Huanglian section, Songtao, Guizhou Province) have high Y/Ho_{PAAS} ratios up to 1.9 and Pr/Yb_{PAAS} of 0.45 to 0.8 and may reflect relatively undisturbed seawater signatures. In detail, the base of the section shows a relative enrichment in MREE, no Ce anomaly and a positive Eu anomaly (1.2). The middle part of the section displays weak negative Ce anomalies (Ce/Ce* = 0.8-0.9) whereas the upper part of the section shows no Ce but a small positive Eu anomaly. These results are in contrast with data from nearby Panmen section [Becker et al., this meeting], where no or positive Ce anomalies are obtained from acetic acid leachates of cap dolostones.

REE+Y patterns of cap dolostones of the shallow water facies from Hubei Province (Tianjiayuanzi, Wuhe-Gaoxi, Jijiawan sections) are flat to variably depleted in the LREE and show variable Y/Ho_{PAAS} (1-1.3) or Ce/Ce* (1-1.4). These results are different from the shallow water section at nearby Jiulongwan section (Hubei Province), the latter displaying prominent negative Ce anomalies [1]. The most compelling explanation for the section to section variability in REE+Y systematics in both shallow and deep water sections is the variable influence of secondary processes such as diagenesis and fluid flow. $^{87}Sr/^{86}Sr$ ratios in deep water cap dolostones at Huanglian range from 0.7246 right above the diamictites and drop to values of 0.7175 at the top of the section. The $^{87}Sr/^{86}Sr$ ratios of cap dolostones from the shallow water sections are lower (0.7081 - 0.7113) and similar to recently published data for the Three Gorges Area [2]. Samples from slope sections show a strong overprint by hydrothermal fluids containing very radiogenic Sr, with limited redistribution of REE+Y. Cap dolostones from shallow water sections also reveal variable redistribution of REE+Y abundances. These observations indicate decoupling of REE+Y behavior from fluid mobile elements such as Sr or O. SEM work is helpful in the identification of homogeneous carbonate domains, but it does not guarantee that such domains have retained pristine compositions.

C-, O- and Sr-isotopes in marbles from the Eastern Alps

BARBARA PUHR[1], RALF SCHUSTER[2], GEORG HOINKES[1*], SYLVAIN RICHOZ[1], BEATRIX MOSHAMMER[2]

[1]University of Graz, Graz, Austria, barbara.puhr@edu.uni-graz.at, georg.hoinkes@uni-graz.at (* presenting author), sylvain.richoz@uni-graz.at
[2]Geologische Bundesanstalt, Vienna, Austria, ralf.schuster@geologie.ac.at, beatrix.moshammer@geologie.ac.at

Introduction

Marbles of the polymetamorphic, medium-grade, greenschist to eclogite facies Koralpe-Wölz nappe system (Eastern Alps) were investigated regarding their geochemical and isotope compositions. Focus was set on a characterization of different lithostratigraphic units by their distinct compositions and a comparison of revealed chemostratigraphic information with un- to weakly metamorphosed equivalents of the Austroalpine and Southalpine units.

Results and conclusion

Geochemical screening of the marbles using Mn/Sr, Rb/Sr-ratios and C-, O- and Sr-isotope signals, which reflect the diagenetic and metamorphic imprints, allows distinguishing between primary compositions and altered samples, as can be expected from highly metamorphosed metacarbonates. A limiting factor for Mn/Sr is proposed by ≤2 and for Rb/Sr by ≤0.02. The upper limit of primary Sr-values is given by 0.709250 reflecting the highest Sr-seawater value. Feasible samples with regard to C- and O-isotope contents fall within -1 to 4 and -8 to 0, respectively. Mn/Sr-ratios scatter in a range of 0.036 and 2.814, from which just 4 samples exceed values above 2. The Rb/Sr-values vary between 0 and 0.132 (17 samples exceeding the upper limit). Two distinct groups of marbles, based on isotope compositions and different alteration signals, are present. Group I is characterized by relatively low and solely slightly variable Sr-values between 0.707997 and 0.708465. However, these marbles possess strongly scattering $\delta^{18}O$- (-11.08 - 0.10‰) and $\delta^{13}C$-data (-1.58 - 4.78‰). Group II shows Sr-ratios above 0.708556 with a maximum at 0.711090. Δ18O-values of this group are strongly scattering (-12.95 - -4.01‰), whereas $\delta^{13}C$-isotope signatures fluctuate in a narrow span between -0.9 and 2.02. Due to best fitting geochemical and isotope constraints, marbles of at least two lithostratigraphic complexes, namely the Rappold and Millstatt Complexes, reflecting group I and group II respectively, are interpreted to possess most likely primary geochemical signatures.

These best preserved samples were used for further chemostratigraphic interpretation by means of a correlation with isotope seawater curves. For marbles of group I a depositional age in the late Early to Middle Devonian (400-385 Ma) is indicated. For metacarbonates of group II a sedimentation in the latest Silurian to Early Devonian (420- 405 Ma) is concluded.

Based on the depositional age, geochemistry and on its lithological successions, group I occurring in the southeastern part of the Austroalpine unit show similarities with the directly overlying Graz Palaeozoic, whereas units of group II which is present further north and west can be attributed to the other weakly metamorphosed Palaeozoic sequences of the Austroalpine and Southalpine units.

Migration and evolution of oil sands tailings pond seepage through glacial till sediments: combined field and laboratory investigations

A. HOLDEN[1*], M. KONE[1], K. U. MAYER[2], A. ULRICH[1]

[1] University of Alberta, Civil and Environmental Engineering, Edmonton, Canada, aholden@ualberta.ca (*presenting author), macoura@ualberta.ca, aulrich@ualberta.ca

[2] University of British Columbia, Earth and Ocean Sciences, Vancouver, Canada, umayer@eos.ubc.ca

In Northern Alberta, at least three major oil sands tailings impoundments have been constructed atop aquifers, mantled by a layer of glacial till. Despite these favourable conditions, absolute containment within these enormous, man-made structures is not achievable, and oil sands process water (OSPW) from the ponds is expected to infiltrate through the aquitard, impacting groundwater quality on site and potentially beyond [1]. However, to date, there has been no research investigating the evolution and migration of OSPW in glacial till sediments, and thus the nature of contaminants entering the groundwater-bearing formations remains unclear.

The present study seeks to a) characterize the potential for glacial till sediments to attenuate, or to modify the composition of, ingressing major ions contributing to salinization; and b) to clarify the key geochemical processes governing system behaviour. Of novelty, groundwater was monitored for 6 years, from its pristine state through to first ingress of OSPW, and results are interpreted in conjunction with radial diffusion cell experiments [2] using the same sediments.

Field observations show that OSPW intrusion resulted in high concentrations of Na, Cl and alkalinity (likely HCO_3), at approximately 900, 370 and 1350 (as $CaCO_3$) mg L^{-1} respectively. In agreement with findings from radial diffusion experiments, initial ingress of sodium-rich OSPW exchanged with sediment-bound Ca, while NO_2, NO_3 and high concentrations of SO_4 were mitigated, due to reduction reactions. However, displacement of exchangeable Mg was observed in the laboratory but not on site, though perhaps the change too subtle or localized to be detected by annual sampling.

Field monitoring enables the detailed assessment afforded under the well-controlled conditions of the diffusion cells, to be expanded to include field-scale heterogeneity in mineralogy and hydrology, and variable climate. Together, the unified results are expected to aid future remediation and environmental management strategies.

[2]Syncrude Canada Ltd., Edmonton, AB, Canada, Penner.Tara@syncrude.com

Sustainable reclamation of tailings, process water, and disturbed land represents the largest environmental challenge facing the Alberta Oil Sands industry. Bitumen extraction generates immense quantites of composite tailings (CT), a material that remains, to date, uncharacerized with regards to bacterial genetic diversity. Syncrude Canada Ltd. is currently building the first large-scale reclamation freshwater fen overlying sand-capped CT. Unexpected hydrogen sulfide (H_2S) gas emissions coinciding with dewatering of the CT associated with fen construction has highlighted the need to more thoroughly constrain S biogeochemistry in these materials. Recently initiated work is now investigating microbial linkages between S cycling and the generation of H_2S gas in untreated CT as well as CT undergoing reclamation fen development. CT consists of process water, gypsum, sand, and fluid fine tailings (FFT), a process waste that is rich in microbial life as well as Fe-bearing clay content. Understanding the putative microbial links to H_2S generation thus requires a thorough characterization of the microbial players that may be present in the starting materials, as well as those in the composite tailings *in situ*, and their potential impact for S cycling. The objectives of this work are to characterize the bacterial diversity of FFT, CT, and overlying sand cap materials, as well as process water, via molecular, cultivation-independent 16S approaches. Results of this genetic charactierzation, as well as Fe and S metabolic enrichment from these materials, and the potential linkages to H_2S gas generation will be presented.

4Institute of Geological Sciences, Department of Earth Sciences, Freie Universität Berlin, Berlin, Germany.

The aim of this work is to assess the effect of ligand strength, symmetry, and coordination number on solid solution formation of trivalent actinides and lanthanides in carbonate and sulfate minerals. This is of particular importance in radionuclide migration where trivalent actinides such as Pu, Am, and Cm are responsible for the majority of radiotoxicity after 1,000 years. Time-resolved laser fluorescence spectroscopy was used to study trace concentrations of the dopant ion after interaction with the mineral phase. This study expands on previous work with aragonite and gypsum where it was found that aragonite incorporates Eu^{3+} and Cm^{3+} while only surface sorption is observed in gypsum. This study uses isostructural minerals strontianite ($SrCO_3$) and celestite ($SrSO_4$) to decouple the effect of structure from that due to the anion. It is demonstrated that while distribution coefficients can predict the amount of dopant ion associated with the mineral phase, they do not have any correlation with solid solution formation. This substitution mechanism is most likely dictated by the symmetry of the site being substituted and the electronic structure of the dopant atom.

Table 1: Lifetime and position of fluorescence emission in Eu^{3+} and Cm^{3+} doped aragonite, strontianite, and celestite.

Sample	Wavelength (F_0 or $S_{7/2}$)/nm	Lifetime/ms
Eu-$CaCO_3$[1]	579.4	1.6
Eu-$SrCO_3$	578.5	1.6
Eu-$SrSO_4$	577.7	3.1
Cm-$CaCO_3$[1]	612.7	0.64
Cm-$SrCO_3$	608.5	0.47
Cm-$SrSO_4$	596.3	1.1

Dissolved organic matter characterization for a Prairie Potholes ecosystem

JOANN M. HOLLOWAY[1]*, MARTIN B. GOLDHABER[1], CHRISTOPHER T. MILLS[1], GEORGE R. AIKEN[2], AND KENNA D. BUTLER[2]

[1]U.S. Geological Survey, Denver, CO, USA, jholloway@usgs.gov (* presenting author), mgold@usgs.gov, cmills@usgs.gov

[2]U.S. Geological Survey, Boulder, CO, USA, graiken@usgs.gov, kebutler@usgs.gov

The Prairie Potholes region of the northern Great Plains includes an extensive system of small (< 0.5 hectare), discrete wetlands that occur within a hummocky topography formed by the retreat of Pleistocene glaciers. The Cottonwood Lake Study Area, located in the Prairie Potholes region near Jamestown, North Dakota (USA), includes 16 wetlands. These wetlands receive water primarily from snowmelt and are hydrologically connected by groundwater flow within a 92-hectare basin that lacks surface drainage. The objectives of this study were to 1) determine if different wetland vegetation communities affect the quantity and quality of dissolved organic matter (DOM), and 2) determine the extent to which vegetation-DOM is partitioned into groundwater.

Wetland salinity ranged from 150 mg kg^{-1} in recharge wetlands receiving only meteoric input to >3000 mg kg^{-1} in discharge wetlands receiving groundwater flow from topographically higher wetlands. The pH of individual wetlands ranged from 6.7 to 8.8 and has been linked to variable wetland salinity that supports differing plant community structures. Unusually high concentrations of dissolved organic carbon (DOC) accumulate from the decay of vegetation and algae in wetland waters (27 to 56 mg C L^{-1}), an order of magnitude greater than most natural waters. The hydrologic connection between the wetlands and shallow groundwater was reflected by elevated DOC concentrations (20 to 46 mg C L^{-1}) from wells screened within this flow path. Deeper groundwater isolated from direct wetland recharge had lower DOC concentrations (2.5 to 10 mg C L^{-1}). Specific UV absorbance ($SUVA_{254}$) is an index of aromaticity. Wetlands with near neutral pH had a greater $SUVA_{254}$ than alkaline wetlands, although aromatic dissolved organic matter is generally more soluble in alkaline waters. Thus, we interpret this trend to be in part a function of organic matter source. Groundwater had a lower $SUVA_{254}$ than the wetlands, indicating a lower proportion of aromatic compounds. We are also applying fluorescence-based techniques in evaluating the quality of DOM associated with these wetlands. These data give insights on how varying vegetation communities can affect types of DOM associated with these wetlands and the exchange of organic matter between surface and groundwater.

Subduction eroded continental crust and sediment derived fluids in the genesis of arc magmas in the SVZ, Andes

PAUL MARTIN HOLM[1*], NINA SØAGER[1], CHARLOTTE THORUP DYHR[1]

[1] University of Copenhagen, Copenhagen, Denmark, paulmh@geo.ku.dk (*presenting author)

New Sr, Nd and Pb isotope and trace element data is presented from young volcanic rocks from Maipo and Laguna del Maule Transitional and Northern Southern Volcanic Zone (SVZ) of the Andes, respectively. The trace element enrichment of many of the volcanic rocks from the 34-38°S in the Southern Volcanic Zone, SVZ, display a relative enrichment of Th to Ba indicating that source enrichment by fluids is not the most important process. All rocks have negative Nb and positive Pb anomalies indicating that the magmas have an important component of continental crust or/and had a fluid-enriched source.

To avoid most effects on incompatible trace element ratios from fractional crystallization and from afc processes we used only incompatible element ratios of the most primitive rocks in our modelling (Mg# > 60).

Nb/Th, Ba/Th and La/Th ratios in rocks from the Central-Transitional-Northern SVZ correlate well and suggest that two components dominate their compositions. In this respect the Andes rocks with the relatively highest ratios are comparable to the Marianas and Tonga, which have been argued to be derived from a fluid-enriched source [2,3]. The low Ba/Th component has lower Ba/Th and La/Th than GLOSS, local trench sediments and average continental crust. This end-member most resemble average upper crust, and its relatively low Ba/Rb and La/Rb suggest it to be of evolved magmatic composition. Volcan Maipo rocks approximates this end-member for the Northern SVZ and very little fluid-borne enrichment is required to generate these magmas. This is in accord with the radiogenic Sr ($^{87}Sr/^{86}Sr$ = 0.7049-0.7055) and unradiogenic Nd ($^{143}Nd/^{144}Nd$ = 0.5125-0.5126) of the Maipo rocks, lower than 0.5127-.5128 of Chile Trench sediments. For the Transitional and Central SVZ crust with similar geochemistry but different isotopic composition is indicated. We suggest that the subducting Nazca plate abraded the South American upper crust at the leading edge and transported it below the lithosphere where it partially melted, as also suggested by e.g. [4]. The fluid-borne enrichment is characterized by its Sr and Nd isotope composition of $^{87}Sr/^{86}Sr$ around 0.7040 and $^{143}Nd/^{144}Nd$ 0.5128. This composition is common for several SVZ volcanoes and isotopically overlap with Chile Trench sediments in Sr, Nd and Pb isotopic composition, and is very different from both Pacific MORB and the OIB-type source of the back-arc magmas which probably is an important end-member in the local asthenosphere. The fluid borne enrichment is therefore indicated to be derived from subducted sediments. The well defined trend towards higer Nb/Th for the rocks rich in this end-member show that they were derived from a rather fixed proportions of fluid plus mantle.

Organic geochemical insights into the formation of the Here's Your Chance lead-zinc-silver deposit

ALEX HOLMAN[1*], KLITI GRICE[1], CAROLINE JARAULA[1], JEFFREY DICK[1], ARNDT SCHIMMELMANN[2] AND KATY EVANS[3]

[2]Department of Geological Sciences, Indiana University, Bloomington, United States of America

[3]Department of Applied Geology, Curtin University, Perth, Australia

The Here's Your Chance (HYC) lead-zinc-silver deposit is located in the Barney Creek Formation (BCF), a 1639 ± 2 Ma carbonaceous marine deposit in the Northern Territory of Australia. The HYC deposit has been extensively studied as an example of hydrothermal alteration of well-preserved Proterozoic organic matter [1,2].

Samples were collected from five sites along the flow path of hydrothermal fluid. The freely-extractable hydrocarbons (Bitumen I) from these samples have been analysed by Williford *et al.* [2]. This study has investigated hydrocarbons that were occluded within the kerogen/mineral matrix (Bitumen II), following hydrofluoric acid digestion and extraction as per Nabbefeld *et al.* [3].

Bitumen II *n*-alkanes display a markedly different distribution to those of Bitumen I, characterised by an unusual even-over-odd distribution and the preservation of long-chain alkanes up to *n*-C_{38}, indicating a biological source such as sulfate-reducing bacteria [4]. It is believed that hydrocarbons in Bitumen II have been protected from alteration by the kerogen / mineral matrix; hence it is likely that these bacteria were associated with the depositional environment. Bitumen II *n*-alkanes are 5 ‰ more negative in $\delta^{13}C$ compared to Bitumen I, suggesting that Bitumen I hydrocarbons originate from a different source. Other explanations for the origin of Bitumen II are also under investigation.

The isomer ratios of Polycyclic Aromatic Hydrocarbons (PAHs) in sediments are temperature dependant, and are widely used to estimate thermal maturity [3]. Bitumen I PAH ratios indicate a higher maturity than Bitumen II, supporting the theory that PAHs were generated at higher temperatures below the BCF, then transported up with the mineralising fluid [2]. Preliminary thermodynamic calculations based on PAH distributions in these proceedings [5] have placed an upper limit on mineralising fluid temperature which is in agreement with previous studies [2].

Molecular dynamics simulations of the three-layer hydrate in smectites: A sensitivity analysis

MICHAEL HOLMBOE* AND IAN C. BOURG

Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, USA,
mholmboe@lbl.gov (* presenting author)

Abstract

Bentonite (smectite-rich) clays is under consideration as a buffer material for geological nuclear waste repositories in many countries. Molecular simulation techniques such as Monte Carlo (MC) and molecular dynamics (MD) simulations have played an important role in characterizing these materials by yielding detailed atomistic insights into the structural, dynamical and thermodynamic properties of water in smectite interlayer nanopores. Most of these studies used classical MD simulations of small smectite/water systems (< 10^4 atoms) with fixed smectite clay layers, in order to save computational time, although size dependent effects using more realistic and flexible smectite layers were observed in large-scale MD simulations (> 10^5 atoms) of flexible smectite layers [1]. In this work we compare the results of MD simulations with 6900, 7710 and 8520 atoms, carried out with either fixed or flexible smectite layers of a typical 2:1 sodium exchanged smectite (Wyoming montmorillonite), at different water contents and temperatures. The simulations were performed using the MD code LAMMPS with the SPC/E water model and the ClayFF force field, which are known to correctly reproduce structural and thermodynamical properties of smectite interlayer water and exchangeable cations [2]. We focus in particular on the diffusion coefficents and structural data for the three-layer hydration state, which is expected to be the predominant hydration state in different concepts for geological nuclear waste disposal, such as the Swedish KBS-3 method [3].

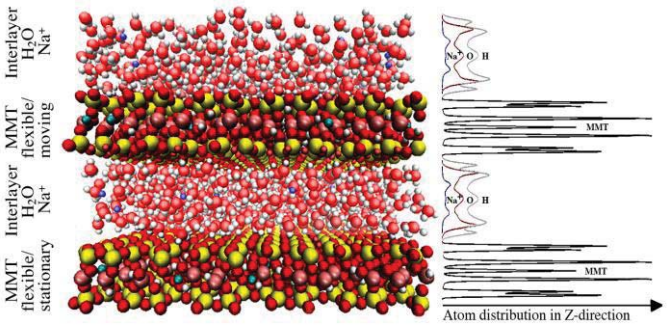

Figure 1: Typical "snapshot" from a MD simulation of two montmorillonite layers in the three-layer hydrate state. Right hand side shows the atom distribution in the vertical direction.

Ca-isotope tracing of submarine groundwater discharge—Florida Bay

C. HOLMDEN[1], D. A. PAPANASTASSIOU[2], P. BLANCHON[3] AND S. EVANS[4]

[1]Saskatchewan Isotope Laboratory, Saskatoon, Canada
[2]Jet Propulsion Laboratory/Caltech, Pasadena, USA
[3]Instituto de Ciencias del Mar y Limnologìa, Natl. Univ. of México
[4]Dept. of Geosciences, Boise State University, USA

Florida Bay is a seasonally hypersaline estuarine lagoon located on the southernmost tip of the submerged Florida shelf. It is roughly triangular in shape with barriers that limit circulation with open marine waters. To the east, the nearly continuous exposure of Pleistocene limestone, composing the Florida Keys, keeps surface Atlantic waters out of Florida Bay (with the exception of a few tidal passes). To the south, a series of shallow mudbanks limits circulation with the Gulf of Mexico. To the north, Florida Bay is bounded by mangrove wetlands of the Florida Everglades. Waters are typically <3 m deep, and it is common to find areas that have been scoured of sediment to reveal the underlying Pleistocene limestone bedrock. Outcrop exposures of Pleistocene limestone occur in the coastal region of northern Florida Bay extending into the wetlands of the southern Everglades.

The coastal region of northeastern Florida Bay has been indentified in hydrogeological models as an area of submarine groundwater discharge (SGD) [1]. Other studies have shown seawater penetration beneath the southern Everglades extending for 25 km inland from the coastline [2], and that brackish groundwaters are not conservative with respect to Ca, showing an 'excess Ca' effect; i.e., more Ca than would be expected on the basis of seawater-freshwater mixing in the subterranean estuary [3]. The excess Ca originates from the dissolution of carbonate-aquifer minerals.

The tracer potential of Ca-isotopes ($\delta^{44/40}$Ca values) in this setting stems from the ~1.1‰ difference between $\delta^{44/40}$Ca values of carbonate bedrock (–1.1‰) and seawater (0‰). Therefore, the excess Ca picked up during the circulation of seawater in the subsurface serves as a fingerprint of SGD inputs into coastal Florida Bay, where water circulation restriction enables the seepage flux of isotopically light Ca to be resolved before it is 'mixed out' by circulation with the ocean. A 0.7‰ gradient in $\delta^{44/40}$Ca values is found in both waters and sediment of northeastern Florida Bay, decreasing towards the Florida Everglades. Results of a quantitative Ca-isotope mixing model indicate that 20% of the water and 30% of the Ca in Joe Bay is from SGD. The estimates are even higher in the southern Mangrove fringe of the Florida Everglades [4].

More work is needed to determine the global-scale SGD Ca-flux to the oceans. Quantitative flux estimates would help to close the Ca isotope budget of the oceans, where the traditional input Ca-fluxes from rivers and hydrothermal fluids are too small to balance the output Ca-flux into carbonate sediments.

[4]Finnish Meteorological Institute, Helsinki, Finland

Introduction

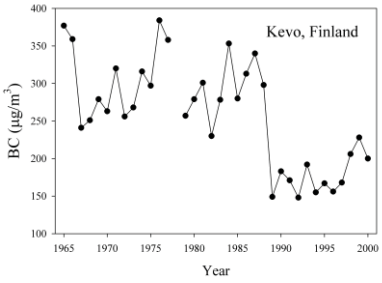
Carbon, primarily a byproduct of incomplete combustion of fossil fuel and biomass burning constitute only a few % of the total PM mass, but disproportionately affect the global climate by absorbing the incoming sunlight and directly warm the atmosphere. BC coated with sulfate is even more effective than externally mixed BC and SO4 particles. Recent studies have indicated that substantial radiative forcing in the Arctic is due to the indirect impact of BC on the albedo of snow and ice surfaces. We are determining the concentrations of BC, SO4, selected trace elements in weekly samples collected at Kevo, Finland, from 1964-2010 to assess the impact of aerosols on (1) radiative forcing, (2) source regions that have contributed to the burden of BC and SO4 in the Arctic region, and (3) how the regional emissions impacting Arctic have changed with time.

Methods

Samples were collected over 7 day periods beginning in October 1964 through the present in Kevo [1], Finland in an automated system to measure airborne radioactivity. These samples were analyzed using the approach developed by Husain et al. [2]. The light absorption of each new filter was measured with a Magee OT21 transmissometer.

Results and Conclusions

Figure 1 shows the annual average values for 1965 to 2000. The concentrations of BC aerosols during 1965 were 430 ng m^{-3}. From 1966 thru 1987 it varied from ~250 to 430 ng m^{-3}. Beginning in 1989, concentrations showed a systematic decrease to about 150 ng m^{-3}. From 1989 to 2002, the concentrations have remained between 150 and 230 ng m^{-3}. The data from 2003 to 2010 is not yet available.



These data show that there was a substantial decrease in BC concentrations around the time of the collapse of the Soviet Union and the change in political systems in eastern Europe. More detailed analyses will be performed in the future.

Aluminium affecting copper speciation in Swedish freshwaters

SABINA HOPPE[1*], KURIA N´DUNGU[1], HANS BORG[1]

[1]Stockholm University, Dept. of Applied environmental science, Sabina.hoppe@itm.su.se (* presenting author)

Abstract

Swedish fresh waters are often rich in aluminium depending on the underlying bedrock, water chemistry e.g. acidification status and TOC. Aluminium forms, present at circum neutral pH are not toxic to aquatic biota, but may however influence the bioavailability of other metals. This will occur due to competition of Al on organic carbon binding sites which will relese free metal ions affecting metal speciation (Fig.1) as well as toxicity. Measured free/labile Cu levels, using electro chemical detection - Anodic Stripping Voltammetry (ASV), combined with modeling (Visual minteq) showed that this occurs until a threshold level of Al in the water is reached. The concentration of free Cu increased and the organically complexed Cu (Cu-FA) decreased when Al was added (Fig. 1)

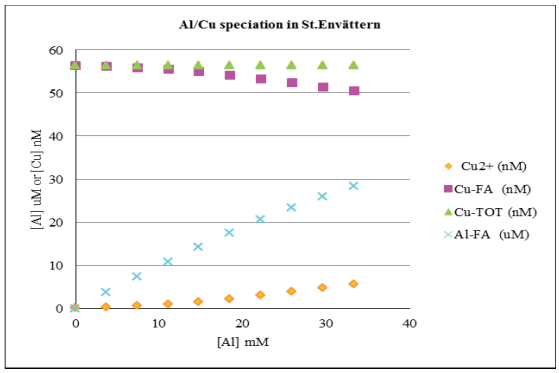

Figure 1: Cu-species at increased amount of Al added to water from Lake St. Envättern, Sweden. Cu-FA, Al-FA: metal complexes with humus.

These findings also have a marked influence on the Cu-toxicity to crustaceans (*Daphnia magna*) as shown by preliminary results from toxicity tests using lake waters in the presence of Al well below the toxic concentration of Al (Fig.2).

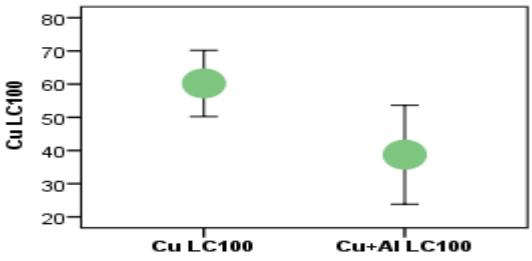

Figure 2: Cu LC_{100} values with and without Al addition (20 µg/L) for *D.magna*.

Conclusion

Aluminium, thou not bioavailable at circum neutral pH-values, can affect Cu speciation, toxicity and bioavailability in freshwaters already at moderately elevated Al-concentration.

EVOLUTION, ECOLOGY AND BIODIVERSITY IN OLD, INFERTILE LANDSCAPES

STEPHEN D. HOPPER[1]

[1]Royal Botanic Gardens, Kew, Richmond, Surrey, UK, s.hopper@kew.org

OCBIL theory[1] aims to develop an integrated series of hypotheses explaining the evolution and ecology of, and best conservation practices for, biota on very old, climatically buffered, infertile landscapes (OCBILs). Conventional theory for ecology and evolutionary and conservation biology has developed primarily from data on species and communities from young, often disturbed, fertile landscapes (YODFELs), mainly in the Northern Hemisphere. OCBILs are rare, but are prominent in the Southwest Australian Floristic Region, South Africa's Greater Cape, and Venezuela's Pantepui Highlands (Fig 1). They may have been more common globally before Pleistocene glaciations. Based on the premise that natural selection has favoured limited dispersability of sedentary organisms, OCBILs should have elevated persistence of lineages (Gondwanan Heritage Hypothesis) and long-lived individuals (Ultimate Self Hypothesis), high numbers of localised rare endemics and strongly differentiated population systems. To counter such natural fragmentation and inbreeding due to small population size, ecological, cytogenetic and genetic mechanisms selecting for the retention of heterozygosity should feature (the James Effect). The climatic stability of OCBILs should be paralleled by persistence of adjacent semi-arid areas, conducive to speciation (Semiarid Cradle Hypothesis). Special nutritional and other biological traits associated with coping with infertile lands should be evident, accentuated in plants, for example, through waterforaging strategies, symbioses, carnivory, pollination and parasitism. The uniquely flat landscapes of southwestern Australia have had prolonged presence of saline lakes along palaeoriver systems favouring evolution of accentuated tolerance to salinity. Lastly, unusual resiliences and vulnerabilities might be evident among OCBIL organisms, such as enhanced abilities to persist in small fragmented populations but great susceptibility to major soil disturbances. In those places where it is most pertinent, OCBIL theory hopefully lays a foundation for future research and for better informed conservation management.

Reconstructing deep-ocean nutrients with paired Cd/Ca and Cd isotopes in deep-sea corals

TRISTAN J. HORNER[1]*, GIDEON M. HENDERSON[1], ROSALIND E.M. RICKABY[1], AND JESS F. ADKINS[2]

[1]Dept. Earth Sci., University of Oxford, Oxford OX1 3AN, UK *Tristan.Horner@earth.ox.ac.uk (presenting author)

[2]Div. Geol. Planet. Sci., Caltech, Pasadena, CA 91125, USA

The abyssal ocean is a major sink for nutrients, heat, and carbon, and plays an important role in modulating glacial-interglacial climate. Archives of deep-water chemistry, particularly those which can be precisely dated, are therefore of great use in understanding the temporal interactions between ocean circulation and global climate.

Deep-sea corals, which typically live between 500–2,000 m, are well positioned to record changes in deep-water chemistry in their aragonitic skeletons, which can be absolutely dated with U-series techniques [1]. In particular, they have shown some utility in recording oceanic Cd/Ca [2] which can be used to reconstruct seawater phosphate concentrations (because Cd is pseudo-linearly correlated with P). However, physiological 'overprinting' of the environmental signal is a significant issue in deep-sea corals and requires empirical calibration before such archives can be used to reconstruct seawater compositions (e.g. [3]).

Here, we investigate the controls on the Cd isotope composition of deep-sea coral aragonite using a previously collected series of modern and fossil samples from the New England Seamounts located in the North Atlantic [4]. Inorganically precipitated calcium carbonate has previously been shown to have a constant fractionation from seawater [5], therefore deviations from constant fractionation in coral aragonite would indicate a biological overprint that may enable interpretation of Cd/Ca ratios in terms of biomineralization and past seawater composition. The isotope composition of coral aragonite may also allow reconstruction of the past isotope composition of deep-waters, providing clues to changing nutrient cycling during periods of global change.

Greenhouse gas footprint of shale gas obtained by hydraulic fracturing

ROBERT W. HOWARTH[1*], RENEE SANTORO[2], ANTHONY INGRAFFEA[3]

[1]Cornell University, Ecology & Evolutionary Biology, howarth@cornell.edu (* presenting author)
[2]Cornell University, Ecology & Evolutionary Biology, rls75@cornell.edu
[3]Cornell University, Civil & Environmental Engineering, ari@cornell.edu

Introduction

Only in the past 10-15 years have high-volume hydraulic fracturing and precision directional drilling been combined to make extraction of natural gas from shale commercially viable. Industry and many governments promote shale gas, often describing shale gas as a bridge fuel that allows continued use of fossil fuels while reducing greenhouse gas emissions (GHG) compared to other fuels. In April 2011, we published the first comprehensive analysis of the GHG footprint of shale gas, concluding that in fact full-lifecycle GHG emissions from shale gas are comparable to or larger than those from oil and coal [1]. Since our paper was published, the US EPA issued new estimates on GHG emissions from natural gas systems, and many other papers and reports have also evaluated aspects of the GHG footprint of shale gas. In Feburary 2012, we published a paper synthesizing and summarizing this new information [2]. In this talk, I will further update the rapidly changing state of knowledge on the GHG footprint of shale gas.

Uncertainties and sensitivity analysis

Methane venting and leakage dominates the GHG footprint of shale gas, particularly when considered using the most recently available information on global warming potential that integrates the effect of methane over a 20-year time period. The influence of methane is diminished at the 100-year time frame. Over a wide range of estimates of methane emission, the GHG footprint of shale gas is worse than other fossil fuels, when viewed at the 20-year scale. The most recent evidence suggests that many studies continue to underestimate the magnitude of methane emisisons.

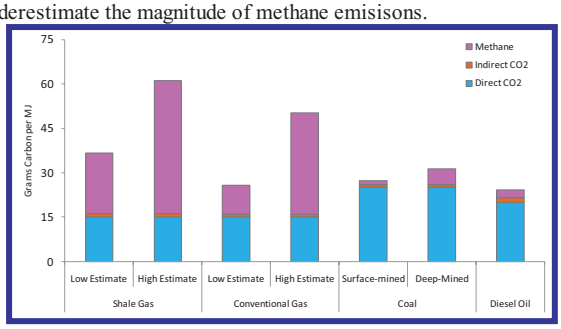

Figure 1: Comparison of the GHG footprint of shale gas with other fuels, using 20-year global warming potentials for methane. From [1].

Trace element partitioning in mixed-habit diamonds

D. HOWELL[1]*, W.L. GRIFFIN[1], W. POWELL[1], P. WIELAND[1], N. PEARSON[1], S.Y O'REILLY[1]

[1]CCFS ARC Centre of Excellence, GEMOC, Macquarie University, Sydney, NSW 2109, Australia (*daniel.howell@mq.edu.au)

Mixed-habit diamonds are those that exhibit periods of growth during which they were bound by two surface forms [1], namely smooth faceted octahedral growth in combination with hummocky, non-facetted "cuboid" surfaces whose mean orientation is {100} [2]. This type of diamond is commonly referred to as *star* or *centre-cross*, because the cuboid sectors can sometimes have a much darker appearance compared to the gem-quality octahedral sectors.

Analysis of mixed-habit diamonds has already revealed a preferential partioning of nitrogen between the two sectors [3]. Nickel has also been identified as being present and the cause of the green luminescence in these diamonds [3]; however, exact concentrations or trace element patterns have never been reported.

Laser ablation inductively coupled plasma mass spectrometry (LA-ICPMS) analysis of diamonds has yielded abundant valuable trace-element information and helped to further our understanding of metasomatic fluids in the deep Earth. Traditional *in situ* techniques have had to overcome the issue of using a suitable standard reference material [4-8], but have provided great insights when applied to fluid inclusion-rich diamonds. More recently a closed-system (i.e. off-line) laser ablation technique has been developed [9] that has been applied succesfully to measure the low impurity levels present in gem-quality diamonds. The sacrifice made to obtain these low detection limits is a loss of spatial resolution. This is due to the large ablation areas required (approximately 500 × 500 μm in area, with depths ranging from 200 – 400 μm).

In this study we present a modified off-line LA-ICPMS method for analysing diamonds. Instead of trapping the ablated material in a closed cell, it is collected in a liquid. We apply this larger-scale ablation technique to investigating the partitioning of trace elements between octahedral and cuboid sectors in a collection of large (>6mm) mixed-habit diamonds. This is the first set of trace element data to be collected from mixed-habit diamonds, and integrated with several other types of analysis (infrared mapping, cathodo-luminescence imaging and spectroscopy, in-situ carbon-isotope analysis by secondary ion mass spectrometry), they will provide further insights into the specific geochemical conditions of formation for this interesting subset of diamonds.

Engineering controls on fly ash chemistry: Examples from Kentucky power plants

JAMES C. HOWER[1]

[1] University of Kentucky Center for Applied Energy Research, 2540 Research Park Drive, Lexington, KY 40511, james.hower@uky.edu

The chemistry of fly ash is controlled by a number of factors: 1/ chemistry of the feed coal (and added fuels, such as petroleum coke, tires, biomass, etc.), 2/ size consist of the fuel feed (controlled by pulverized fuel vs. cyclone combustion, maintenance of pulverizers, etc.), 3/ design of the boiler and pollution control system, and 4/ temperature of the flue gas at the collection point. In general, for any electrostatic precipitator (ESP) or baghouse system, the concentrations of volatile trace elements in fly ash will increase with a drop in the flue gas temperature and a decrease in the particle size. Mercury is an exception, requiring carbon to be present in the fly ash for any appreciable amount of Hg to be captured.

Changes in the design of two Kentucky power plants, both originally using central Appalachian coal sources, and the consequent impact on the fly ash chemistry were examined through sampling for a number of studies from 2000 to 2012. One plant, typically burning medium-S eastern Kentucky coals, bypassed two rows of mechanical (cyclone) collectors, consequently sending coarser fly ash to the ESPs. Among the consequences of the design change are a 1st-row ESP C, As, and Hg content than in the ESP fly ash without the coarse ash. The utility is currently installing dry scrubbing to control SO_2 emissions, allowing them to broaden their fuel supply to include high-S coals.

A second plant was burning low-S coal, but installed flue-gas desulfurization (FGD) in anticipation of more stringent regulation of emissions. As with the first plant, this change allows them to pursue a wider range of coals than the central West Virginia sources previously utilized; over 2.5% total S vs. 0.8% prior to the FGD installation. The post-FGD-installation fly ash contains much higher Fe_2S and CaO and lower Al_2O_3 and SiO_2 than the pre-FGD fly ash. The Hg content, while never as high as at some power plants, is below the detection limit in the post-FGD fly ash.

The Coupling of Voltammetric Microelectrodes with Optical Microscopy: A Novel Combination as Applied to the Study of Neutrophilic Iron Oxidizers

PATRICIA L. HREDZAK-SHOWALTER[1*], SEAN T. KREPSKI[2], CLARA S. CHAN[2], DAVID E. EMERSON[3], GEORGE W. LUTHER III[1]

[1]School of Marine Science and Policy, College of Earth, Ocean and Environment, The University of Delaware, Lewes, DE 19958, USA (*hredzak@udel.edu)

[2]Department of Geological Sciences, The University of Delaware, Newark, DE 19716, USA

[3]Bigelow Laboratory for Ocean Sciences, West Boothbay Harbor, ME 04575, USA

Voltammetric solid-state Au/Hg microelectrodes measure multiple analytes, including dissolved oxygen, sulfide, thiosulfate, polysulfides, iodide, Fe^{2+}, Mn^{2+}, and FeS simultaneously at the (sub)millimeter scale. These electrodes are ideal for the *in situ* quantification of the chemical gradients within redox transition zones, ubiquitous in the natural environment or created in the laboratory, and have been used to examine Fe(II) oxidation by neutrophilic iron oxidizers. Use of Au/Hg microelectrodes alone in redox transition zones have inherent limitations as the exact location of the electrode tip where analytes are detected cannot be pinpointed.

To advance chemical and microbial studies we have coupled voltammetric solid-state Au/Hg microelectrodes with optical microscopy using an optical resolution of 0.55 μm in specially designed microslide growth chambers. Higher optical resolutions can be used on the microslides alone. The resulting microslide profiles yield quantifiable chemical gradients including O_2 and Fe(II) associated with both isolated species in artifical media and with samples of naturally occuring flocculent material in freshwater believed to contain iron oxidizers. These profiles are consistent with other profiles obtained from sediments and microbial mats. This novel combination allows for high resolution images to be simutaneously aquired with the electrochemical measurements and the exact location of the electrode tip is known. The coupling of voltammetric microelectrodes with high resolution microscopy is applicable to the study of the chemistry of the microenvironments of other types of microbes as well as microbial biofilms.

Clumped Isotope Paleothermometry: Interpreting Lacustrine Climate Records

HREN, M.T. [1*], SHELDON, N.D.[2], LOHMANN, K.[2]

[1]University of Tennessee, Knoxville, TN, USA mhren@utk.edu (* presenting author)
[2]University of Michgan, Ann Arbor, MI, USA, ndsheldon@umich.edu
[3]University of Michgan, Ann Arbor, MI, USA, kacey@umich.edu

"Clumped Isotope" measurements of carbonate offer a powerful tool for reconstructing the paleotemperature of past environments. One of the key challenges to interpreting clumped isotope measurements is to understand both the temperature-dependent relationship of the system, and how carbonate formation temperatures relate to broader climatic conditions. We examine timescales of carbonate formation in terrestrial systems to determine how clumped isotope temperature measurements relate to climate. Specifically, we use surface temperature records from lakes spanning a wide range of latitudes and elevation to develop transfer functions that relate seasonal temperature to mean annual air temperature. These functions enable determination of mean annual climate from proxies that record a seasonal signal. Transfer function relationships are applied to an example from the Isle of Wight, UK, to constrain the magnitude of temperature change during the Eocene-Oligocene transition using freshwater biotic carbonate. Δ_{47} measurements of pristine, aragonitic gastropod carbonate produce unreasonably high Eocene and Oligocene paleotemeprature estimates using established temperature-dependent relationships. However, transfer functions that account for timing of carbonate formation produce reasonable measures of mean annual temperature and the overall change in MAT during the Eocene-Oligocene transition. These data show that the Δ_{47} paleotemperature proxy provides a powerful and accurate measure of paleoclimate when appropriate transfer functions that relate timescales of carbonate formation are employed. Such an approach must be considered in the application of this proxy to terrestrial systems for problems ranging from paleoclimate to paleoelevation studies.

Evaporite assimilation 'window' triggers sulfide immiscibility

HRYCIUK, M.[1*], BÉDARD, J.H.[2], MINARIK, W[1]. AND WING, B.[1]

[1]McGill University, Montréal, Canada, matthew.hryciuk@mail.mcgill.ca * (presenting author)
[2]Geological Survey of Canada, Québec, Canada

The assimilation of sulfur from sedimentary evaporites by mafic and ultramafic intrusions may trigger the formation of Noril'sk-Type Ni-Cu-PGE (platinum group element) deposits. The Neoproterozoic Minto Inlier on Victoria Island of the western Canadian Arctic exposes dikes, sills and flood basalts from the Franklin Large Igneous Province and sedimentary rocks of the Shaler Supergroup. The Franklin intrusives have many features in common with those in the Noril'sk region of Russia. Both intrude a sequence of carbonates, shales, evaporites and sandstones and are sill-dominated with fault-controlled conduit systems. The excellent exposure on Victoria Island enables intrusive-host rock interactions to be studied directly.

In order to investigate the process of evaporite assimilation, we collected samples through a 5m thick evaporite-hosted sill and the underlying 5m of sedimentary rocks. The host evaporites are part of the Minto Inlet Formation and consist of interbedded carbonate, gypsum and anhydrite. The host sulfate evaporites have $\delta^{34}S$ values between +15.9 and +16.2‰ and the sill has elevated $\delta^{34}S$ values between +11.4 and +12.9‰ in the core and upper sill that imply contamination from crustal sulfate source. However, the lower chilled margin has a $\delta^{34}S$ value of only +1.9‰, within the range of primary igneous values from other sills in the area.

The sulfur isotope value of the chill margin indicates that sulfur was not directly introduced into the sill from the sedimentary rocks below. Possible explanations for elevated S-isotope values within the sill include stoping and mechanical assimilation along the upper sill contact; or the delivery of sulfate contamination from upstream in a later magma pulse. Using simple mixing calculations, we estimate that the sill has assimilated up to 0.4 to 0.7 wt% anydrite. Based on calibrated relationships between evaporite assimilation, sulfur solubility and oxidation state, this range of evaporite assimilation is within a favourable 'window' for ore deposits. It is enough to generate sulfide immiscibility, while being low enough to avoid oxidation of the magma and resorption of the sulfur.

Using ^{228}Ra to assess ocean mixing and nutrient fluxes in the Cape Basin

YU-TE HSIEH[1*], WALTER GEIBERT[2,3], E. MALCOLM S. WOODWARD[4], AND GIDEON M. HENDERSON[1]

[1]University of Oxford, Department of Earth Sciences, Oxford, UK, yuteh@earth.ox.ac.uk (* presenting author)
[2]University of Edinburgh, School of Geosciences, Edinburgh, UK

[4]Plymouth Marine Laboratory, Plymouth, UK

In the South Atlantic Ocean, the Cape Basin holds an important position for dynamic inter-ocean exchange between the Atlantic Ocean and the Indian Ocean (e.g. Agulhas Current Leakage), and for transition from the macronutrient-limited subtropical gyre to the micronutrient-limited Southern Ocean [1]. Nutrients and micronutrients play important roles in marine productivity in the Cape Basin, but their sources and fluxes to this region remain unclear.

Radium-228 has been applied to the study of a variety of oceanographic processes, including tracing of water masses; quantifing mixing processes; and constraining fluxes of dissolved species to the ocean [2]. With a short half-life of 5.75 years, ^{228}Ra is very suitable to assess ocean mixing rates, and the fluxes of nutrients and trace metals into the euphotic zone by vertical and horizontal mixing [3]. In this study, we measure the distribution of seawater ^{228}Ra and ^{226}Ra in the water column of the Cape Basin during the UK-GEOTRACES cruise (GA10E) and use these measurements to calculate horizontal and vertical mixing rates, and resulting nutrient fluxes to the surface ocean of the Cape Basin. A newly developed MC-ICP-MS technique with improved analytical precision has been applied to measure of seawater ^{228}Ra and ^{226}Ra in this study [4]. Vertical and horizontal ^{228}Ra profiles are used to determine the diapycnal and isopycnal mixing rates respectively in the surface ocean of the Cape Basin. The ^{228}Ra-derived vertical mixing rates coupled with the vertical nutrient profiles (nitrate, phosphate and silicate) are then used to estimate the upward nutrient fluxes into the euphotic zone. Assuming steady state, the upward nitrate fluxes are coverted to the organic carbon fluxes in the surface ocean. The observations of the vertical nutrient fluxes suggest that the marine productivity in the Cape Basin is nitrogen-limited in early spring of the southern hemisphere. This study provide important estimates of ocean mixing and nutrient fluxes in the Cape Basin, which enable us to understand the nutrient cycles and biological activities in the macronutrient-limated subropical gyre.

The Reduction and Surface Complexation of Mercury by *Geobacter sulfurreducens* PCA

HAIYAN HU[1,2], WANG ZHENG[1], JEFFRA SCHAEFER[3], XINBIN FENG[2], LIYUAN LIANG[1], DWAYNE ELIAS[1], AND BAOHUA GU[1*]

Understanding the biogeochemical processes that control mercury (Hg) redox transformations is necessary to predict Hg availability for microbial methylation, its fate and transport in the environment. Previous studies have shown that a wide variety of microorganisms are capable of reducing the mercuric Hg(II) to elemental Hg(0) under anaerobic conditions, but others have indicated an inverse correlation between microbial biomass and Hg(0) production. In this study, we systematically examined the reduction kinetics and surface interactions between Hg(II) and washed cells of *G. sulfurreducens,* as influenced by the growth stage of cells, cell density, the presence or absence of various complexing ligands, including glutathione and naturally dissolved organic matter (DOM). We found that Hg(II) can be rapidly reduced to Hg(0) upon contact with washed cells, but reduction rates and extent are influenced by the growth stage, cell density and Hg(II)/cell ratio. The initial reduction rates can generally be described by a pseudo-first order kinetics with half-lives on the order of minutes to less than 2 hr. An optimal reduction of Hg(II) at a fixed concentration of 50 nM was observed at a cell density of ~10^{11} L^{-1}; an increase in cell density inhibited the reduction of Hg(II) due to surface adsorption and complexation of Hg(II) on bacterial cells. Similarly, the presence of complexing organic ligands inhibited the Hg(II) reduction at varying degrees, with glutathione among the most effective in inhibiting Hg(II) reduction and surface complexation by *Geobacter* cells. Our findings explain some previously observed inconsistencies with respect to the roles of microorganisms in Hg(II) reduction and may have important implications to the availability and bioaccumulation of Hg in the aquatic food web.

Mg isotope composition of the bulk silicate earth constrained by first princeples calculation

FANG HUANG[1*], ZHONG-QING WU[2], LI-JUAN CHEN[1]

[1] CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, USTC, Hefei, Anhui 230026. Email: fhuang@ustc.edu.edu

[2] School of Earth and Space Sciences, University of Science and Technology, Hefei, Anhui 230026, China

Comparisons of stable isotope composition of the bulk silicate earth (BSE) with chondrites have provided a plethora of important insights into the Earth's generation and evolution processes. Many recent studies argue that the Earth may have similar Mg isotope composition with the CI chondrites, suggesting that planetary accretion or mantle melting does not significantly fractionate Mg isotope composition [e.g., 1,2]. Because mantle samples from the depths greater than 150 km are rare, most studies used basalts and spinel-peridotite xenoliths representing the BSE assuming no measurable variation of δ^{26}Mg (<0.1‰) at the mantle's P-T conditions. However, recent studies clearly show that substantial equilibrium Mg isotope fractionation could occur to mantle minerals due to different C.N. and ionic strengths of Mg in the minerals [e.g., 3,4]. Thus it is necessary to examine the assumption before using shallow mantle samples to represent the BSE.

We use first-principles calculation to predict Mg isotope variations in mantle minerals with depths down to the core-mantle boundary. Our results show that increasing temperature dramatically decreases isotope fractionation, while increasing pressure can enhance it. Therefore, significant fractionation of Mg isotopes between mantle minerals at high P-T can still be expected. Along the mantle's geotherm, $\Delta^{26}Mg_{olivine\text{-}garnet}$ varies from ~0.5‰ (2GPa) to 0.2‰ (13.4 GPa, ~410 km), owing to the combined effects of different C.N. (6 in olivine vs. 8 in garnet) and increasing temperature. Wadsleyite is enriched in heavy Mg isotopes relative to olivine and ringwoodite likely due to mineral structure change. At 670 km discontinuity, ringwoodite (C.N.=6) is isotopically heavier than Mg-perovskite (C.N.=8) by 0.28‰ while it is identical with periclase (C.N.=6).

Our preliminary results suggest that Mg isotope compositions of the mantle peridotites could be quite heterogeneous. This brings up some uncertainties when extrapolating δ^{26}Mg of the BSE from basalt and spinel-peridotite data. Specifically, olivine and garnet, the two dominant Mg-bearing minerals in the upper mantle, show varying Δ^{26}Mg by ~ 0.3‰ with increasing the depth, meaning that olivine, garnet, or both have variable δ^{26}Mg. Therefore, it is difficult to predict variations of δ^{26}Mg of olivine and garnet along the temperature-pressure gradient. As δ^{26}Mg of the bulk mantle is a weighted average of the six- and eight- coordinated minerals, Mg isotope composition of the BSE may still be an open question.

Acanthomorphic acritarch fossils, including some interpreted to be early animal embryos and the resting stages of Metazoa offspring, first appear in the Doushantuo Formation of the Yangtze Gorges area (YGA)[1]. Previous investigators have linked the rise of acanthomorphic acritarchs to the termination of the Marinoan glaciation and diversafacation of early eumetazoans, but without specific ties to conditions in the YGA. Recently, however, Bristow *et al*. suggested that non-marine environments might have hosted the acanthomorphic acritarchs preserved in YGA[2]. Their principal argument supporting the non-marine hypothesis is the appearance of the trioctahedral clay mineral saponite in the lower part of Doushantuo Formation, which can form in alkaline conditions (pH > 9) most commonly found in non-marine settings. However, other possibilities exist for its formation. For instance trioctahedral clays can forms during weathering of mafic rocks.

Major and trace elemental compositions of the Doushantuo Formation from the YGA imply that sediments overlying the cap carbonate reflect two distinct sources. Member 2 was derived from surrounding Neoproterozoic mafic-to-ultramafic rocks, and Members 3 and 4 were likely sourced from recycled sediments with an average shale composition. Using a coupled geochemical and sedimentological approach we argue that the trioctahedral clay mineral saponite in the lower Doushantuo of the YGA are better explained as weathering products from the regional mafic-to-ultramafic hinterland delivered by rivers to a shelf lagoon of the Yangtze Gorges Basin. Therefore, the saponite of the YGA and the associated fossils are easily interpreted within a marine depositional context and, thus, the semi-restricted setting may have favored deposition of sediments with a local provenance signature.

Although weathering of mafic volcanics commonly leads to the formation of a mix of trioctahedral and dioctahedral clays, there have been reported cases of the formation of predominantly trioctahedral clays. Further, trioctahedral clays are the dominant products during the early stages of mafic rock weathering, with subsquent formation of dioctahedral clays. Thus, it is reasonable to imagine that rapid weathering rates after the Neoproterozoic Snowball Earth favored trioctahedral clay formation and preservation.

Towards an improved understanding of Paleoceanographic proxies for Antarctic Intermediate Water Circulation: A core-top perspective

KUO-FANG HUANG*, DELIA W. OPPO, WILLIAM B. CURRY AND JERZY S. BLUSZTAJN

Department of Geology and Geophysics, Woods Hole Oceanographic Institution, Woods Hole, MA, USA.

kfhuang05@gmail.com (*presenting author)

Abstract

The Atlantic Meridional Overturning Circulation has been recognized as a major component of the climate system and is important for oceanic heat transport on millennial and glacial-interglacial timescales (Burton et al., 1997; Rutberg et al., 2000; Piotrowski et al., 2005; Roberts et al., 2010). The records for an important component of this circulation - Antarctic Intermediate Water - are ambiguous, giving rise to conflicting interpretations about the long-term history of AAIW flow into the North Atlantic (Came et al., 2008; Pahnke et al., 2008). To further constrain the past AAIW variability, we systematically examine water mass proxies, such as nutrient tracers (Cd/Ca and $\delta^{13}C$) in benthic foraminifera and the Nd isotopes in uncleaned planktonic foraminifera using a set of multicore tops (KNR197-3, spanning depths of 380 to 3300 m) and measured seawater chemistry from the Demerara Rise in the western tropical Atlantic. AAIW and NADW overlie the Demerara Rise sediments at these water depths.

Both seawater Cd and $\delta^{13}C$ at Demerara Rise closely mimic salinity. Cd/Ca of the three benthic foraminifera (*C. pachyderma*, *C. wuellerstorfi* and *Uvi. spp*.) capture the regional seawater Cd profiles and are best explained by a single partition coefficient D_{Cd}= 2.7, similar to values typically found below 2000 m. $\delta^{13}C$ of individual specimens (*C. pachyderma* and *C. wuellerstorfi*) from multicore tops also reflect the different water mass isotopic compositions. Our seawater Nd isotope data follows the distribution of salinity, demonstrating conservative mixing of Nd in the water column at Demerara Rise. Furthermore, ε_{Nd} in uncleaned planktonic foraminfera faithfully record the seawater ε_{Nd}, suggesting that we will be able to reconstruct changes in the shape of bathymetric profile of ε_{Nd} through time and downcore ε_{Nd} changes at a single site in our study area. Preliminary downcore work will be presented.

Relationship between the Isotopic Compositions of Earth and Chondrites: Constraints from Calcium Isotopes

SHICHUN HUANG[1]* AND STEIN B JACOBSEN[1]

[1]Department of Earth and Planetary Science, Harvard University, huang17@fas.harvard.edu; jacobsen@neodymium.harvard.edu

Chondritic meteorites have been used to estimate the elemental and isotopic compositions for refractory lithosphile elements of the bulk Earth. Recent studies reported both mass-dependent and mass-independent isotopic differences between terrestrial rocks and chondrites. Such isotopic differences have been used to argue for (i) a hidden reservoir burried deep at the bottom of the mantle; (ii) certain elements partitioning into the Earth's core; or (iii) that the bulk Earth does not have a chondritic composition for the refractory lithosphile elements.

Here we present Ca isotopic measurements of three groups of chondrites (carbonaceous, ordinary and enstatite chondrites). Our results show that Ca is the only major element in addition to O that show both mass-dependent (δ-values) and mass-independent (ε-values) isotopic variations among chondrite groups. In contrast, all chondrite groups have essentially the same Mg, Si and Fe isotopic compositions. Our results show that $\delta^{44/40}Ca$ decreases in the order of enstatite chondrites > ordinatry chondrites > carbonaceous chondrites, with enstatite chondrites having the same $\delta^{44/40}Ca$ as the estimated bulk Earth value. Carbonaceous chondrites also have up to 3 ε units of ^{48}Ca excess compared to the Earth. In contrast, such ^{48}Ca excess is not observed in ordinary or enstatite chondrites.

Enstatite chondrities and the Earth have the same isotopic compositions for all major and minor elements (O, Ca, Ti, Cr) which exhibit substantial isotopic variations among different chondrite groups, with Si being the only exception. Available data show that enstatite chondrites have lower $\delta^{30}Si$ compared to the Earth's mantle. Since only EH chondrites, which have high metal contents and whose metals have very different Si isotopic composition, have been analyzed for Si isotopes, the measured Si isotopic compositions in EH chondrites may not represent the isotopic composition of their parental nebular reservoir.

The identical isotopic compositions of the Earth and enstatite chondrites and their very different chemical compostions imply that they are derived from the same parental nebular reservoir, but experienced different formation processes.

[3]State Key Lab of Oil and Gas Reservoir Geology and Exploitation, Chengdu University of Technology, Sichuan, PRC

Abstract

Samples were collected from marine carbonate reservoir of northeast of Sichuan province, China. And REE of those samples were analyzed to statement ΣREE, LREE, HREE, δEu and δCe geochemical characteristics. Using the mechanism of REE migration, enrichment and fractionation, the nature of fluid and diagenesis environment were distinguished. The impact of deep fluid was also analyzed to study the formation of carbonate rock geochemistry and the diagenesis environment.

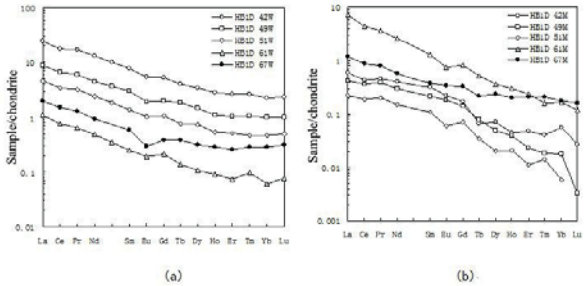

Figure 1. The REE partitioning patterns for (a) wall rock, and (b) veins

Results and Conclusion

The results show that during the diagenesis process of the original marine limestone, REE in protolith has been constantly depleted and manifested similar ΣREE values between wall rock and the veins. The δEu value of samples from wells Heba1 and Ma2 are greater than zero and less than 1, which indicates an open oxidizing environment. The δEu values of other drilling samples are greater than 1, which suggests an effect of high temperature hydrothermal fluids with Eu anomalies and hot water dissolution. Comparing with the veins and the Earth REE patterns, there're similar REE patterns between veins and the original mantle, which could be related to the activities of the mantle fluids.

A new pore-scale model of diffusion and advection of reactant in a dissolving porous media

CHRISTIAN HUBER[1*], BABAK SHAFEI[1], AND ANDREA PARMIGIANI[2]

[1]Georgia Institute of Technology, Atlanta, GA 30332, USA, christian.huber@eas.gatech.edu , babakshafei@gatech.edu
[2]University of Geneva, Geneva, Switzerland, andrea.parmigiani@unige.ch

We have developed a new model of pore-scale reactive transport based on the lattice Boltzmann method (LBM). LBM has already been successfully applied to reactive transport by Kang and co-workers [1 & 2]. Our model offers a natural approach to handle porosity changes in the solid matrix during dissolution and precipitation. It also uses an iterative solver for the coupling of the reactant transport with surface reactions which allows us to explore a wide range of reaction rates and non-linear heterogeneous reactions. In a first application, we present the results of calculations aiming at investigating the effect of matrix dissolution during multiphase flow (e.g. CO_2 injection into an aquifer). We find that although dissolution processes and multiphase flows in porous media generally lead to channelization, i.e. wormhole structure and capillary instabilities respectively, dissolution during multiphase flows stabilizes the reactive front leading yielding a homogeneous distribution of CO_2 in the pore space (see Fig. 1) [3]. In a second application, we incorporate subgrid-scale roughness at the solid-fluid interface in a single phase reactive transport model. The presence of surface roughness can significantly increase the reactive surface area at the pore-scale. We propose some simple laws for the development and evolution of a time-dependent local surface roughness as function of reaction rates and local chemical disequilibrium and investigate its effect on the development of flow and reactive patterns at the mesoscale (~100 pores/physical dimension).

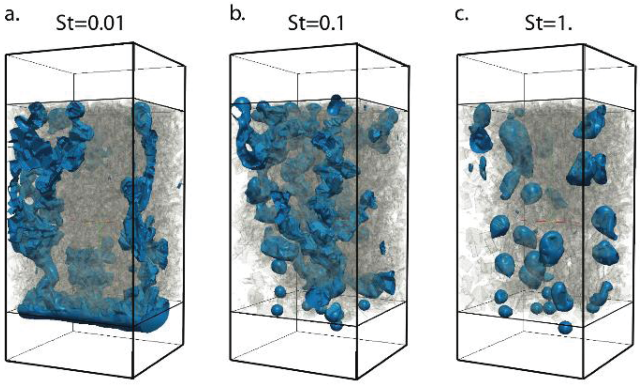

Figure 1: Snapshots of volatile (CO2) transport (blue) in a dissolving porous media with dissolution rates increasing from left to right.

Shale Gas: A Panacea for the Energy Woes of America?

J.D. HUGHES[1]

[1]Post Carbon Institute and Global Sustainability Research Inc., davehughes@xplornet.com

The Hype

Shale gas has been heralded as a "game changer" in the struggle to meet America's demand for energy. The "Pickens Plan" of Texas oil and gas pioneer T.Boone Pickens suggests that gas can replace coal for much of U.S. electricity generation, and oil for, at least, truck transportation[1]. Industry lobby groups such as ANGA declare "that the dream of clean, abundant, home grown energy is now reality"[2]. In Canada, politicians in British Columbia are racing to export the virtual bounty of shale gas via LNG to Asia (despite the fact that Canadian gas production is down 16 percent from its 2001 peak). And the EIA has forecast that the U.S. will become a net exporter of gas by 2021[3].

The Reality

Shale gas is expensive gas. In the early days it was declared that "continuous plays" like shale gas were "manufacturing operations", and that geology didn't matter. One could drill a well anywhere, it was suggested, and expect consistent production. Unfortuately, Mother Nature always has the last word, and inevitably the vast expanses of purported potential shale gas resources contracted to "core" areas, where geological conditions were optimal. The cost to produce shale gas ranges from $4.00 per thousand cubic feet (mcf) to $10.00, depending on the play. Natural gas production is a story about declines which now amount to 32% per year in the U.S. So 22 billion cubic feet per day of production now has to be replaced each year to keep overall production flat. At current prices of $2.50/mcf, industry is short about $50 billion per year in cash flow to make this happen[4]. As a result I expect falling production and rising prices in the near to medium term.

The Environmental Costs

The mantra that natural gas is a "transition fuel" to a low carbon future is false. The environmental costs of shale gas extraction have been documented in legions of anecdotal and scientific reports. Methane and fracture fluid contamination of groundwater, induced seismicity from fracture water injection, industrialized landscapes and air emissions, and the fact that near term emissions from shale gas generation of electricity are worse than coal. A sane energy security strategy for America must focus on radically reducing energy consumption through investments in infrastructure that provides alternatives to our current high energy throughput. Shale gas will be an important contributor to future energy requirements, given that other gas sources are declining, but there is no free lunch.

Spatial and seasonal variations of the δ^{30}Si signatures in the Amazon Basin

H.J. HUGHES[1], F. SONDAG[2], L. ANDRÉ[1]*, D. CARDINAL[3]

[1]Royal Museum for Central Africa, Tervuren, Belgium (* presenting author), harold.hughes@africamuseum.be
[2]LMTG (Université de Toulouse III, CNRS, IRD), Brasilia, Brazil
[3]LOCEAN, Université Pierre et Marie Curie, Paris, France

The Amazon Basin is the world's largest basin and covers an area of 6.1 million km^2 occupied for more than 96% of its surface by silicate rocks [1]. We present here the first large-scale study of riverine silicon isotopes signatures in the Amazon Basin. The Amazon and its main tributaries, which can be considered as representative of the main types of rivers in the basin, were studied at different seasons of the annual hydrological cycle. Concentrations of dissolved silicon (DSi) and of biogenic silica particles were measured as well as isotopic signatures of DSi. An occasional impact of diatoms growth on the silicon cycle and isotopic signatures is observed, but outside these periods of high biologic influence, δ^{30}Si signatures of the different rivers are shown to correlate with DSi concentrations. This is probably a consequence of the more important impact of clay formation during low flow period. The mean δ^{30}Si signature measured in the Amazon River itself is +1.0‰ (n=6), a value similare to that measured in the Congo River (+0.96‰ [2]). Very low isotopic signatures were measured in the upper Río Negro, confirming recent observations in Congolese black rivers. We also tested the homogeneity of the Amazon River regarding DSi concentration and isotopic ratio: A river cross-section shows the homogeneity of the Amazon River when diatoms activity is low. Our data provide evidences that silicon isotopic signatures of rivers result from a complex combination of biological and geological processes which contribution to the silicon biogeochemical cycle varies spatially and seasonally.

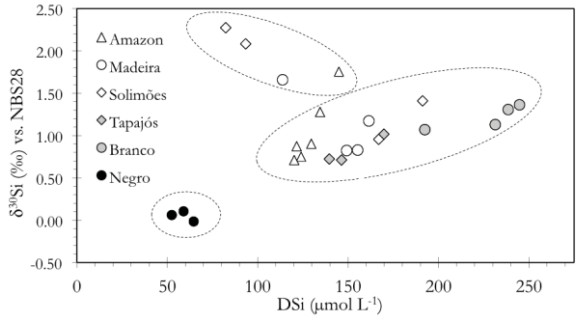

Figure 1:. Three groups of samples can be defined in the Amazon Basin: Samples showing a decreasing DSi concentration for increasing δ^{30}Si ratio, most probably due to diatoms uptake; samples showing a simultaneous increase of DSi concentration and δ^{30}Si ratio; and the Rio Negro samples

Experimental climate warming in a French peatland: impact on the abundance and distribution of branched GDGTs

A. HUGUET[1*], C. FOSSE[2], F. LAGGOUN-DEFARGE[3], AND S. DERENNE[1]

[3] ISTO, UMR 7327 CNRS–Univ. d'Orléans, Orléans, France

Branched glycerol dialkyl glycerol tetraethers (GDGTs) are complex lipids of high molecular weight, recently discovered in soils and produced by still unknown bacteria. They are increasingly used as paleoclimate proxies. Their degree of methylation, expressed in the MBT, was shown to depend on mean annual air temperature (MAAT) and to a lesser extent on soil pH, whereas the relative abundance of cyclopentyl rings of branched GDGTs, expressed in the (CBT), was related to soil pH. Northern peatlands contain approximately one third of the world's organic carbon and may play an important role in the responses of the global carbon cycle to climate change. The aim of this work was to study the effects of experimental climate warming on the abundance and distribution of branched GDGTs in a *Sphagnum*-dominated peatland (French Jura Mountains). Air temperature was experimentally increased using a warming system consisting of in situ open mini-greenhouses (Open-Top Chambers – OTCs). The effect of the OTCs was especially apparent in spring and summer, with an increase of mean and maximal air temperatures of ca. 1 and 3°C respectively. Branched GDGTs either present as core lipids (CLs; presumed of fossil origin) or derived from intact polar lipids (IPLs, markers for living cells) were analysed. Results showed that despite the short duration of the climate experiment (26 months), branched GDGT distribution was significantly affected by the temperature rise, supporting the empirical relationship between MBT and MAAT established from a large range of soils. The difference in branched GDGT-derived temperatures between the control and the OTC plots was in the same range as the increase in maximal temperature induced by the OTCs in spring and summer, suggesting that branched GDGT-producing bacteria might be more active during the warmest months of the year. The OTC treatment had no significant effect on the abundance of branched GDGTs, mainly present as "fossil" CLs (70 to 85% of the total extractable branched GDGTs). Furthemore, no significant differences in branched GDGT distribution were observed between CLs and IPLs, which both provided higher MBT and MAAT values for the OTCs. This suggests that the fossil pool of branched GDGTs has a very fast turnover (less than the 2 year duration of the experiment) at peat surface and that branched GDGT distribution may rapidly reflect changes in environmental conditions.

This work was funded as part of the PEATWARM initiative through an ANR (French National Agency for Research) grant (ANR-07-VUL-010).

Dissolved platinum in major rivers of East Asia

YOUNGSOOK HUH[1*], TSEREN-OCHIR SOYOL-ERDENE[2]

[1]Seoul National University, Seoul, Korea, yhuh@snu.ac.kr (* presenting author)
[2]Korea Polar Research Institute, Incheon, Korea, soyoloo@kopri.re.kr

Dissolved platinum concentrations of eleven large pristine river systems in East Asia (~200 samples) were determined to better constrain the oceanic platinum budget. Most samples had concentrations less than 1.4 pM, and relatively high concentrations up to 5.8 pM were measured in only approximately 6% of the samples. Principal component analysis was carried out using Pt, major elements (Na, K, Mg, Ca, HCO_3^-, Cl^-, SO_4^{2-}, Si), Sr, and $^{87}Sr/^{86}Sr$ of the dissolved load to derive the potential sources of Pt. The Pt in the main (<1.4 pM) group was best clustered with Mg, HCO_3^-, Ca, Sr, and SO_4^{2-}, interpreted as weathering of carbonates and associated gypsum. The Pt in the outlier group was best clustered with Si, K, $^{87}Sr/^{86}Sr$, Ca, and HCO_3^-, interpreted as weathering of silicates. The median Pt concentrations of the individual river systems had only a small range, from 0.18 pM (Duman) to 0.63 (Huang He), and the difference in Pt yield mainly resulted from the difference in runoff. The rivers draining the eastern Tibetan Plateau – the Salween, Mekong, Chang Jiang (Yangtze), Hong (Red), and Huang He (Yellow) – had relatively higher Pt yield than the rivers of the Russian Far East – the Amur, Lena, Yana, Indigirka, and Kolyma. The discharge-weighted mean Pt concentration was 0.36 pM for the eleven river systems of East Asia. If this value is extrapolated globally, the estimated riverine flux of dissolved Pt to the ocean is 13×10^3 mol y^{-1}. Based on this riverine flux, the estimated oceanic residence time of Pt is 3×10^4 years.

Atom exchange between aqueous Fe(II) and Fe oxides: Fate of As(V)

BRITTANY L. HUHMANN*, MICHELLE M. SCHERER, AND ANKE NEUMANN

Department of Civil and Environmental Engineering, The University of Iowa, Iowa City, USA (*correspondence: brittany-huhmann@uiowa.edu)

Human exposure to arsenic in groundwater is a global concern, and arsenic mobility in groundwater is often controlled by iron minerals. Recently, it has been shown that electron transfer and atom exchange between aqueous Fe(II) and iron oxides can enable structural incorporation of trace elements into iron oxides [1]. The structural incorporation of As(V) into magnetite has been observed during magnetite precipitation [2], and during the reductive transformation of lepidocrocite [2] and 2-line ferrihydrite [3] to magnetite. As(V) does not appear, however, to be incorporated into goethite and hematite in the presence of aqueous Fe(II) [4]. To better understand the controls on As(V) incorporation into iron oxides, we investigate whether the presence of As(V) inhibits atom exchange between aqueous Fe(II) and goethite or magnetite, and whether As(V) is incorporated into goethite, magnetite, and ferrihydrite in the presence of Fe(II).

Enriched Fe isotope experiments were used to investigate the extent of Fe atom exchange between aqueous Fe(II) and goethite in the presence of varying concentrations of As(V). Near-complete atom exchange between aqueous Fe(II) and goethite was observed at 1 mg/L As(V), whereas exchange was severely inhibited at the exceedingly high concentration of 20 mg/L As(V). Surface-adsorbed As was determined by phosphate extraction, and the remaining As was recovered by complete dissolution of the solid. As(V) remained adsorbed to the surface of the goethite rather than being incorporated, with 96% of the As(V) recoverable by a phosphate extraction on the time frame of near-complete atom exchange.

Additional experiments are underway to explore the fate of As(V) during Fe atom exchange between aqueous Fe(II) and magnetite and ferrihydrite. We hypothesize that atom exchange between aqueous Fe(II) and magnetite will occur in the presence of As(V) and that that As(V) may be incorporated into the magnetite structure, since As incorporation into magnetite has been observed in other systems [2,3].

Tungsten isotopic evolution of the earliest terrestrial mantle

MUNIR HUMAYUN[1*], ALAN D. BRANDON[2], KEVIN RIGHTER[3],

Introduction

Recently, two reports of $\varepsilon^{182}W>0$ in Archean samples [1-2] challenge previous conceptions of a homogeneous W isotopic composition of the mantle. The removal of these positive anomalies by late accretion of a chondritic veneer [1] can be quickly refuted by comparison with lunar breccia siderophile element abundances which contain too low an accreted meteoritic component to affect a mantle-wide change in W isotope composition. Here, we present two sets of alternative models to interpret this incredible finding.

Results and Conclusions

Post core-formation mantle: Because D(metal-silicate) for W diminishes with increasing depth [3], the deep mantle has a higher W abundance, and a lower Hf/W ratio and consequently evolves a negative anomaly in $\varepsilon^{182}W$ while the upper mantle evolves a positive $\varepsilon^{182}W$. Subsequent solid-state convection (4.55-2.8 Ga) mixes away the complementary $\varepsilon^{182}W$ anomalies. This set of models predicts that the complementary negative anomalies in $\varepsilon^{182}W$ should eventually be discovered in ancient magmatic rocks.

Hadean melting models: Tungsten is significantly more incompatible (like U, Th and Ba) than Hf, the latter being similar in compatibility to Nd and Sm. Our results show that extraction of low-degree partial melts (<2%) leaving a Hadean depleted mantle that can have Sm/Nd~20% higher than chondrites [4] also creates a $f_{Hf/W}$~2-3, sufficient to generate the anomalies observed [1,2] in the first 100 Ma of Earth history. These models increase Hf/W and Sm/Nd ratios in a correlated fashion explaining the tendency of positive anomalies of $\varepsilon^{182}W$ to occur in rocks with positive $\varepsilon^{142}Nd$. Recycling of the complementary Hadean crust would result in negative anomalies, while partitioning of W into an enriched "hidden reservoir" [5] would not. Evidence from Hadean zircons indicates crust was preserved from 4.4 Ga onwards [6], too late to constrain $\varepsilon^{182}W$ anomalies which are more challenging to create after the first 100 Ma. ^{142}Nd anomalies indicate a melting event around 35-75 Ma after solar system formation [4], the upper end of which is consistent with our models of Hf/W fractionation that also yield a depleted mantle composition consistent with DMM [7]. The presence of $\varepsilon^{182}W$ anomalies in the Hadean mantle complicates the search for W isotopic evidence of core-mantle interaction, now predicted to be $\varepsilon^{182}W$~ -0.1 [8].

[2]MINES PARITECH, Fontainebleau, France

Enhanced water-rock interaction in aquifers overlying CO_2 storage sites in deep saline formation can be expected in the case of CO_2 leakage, leading to a release of geogenic compounds into freshwater resources. Our study investigates the use of trace elements and several isotope systematics (B, Li, C, O, D, Sr) as monitoring tools to detect CO_2-leaks in aquifers. For this, we develop batch experiments under controlled pCO_2 conditions. The glauconitic Albian greensands of the Paris Basin were chosen as interacting solid phase because i) the Paris Basin contains aquifers identified as CCS targets and ii) the Albian aquifer is a deep freshwater resource of strategic national importance. The selected greensand sample consists mainly of quartz with presence of glauconitic minerals and traces of apatite, rutile, ilmenite. The water used for the experiments was pumped from the confined part of the Albian aquifer. PTFE reactors (liquid/solid ratio of 10, pCO_2= 2 bar; room temperature, continuous pH measurements) were run simultaneously, over 1 day, 1 week, 2 weeks and 1 month. A pH drop from 6.6 to 4.9 was noticeable immediately after the injection, due to CO_2 dissolution (ΔHCO_3 = 0.8 mmol/L). Cations and silica increased by a factor of 2 (Ca), 2 (SiO2), 1.5 (K), 1.3 (Mg), 1.5 (Sr), 3.7 (Li), 4.2 (B) for t=1 month. From 1 day to 1 month of contact with CO_2, the $\delta^{13}C_{DIC}$ decreased from -15.7 ‰ to -21 ‰ vs. PDB suggesting a proton-consuming process which entails supplementary CO_2 dissolution. Weathering reactions and surface complexation consume acidity and account for the observed chemical variations. Glauconitic minerals being the main B-bearing phase, the evolution of the aqueous B concentrations indicates their implication in the water-gas-mineral interactions. This is supported by a shift of $\delta^{11}B$ towards more negative values in the presence of CO_2. The $\delta^{11}B$ is different according to the origin of the B (surface or structural), which gives additional information of the actual processes at stake during the evolution.

We focus here on the complex weathering behavior of glauconitic minerals, as poorly defined phases with regards to its mineral structure, under pCO_2 and low-pH conditions, constraining e.g. dissolution rates and surface complexation models through isotope and geochemical data.

A comparative mineral magnetic study of the intrabasaltic palaeosols and modern soils from the Deccan volcanic province, India

Sajid Hundekari[1*], Satish Sangode[2] and Mohammed Rafi Sayyed[3]

[1]Geology Department, Poona College, Pune, India, sajid_hundekar@yahoo.com (presenting author)
[2]Geology Department, University of Pune, India, sangode@unipune.ac.in
[3]Geology Department, Poona College, Pune, India, mrgsayyed@yahoo.com

Total 65 samples representing a variety of red, green and brown bole beds (intrabasaltic palaeosols), the associated underlying and overlying Deccan trap basalts and the modern soils (developed upon the basalts during Holocene) are studied for their mineral magnetic characterization augmented with field examination. The red boles show highest Fe-oxide concentrations amongst the studied intrabasaltic palaeosols but lower than the modern soils formed over these basalts. The qualitative mineral magnetic parameters however indicate a polygenetic control of the mineral species for of these bole beds with a unimodal finer superparamagnetic (SP) fraction that may be of pedogenic origin or product of baking. Comparisons of mineral magnetism of with the unbaked modern soils however suggest that the finer faction is from baking effects. This depicts a complex recycled nature for the red boles with pigmentary hematite imparting the red colouration over a combination of detrital mixtures. The green boles with low ferrimagnetic concentration indicate less oxidative but humid conditions that may possibly occur during the short events of volcanic winters. Although the bole beds largely depict the recycled nature of the magnetic mineral concentrates disproportionate to the concentrations of magnetic minerals in the underlying (/parent) basalts (unlike the modern soils). This suggests in a profile indicate the independent controls like the intensity and duration of baking in the red boles in particular and the palaeoweathering and palaeoenvironments in general (in all the bole beds). The mineral magnetic results further do not support existence of systematic soil profiles amongst any of the studied sections and the genesis of bole beds is largely governed by the surface water interaction with the weathering products. A detailed knowledge on these bole beds can lead to understanding on the post-eruptive paleoweathering and palaeoenvironmental conditions and hence demand a during the formation of these intrabasaltic bole beds employing a multi-proxy approach is therefore warranted in further understanding and characterizing the genesis of large variety of intrabasaltic bole beds which abundantly occur in the Deccan volcanic province of India including mineral magnetism.

Helium-4 dating of groundwater in the Green River Formation, Piceance Basin, northwestern, Colorado, USA

ANDREW G HUNT[1*], PETER B. MCMAHON[1], JUDITH C. THOMAS[2] AND RICHARD J. MOSCATI[1]

[1]U.S. Geological Survey, Denver, CO, USA
ahunt@usgs.gov (* presenting author)
pmcmahon@usgs.gov, rmoscati@usgs.gov
[2]U.S. Geological Survey, Grand Junction, CO, USA
juthomas@usgs.gov

Renewed oil and gas production/development in Colorado has highlighted a need to evaluate groundwater resources that overlie current and future production reservoirs in order to define the potential impacts of development activities. Our study focuses on the Piceance Basin in northwestern Colorado, where current hydrocarbon production/development could threaten water quality in the Green River Formation. Given the environmental and economic importance of the bedrock aquifers and associated sediments and the complexity of the bedrock hydrogeology, it is important to develop an understanding of basic system characteristics such as dissolved gas composition, groundwater residence time (or age), and sources of recharge. Our approach was to sample pre-existing well clusters in the basin for dissolved gas compositions, chemistry, noble gas isotopes, and tritium to develop conceptual models of groundwater flow in the upper aquifers.

The application of ^{4}He as an indicator of groundwater residence time has been used to interpret groundwater age for time scales of tens of years to hundred of thousands of years, making it a unique tracer that has both strengths and weaknesses over other radiogenic tracers (e.g. ^{3}H, ^{85}Kr, ^{14}C, ^{36}Cl, and ^{81}Kr) currently in use. Considerable debate has arisen over the interpretation of estimated ^{4}He production rates owing to a lack of understanding of the actual *in-situ* helium production and definition of possible flux of ^{4}He from deeper sources. Error can be further exaggerated by the presence of older reservoirs that interact within the younger, active flow-systems at or near flow boundaries, violating assumptions inherent to the dating application. For the Green River Formation, the possibilities of variable recharge altitudes and migration of gas from deeper sources could complicate the simple application of the ^{4}He dating method. Despite these possibilities, most samples show noble gas compositions that reflect normal air saturated water associated with high altitude recharge, allowing for a simple interpretation of excess helium in the samples. Current age calculations combine the measured concentrations of uranium and thorium in the aquifer and confining units to produce an *in-situ* flux model for ^{4}He accumulation in the basin aquifers, showing an age distribution that agrees well with the conceptual model of groundwater flow and indicate increasing biogenic methane concentrations with increasing age.

Non-gem diamonds from the Diavik diamond mine, Canada: Tracers for cratonic mantle metasomatism

LUCY HUNT[1*], THOMAS STACHEL[1], D. GRAHAM PEARSON[2], RICHARD STERN[1], KARLIS MUEHLENBACHS1 VANESSA MARCHEGGIANI-CRODEN[1] AND HAILEY MCLEAN[2].

[1]University of Alberta, Edmonton, Canada, lchunt@ualberta.ca (* presenting author)
[2]Rio Tinto, Diavik Diamond Mines Inc., Yellowknife, Canada, Hayley.McLean@riotinto.com

Non-gem diamonds are valuable tracers of mantle metasomatism, trapping micro-inclusions of the melt/fluids which formed them and allowing direct analysis of the changing chemical environment in which they grew. Approximately 600 non-gem diamonds were selected for this research, including: coated diamonds; fibrous cubes, and polycrystalline boart. We aim to establish the changes in physical and chemical conditions accompanying the transition from gem to non-gem diamond growth and how this affects the sub-cratonic lithospheric mantle (SCLM).

Cathodoluminescence (CL) of five sectioned non-gem diamonds revealed fine scale complexities not observed in visible light, likely related to differences in nitrogen centres. A subset of diamonds change outward from fibrous cubic {100} to more gem-like octahedral habit. This transition may be linked to decreasing supersaturation in the diamond precipitating melt/fluid (e.g. [1]).

Secondary Ion Mass Spectromotry was used to determine N content and δ^{13}C along transects perpendicular to growth of the diamond sections. The coats are generally higher in N content (average 1700ppm) with more negative δ^{13}C (-8 to -5.5‰) than the associated cores (1300ppm and -4.5 to -5‰). The change from gem to non-gem growth appears visually sharp and may represent precipitation from two distinct fluids. However, a subtle shift in N content and δ^{13}C is already observed prior to the visible core-coat transition in two of the three coated stones. This suggests that a more continuous evolution of the diamond preciptating medium, possibly through mixing processes, may have prompted non-gem growth after a critical point of supersaturation was reached. The mantle-like δ^{13}Cvalues suggest a melt/fluid derived from the asthenosphere. Such an interpretation was also made based on Sr–Nd–Pb isotopes and trace elements of fibrous diamonds [2]. The authors suggested fluid mixing from at least two distinct sources — ancient enriched lithosphere and the underlying convecting mantle.

Detailed research on a 54 carat Diavik boart fragment indicates formation from a different type of fluid/melt. The δ^{13}C is typical of eclogitic diamonds (~23.6‰), however, the intergrown minerals are predominantly G9 garnet and peridotitic clinopyroxene. This suggests interaction of a slab derived melt/fluid with a very negative δ^{13}C with mantle peridotite.

Non-gem diamonds thus provide vessels to carry both samples of, and evidence for, melts/fluids operating as metasomatic agents in the SCLM.

Impact of seasonally variable soil carbonate formation on paleotemperature records from clumped isotopes

KATHARINE W. HUNTINGTON[1*], NATHAN PETERS[2], AND GREGORY D. HOKE[3]

[1]University of Washington, Dept. of Earth and Space Sciences, Seattle, USA, kate1@uw.edu (* presenting author)
[2]University of Washington, Dept. of Earth and Space Sciences, Seattle, USA, petersn@uw.edu
[3]Syracuse University, Dept. of Earth Sciences, Syracuse, USA, gdhoke@syr.edu

Reconstructing environmental temperatures from the continental geologic record is important for investigating the evolution of life, climate, tectonics, and landforms, yet direct temperature estimates are difficult to obtain from conventional isotopic and paleobotanical proxies. Measurement of 'clumped' ^{13}C-^{18}O bonds in calcium carbonate provides independent estimates of the formation temperature, $\delta^{13}C$ value, and $\delta^{18}O$ value of the carbonate and enables calculation of the $\delta^{18}O$ value of the water from which the mineral grew--each of which can provide important paleoenvironmental constraints. When applied to pedogenic carbonates, clumped isotope thermometry can quantify Earth surface paleotemperature and the $\delta^{18}O$ value of ancient surface waters, from which changes in climate or surface elevation might be inferred. However, recent studies suggest a strong seasonal bias in soil carbonate growth, complicating the interpretation of both temperature and $\delta^{18}O$ data from paleosols.

We use clumped isotope thermometry of recent soil carbonates and monitoring of local weather and soil subsurface conditions to investigate how seasonal variations in environmental factors such as soil temperature, precipitation, and vegetation influence rates of soil carbonate formation. Pedogenic carbonate samples formed in Holocene to Recent soils were collected from soil pits along a transect spanning 2 km of relief in the southern Central Andes of Argentina (33°S) with high seasonal variations in precipitation, air temperature, and soil temperature.

Because soil carbonate formation is generally favored in warm, dry conditions, we expected carbonate growth temperatures from clumped isotope thermometry to exceed mean annual soil temperatures at the sample sites. Instead, we find clumped isotope temperatures vary significantly between mean annual and and greater than mean annual soil temperatures. Samples below 2000 m elevation (where winters are dry) record temperatures from 0 to 4.5°C above mean annual soil temperature, while samples above 2000 m (where summers are dry) are >5.5°C above mean annual soil temperature, suggesting the influence of seasonal variations in both temperature and precipitation. For some sites, clumped isotope temperatures for samples at depths >50 cm in the soil profile exceed maximum soil temperatures measured over the period of record, likely reflecting enhanced carbonate formation during warm periods over the last 10^2-10^3 years. Temperatures for these deeper samples also exceed temperatures for samples near the surface, suggesting that sampling paleosols deep in the soil profile, a practice designed to avoid large temperature bias, could actually introduce greater biases in soil temperature estimates used to interpret conventional $\delta^{18}O$ data.

The effect of different metal species on the evolution with pressure of hydration clusters in water vapour

N.C. HURTIG*, A.A. MIGDISOV AND A.E. WILLIAMS-JONES

Earth & Planetary Sciences, McGill University, Montreal, QC, Canada (*presenting author: nicole.hurtig@mail.mcgill.ca)

The hypothesis that transport of metals by vapour is a viable mechanism for ore formation in magmatic-hydrothermal systems is supported by fluid inclusion data and the occurrence of metal-rich incrustations around fumaroles. A feature of this hypothesis is that hydration of metal species in water vapour is an essential factor in making such transport possible [1,2]. Indeed, hydration has been shown to increase concentrations of Ag and Au in the gas phase by several orders of magnitude over those calculated using volatility data. Nevertheless metal concentrations determined experimentally are substantially lower than those reported for vapour inclusions in magmatic hydrothermal systems.

We have shown previously that hydration numbers are not constant but increase exponentially with increasing water pressure. As a result, metal solubility increases by orders of magnitude from its values at low pressure to those at conditions approaching saturation of the vapour with liquid. In the current study, we are building on this earlier work by conducting experiments designed to determine the effect of different metallic vapour species on the nature of the surrounding hydration cluster with changing P_{H_2O}.

The experiments were conducted in batch-type Ti autoclaves at a constant oxygen fugacity, buffered by the assemblage MoO_2-MoO_3. From comparison of the experimental data sets for $AuCl(H_2O)_n$ and $MoO_3(H_2O)_n$, it is apparent that the solubility of these two species is described by different exponential functions. The solubility of the Au-chloride species is, within experimental error, independent of pressure below 87 bars P_{H_2O} and increases with increasing pressure to a value three log units higher at conditions approaching saturation of the vapour with liquid. By contrast, the solubility of the Mo-oxide species is only observed to increase above 150 bars P_{H_2O}, and at conditions approaching saturation, is only 1.5 log units higher than at pressures below 150 bars P_{H_2O}. This likely indicates that the molecular structure or the type of bonding of the metal species has an important control on the nature and size of the hydration clusters.

Experiments performed at conditions of saturation, i.e., with vapour and liquid present, indicate that there is a continuum between metal solubility in the vapour and that in the corresponding liquid. Above the critical point, the form of the hydration curve does not change significantly, indicating the formation of stable hydration clusters under these conditions and a continuous increase in solubility with increasing P_{H_2O} from vapour-like to liquid-like supercritical fluids.

[4]Robarts Research Institute, Imaging Research Lab, London, Canada

Brachinites are thought to be the residuum of a partially melted asteroid [e.g. 1-3] and offer insights into the initial stages of asteroid differentiation. Multiple splits from single brachinites show differences in highly siderophile element (HSE) abundances, likely reflecting the effects of heterogeneous phase distribution and uneven weathering [3]. Weathering is an important issue as it can obscure primary information on parent-body processes. We report a detailed Raman spectroscopy, micro-computed tomography (micro-CT) and laser-ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) study of weathering and phase distribution for brachinite Northwest Africa (NWA) 4872.

Raman analyses employed for investigating weathering products used a Horiba LabRAM Aramis micro-Raman spectrometer with a 532 nm, 50 mW laser (filtered to 10% power). *In situ* mineral REE and HSE abundance analyses used a New Wave Research UP213 (213 nm) laser-ablation system coupled to a Thermo-Finnigan Element 2 ICP-MS. Micro-CT scans employed for investigating phase distribution were run with a GE eXplore speCZT using a X-ray voltage of 110 kV and a beam current of 32 mA.

Raman analyses showed a redistribution of S from the initial troilite resulting in S-rich areas (mostly marcasite) and S-poor areas (mostly Fe-oxide). Studies of weathering in martian meteorites have found marcasite [e.g. 4] and sulphur removal from troilite has been linked to hot desert weathering [5]. Absolute abundances of HSE were hard to determine by LA-ICP-MS due to variable degrees of alteration, but relative abundances reveal that positive Ru-anomalies that are characteristic of brachinites [3] are common to weathered sulphide grains as well as to fresh troilite. Variability in elements were observed relative to the Ru-anomaly and grain-to-grain variations in Re and Os were seen. This accounts for differences in HSE abundances and Re/Os seen in separate splits of NWA 4872.

The light REE, Ba, Sr, U and Pb did not show elevation related to weathering in whole rock analyses [3]. This is consistent with the observed weathering. Weathered sulphide and metal were widespread; however, silicates showed no obvious weathering, no carbonate was found and sulfate was minimal. The measured splits of NWA 4872 appear to be influenced mostly by uneven weathering. However, micro-CT analysis showed a heterogeneous distribution of high density grains. This is likely true of other brachinites and could affect measured bulk trace element abundances.

Experimental constraints on the evolution of alkaline magmas from Ross Island, Antarctica: A case for CO_2-dominated volcanism

KAYLA IACOVINO[1*], CLIVE OPPENHEIMER[1], BRUNO SCAILLET[2], PHILIP KYLE[3]

[1] University of Cambridge, Dept. of Geography, Cambridge, UK, ki247@cam.ac.uk (* presenting author) co200@cam.ac.uk

[2] Université d'Orléans, ISTO, Orléans, France bscaille@cnrs-orleans.fr

Background and Experimental

Erebus volcano on Ross Island, Antarctica is home to the only phonolite lava lake in the world and, in combination with the continuous suite of alkaline lavas found in outcrop, provides an excellent natural laboratory for studying the genesis and evolution of alkaline magmas at a rift setting. Two geochemical lineages make up the majority of lavas erupted from Erebus and the surrounding basaltic volcanic centers at Hut Point Peninsula and Mts. Bird and Terror: The Erebus Lineage (EL) lavas and the Dry Valley Drilling Project (DVDP) lavas taken from drill core [1]. The occurence of kaersutite phenocrysts in DVDP lavas, attributed to a higher f_{H2O} and lower temperatures, is the key mineralogical distinction between these two lineages. Modelling suggests that both lineages evolved through fractional crystallization from parental basanite melt [2].

High pressure and temperature experiments (2−4 kbars; 1000−1150 ° C) with added H_2O and CO_2 (X_{H2O} varying between 0−1) were performed with primitive members from both EL and DVDP lavas to investigate the evolution of these magmas.

Results and Conclusions

Preliminary results show that only very CO_2-rich conditions (X_{H2O} approaching 0) reproduce the mineralogy of natural samples, even for kaersutite-bearing assemblages. This is consistent both with measurements of gas emissions and melt inclusion data. Kaersutite, which only occurs in DVDP lavas, is the liquidus phase in experiments carried out with EL samples, even when no water was added to the experimental capsule (some H_2O is present, however, even in “dry” runs from the reduction of Fe_2O_3 in the melt). This indicates that: a) DVDP and EL lavas are likely sourced from the same parent magma – that is, the differences in mineralogy and geochemistry between DVDP and EL lavas is caused by slight variations in differentiation and eruption conditions, and b) assuming that f_{H2O} controls the presence or lack of kaersutite, only a very small amount (<1 wt%) of H_2O is needed to stabilize the phase, making it a very precise threshold indicator of dissolved H_2O contents in Ross Island melts. In contrast, the occurrence of amphibole in calc-alkaline magmas is typically indicative of at least 4 wt% dissolved H_2O.

Previous work has made the case for deep CO_2-fluxing at Erebus to explain CO_2-rich gas emissions and the induction of crystallization in the magmatic system [2]. Further work aims to determine whether CO_2-fluxing is necessary to achieve the gas composition at Erebus and, ultimately, to determine the deep source of the carbon feeding the volcano.

Late Cretaceous migmatites in the southern Mojave Desert and their contribution to gabbro genesis and magmatic diversity

ADAM J. IANNO* AND SCOTT R. PATERSON

Department of Earth Sciences, University of Southern California, Los Angeles, CA, USA, ianno@usc.edu, paterson@usc.edu

Within the tilted crustal section found at Joshua Tree National Park in the southern Mojave Desert of California, we observe a >100 km long "heterogeneous sheeted complex" composed of meter-thick, tabular, intrusive igneous sheets that were intruded into Proterozoic gneisses that were locally partially molten. The sheeted complex contains a wide range of composition and texture, but is primarily composed of tonalites and two-mica garnet granites. We are testing the hypothesis that the genesis of this sheeted complex is likely intricately connected to the partial melting by a mantle-derived heat source of a heterogeneous package of Proterozoic host rocks.

In this study, we focus on the subset of hornblende gabbros present to better trace migmatization and crystal segregation processes. We have analyzed samples for bulk rock and single mineral chemistry, Sr and Nd isotopes, and U-Pb zircon ages to complement geologic mapping and microscopy for these hornblende gabbros. Samples contain hornblende + plagioclase ± clinopyroxene or biotite ± quartz, are medium to coarse-grained, and are equigranular to porphyritic in texture (hornblendes range up to 3 cm in length in hand sample). Samples range in melt fraction and amount of host rock present, and some sheets and pods observed have a cumulate texture and predominance of hornblende suggestive of fractional crystallization. Later greenschist-facies metamorphism overprints many of the gabbros observed. Crystallization ages are 74-78 Ma (U-Pb in zircon), although all samples have inherited zircon cores of ~1700 Ma. Two diatexites have been measured at 0.707 to 0.709 Sr_I, -12.4 to -13.6 εNd.

The hornblende gabbros of Joshua Tree National Park are primarily formed by a combination of partial melting of metamafic rocks and mantle-sourced magmatism. In some cases, this is followed by a period of fractional crystallization to form hornblende cumulates. Leucosomes derived from partial melting of metamafic rocks or melt extracted from these hornblende gabbro magmas are plagioclase-dominated and leucotonalitic to leucodioritic. As leucosomes and neosomes from metamafic protoliths rise and mix with those from metafelsic/quartzofeldspathic protoliths and mantle-sourced magmas, a continuum of melt compositions between tonalite and peraluminous granite is formed. Evidence of mixing exists down to the thin section scale and may explain the formation of biotite in some samples of otherwise K-deficient hornblende gabbro diatexites. These mixing and fractionation processes occur in igneous compositions beyond the gabbros and can also explain the textural diversity of magmas observed in the heterogeneous sheeted complex.

Sediments are the ultimate long-term sink for organic carbon (OC) on Earth, thus playing an important role in the global cycles of O_2 and CO_2. Estuaries and river deltas are major conduits for terrestrial organic matter (OM) into marine systems, where it is mixed with locally produced OM and is eventually deposited and buried in the sediment bed. About 45% of global OC burial occurs along these river deltas and estuaries [1], therefore it is of interest to follow OM deposition and preservation in these terrestrial to marine transition zones. We chemically fractionated bulk OM from a series of sediments from the St. Lawrence Estuary and Gulf into distinct reactivity classes. We define three such OM fractions based on pioneering work by Hedges and Keil (1995) who classified OM based on chemical reactivities: labile (degradable at similar rate under oxic and anoxic conditions), non-hydrolyzable (degraded primarily under oxic conditions), and refractory (preserved on long time scales independently of redox conditions). Here we present data on the spectroscopic (HR-MAS $^{1}H/^{13}C$ NMR) characterization of the non-hydrolyzable fraction because of its importance in the long-term burial of OC below the seafloor. We used mild oxidation methods (RuO_4) followed by chromatographic and compound-specific isotope analysis ($\delta^{13}C$ CSIA) of the oxidation products. Combining results from the bulk and molecular analytical techniques provides insights into the composition and cycling of non-hydrolyzable OM in transitional system, from which OM preservation can be better understood.

Diamond growth from organic carbon suggested by coupled $\delta^{18}O$-$\delta^{13}C$ variations in diamonds and garnet inclusions

RYAN B. ICKERT[1*], THOMAS STACHEL[1], RICHARD A. STERN[1], JEFF W. HARRIS[2]

[2]Canadian Centre for Isotopic Microanalysis, Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Canada, ryan.ickert@gmail.com
[2]School of Geographical and Earth Sciences, University of Glasgow, Glasgow, Scotland

The sources of carbon in the mantle and the mechanisms of its transport and precipitation as diamond are poorly understood. Diamond itself contains only a limited amount of geochemical information, primarily in the form of carbon isotope ratios and nitrogen abundances, and therefore a substantial effort has focussed on relating syngenetic mineral inclusions to their diamond hosts. For example, it is well known that, on a worldwide scale, diamonds with eclogitic inclusions have a distinct $\delta^{13}C$ distribution when compared to more abundant diamonds with peridotitic inclusions. Eclogitic diamonds have a distribution that extends from mantle-like $\delta^{13}C$ values (ca. -5‰), to very light carbon (<-20‰), whereas peridotitic diamonds have a distribution that clusters close to -5‰, without the long tail. The relatively low $\delta^{13}C$ values have been explained by either the subduction of organic carbon [1], the presence of heterogeneous primordial carbon reservoirs in the mantle [2], or high-temperature fractionation [3].

Here we report high-precision SIMS $\delta^{18}O$ measurements ($2\sigma <$ ±0.4‰) of eclogitic garnet inclusions in diamonds from three distinct deposits, Damtshaa (near the Orapa mine) in Botswana; Argyle in Australia; and ultradeep inclusions from Jagersfontein, South Africa. The measured $\delta^{18}O$ values are highly variable, and the distributions of each locality are clearly distinct. Damtshaa garnet inclusions range from +4.8‰ to +8.8‰ (n=15) and have a broadly similar distribution to $\delta^{18}O$ values of eclogite xenoliths. Argyle garnet-inclusions range from +5.9‰ to +10.8‰ (n=29), and are skewed towards ^{18}O-rich isotopic compositions. Ultradeep, majoritic garnet inclusions from Jagersfontein have a narrow range between +8.6‰ and +10.0‰ (n=11).

All three localities are distinct from each other in their univariate $\delta^{18}O$ and bivariate $\delta^{18}O$-$\delta^{13}C$ distributions. Damtshaa has negatively correlated $\delta^{18}O$-$\delta^{13}C$, Argyle has a distribution that is offset from "mantle-like" ^{18}O-^{13}C distributions, and Jagersfontein has low-variance $\delta^{18}O$-$\delta^{13}C$, but at anomalously high-$\delta^{18}O$ and low-$\delta^{13}C$. Importantly, none have the distribution expected from independent knowledge about $\delta^{18}O$ values of cratonic eclogites and the sampling distribution of $\delta^{13}C$ values in eclogitic diamonds. The association of crustal-like $\delta^{18}O$ values with low $\delta^{13}C$ values suggests that the carbon responsible for the low $\delta^{13}C$ values is subducted organic material.

Nb-Zr systematics of U-Pb dated achondrites

TSUYOSHI IIZUKA[1,2*], WAHEED AKRAM[3], YURI AMELIN[2] AND MARIA SCHÖNBÄCHLER[3]

[1]DEPS, University of Tokyo, iizuka@eps.s.u-tokyo.ac.jp (*presenting author),
[2]RSES, Australian National University
[3]SEAES, University of Manchester,

The short-lived radionuclide ^{92}Nb decays to ^{92}Zr with a half-life of 36 Ma [1]. Nb and Zr are both refractory lithophile elements and can fractionate from each other during partial melting of the mantle. Thus, Nb-Zr isotope systematics can potentially place chronological constraints on early planetary silicate differentiation. This application requires the initial abundabce of ^{92}Nb (or ^{92}Nb/^{93}Nb) and its homogeneity in the solar system to be unambiguosly defined. Yet previously reported initial ^{92}Nb/^{93}Nb values range from ~10^{-5} to >10^{-3} [2-6], and remain to be further constrained. All but one of the previous studies estimated the initial ^{92}Nb/^{93}Nb using Zr isotope data for single phases with fractionated Nb/Zr in meteorites such as zircons and CAIs, under the assumption that their source materials and bulk chondrites had had identical initial ^{92}Nb/^{93}Nb and Zr isotopic compositions [2-5]. To evaluate the homogeneity of the initial ^{92}Nb abundance, however, it is desirable to define internal mineral isochrons for meteorites with known absolute ages. Although Schönbächler et al. [6] defined Nb-Zr internal isochrons for two meteorites (Estacado and Vaca Muerta), their absolute crystallization (or possibly recrystallization) ages are not precisely constrained, leading to uncertainties in the resultant estimate for the initial ^{92}Nb/^{93}Nb of the solar system.

To establish the solar system intial ^{92}Nb/^{93}Nb and its homogeneity, we are studying the Nb-Zr systematics of minerals from achondrites whose absolute crystallization ages were precisely determined with the U-Pb chronometer. Abundances of trace elements including Nb and Zr were determined by LA-ICPMS for pyroxene, plagioclase, pyrite, spinel and/or opaque minerals from 3 eucrites (Agoult, Ibitira and A-881394), 5 angrites (SAH99555, D'Orbigny, NWA2999, NWA4590 and NWA4801) and Acapulco. The results reveal that Agoult, Ibitira and NWA4590 contain phases with reasonably high Zr contents and a good spread in Nb/Zr (<0.01 for pyroxene and ~3 for opaque minerals and spinel) to define precise internal isochrons. These minerals and whole rock samples were further processed for Zr separation and analyzed for Zr isotopes by MC-ICPMS. We found that the spinel and opaque mineral fractions have restricted positive ^{92}Zr anomalies up to 30 ppm relative to the terrestrial standard samples. We are still in the process of determining their Nb/Zr isotopic ratios, but preliminary results of Zr isotope analyses, combined with the approximate Nb/Zr of minerals estimated by LA-ICPMS, suggest that the initial ^{92}Nb/^{93}Nb is in the order of ~10^{-5}, consistent with the results of previous work using the internal isochron approach [6].

The role of extracellular polymeric substances in nanoparticle-biofilm interactions

KAORU IKUMA[1*], ANDREW S. MADDEN[2], AND BORIS L. T. LAU[1]

[1]Department of Geology, Baylor University, Waco, TX, USA, kaoru_ikuma@baylor.edu (* presenting author), boris_lau@baylor.edu
[2]School of Geology and Geophysics, University of Oklahoma, Norman, OK, USA, amadden@ou.edu

Introduction

Environmental surfaces are ubiquitously covered with biofilms that are primarily made of "sticky" bacterial extracellular polymeric substances (EPS). While various nanoparticles (NPs) have previously been shown to interact strongly with biofilms and EPS, the mechanisms of interaction have remained unclear. EPS consist of a range of organic compounds including various polysaccharides, proteins, and lipids that may play different roles in NP-biofilm interactions. Our objective in this work is to determine the different surface interactions between NPs and individual EPS components. A quartz crystal microbalance with dissipation monitoring (QCM-D) was used to quantify the kinetics and extent of the deposition of hematite NPs (FeNPs) and galena NPs (PbNPs) onto surfaces coated with model and natural EPS components.

Results and Discussion

Frequency shifts were observed during the deposition of EPS components and NPs onto QCM-D sensors (e.g., protein and PbNPs in Fig 1A). Such observed shifts were used to calculate changes in NP mass deposited onto various surfaces. For example, FeNP deposition (in 10mM NaCl, pH 6) was 1.6 fold slower but ~10% greater onto surfaces coated with a model polysaccharide (alginate) compared to a model protein (bovine serum albumin; BSA) (Fig 1B). We expect that the observed differences between varying EPS components were due to differences in charge and hydrophobicity. Experiments are currently underway to test this hypothesis.

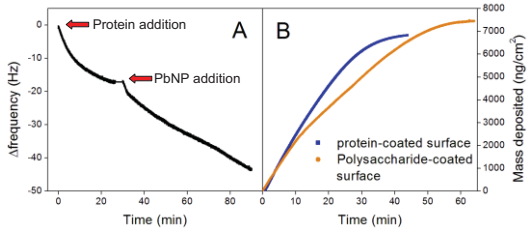

Figure 1: NP deposition onto QCM-D sensor surface coated with EPS components. (A) Frequency shifts measured by QCM-D during protein and PbNP deposition onto the sensor surface. (B) FeNP deposition onto surfaces coated with proteins or polysaccharides.

Environmental Implications

As natural biofilms may act as a major sink for NPs, a detailed mechanistic understanding of the role of EPS and its components in NP-biofilm interactions is crucial for determining the environmental fate and transport of engineered NPs.

Biogenic methane and bacterial community structure in Ordovician shales, Michigan Basin, Ontario

DIMITRI ILIN*, HOSSEIN MOHAMMADZADEH, ALEXANDRE POULAIN AND IAN CLARK

University of Ottawa, Ottaawa, Canada, dilin083@uottawa.ca,, mohammadzadeh@ferdowsi.um.ac.ir, apoulain @uottawa.ca, idclark@uottawa.ca

As a component of geoscientific investigations for a deep geological repository in Middle Ordovician strata of the Michigan Basin near Tiverton, Ontario, methane from hypersaline pore waters ($Cl^- > 6$ molal) in shale and limestone core samples was analysed for concentration, $\delta^{13}C$ and δD.

CH_4 is highly depleted in ^{13}C and D from the top of the Queenston Formation down through the Cobourg Formation. Based on the location of the isotopes on a discrimination diagram for methane, the isotopes are interpreted to be of biogenic origin. An associated zone of ^{13}C-enriched CO_2 strengthens this interpretation and constrains production to the lower Georgian Bay and upper Blue Mountain formations. The $\delta^{13}C$ and δD signatures of methane from the limestones below the Cobourg Formation increase sharply to values consistent with methane of thermocatalytic origin.

In an attempt to resolve whether methanogenic archaea may still be active in these strata, environmental DNA was extracted from core samples and PCR amplified using 16S rDNA primers. PCR performed with archaeal 16S rDNA and methanogen-specific (*mcrA*) primers yielded no DNA, whereas low, but measurable, yields were obtained for bacterial primers. Gene analysis indicated that bacterial sequences similar to *Proteobacteria*, *Cyanobacteria*, *Firmicutes*, and *Actinobacteria* were present.

The majority of identified bacterial species were uncultured extremophilic heterotrophs. We believe that identified bacteria have survived in the rocks for a prolonged period of time by utilizing available energy sources that were trapped during deposition or by assuming a state of dormancy. In contrast, methanogenic archaea are considered to be halophobic and their absence today is not surprising. We hypothesize that the biogenic methane in the Upper Ordovician shales is of para-diagenetic origin, and has been preserved in-situ for some 400 My.

Sulphur isotopy in a sequence of iron-limited organic rich deposits

P. ILLNER[1], Z. BERNER[1], H. ALSENZ[2], S. ASHCKENAZI-POLIVODA[3], T. NEUMANN[1], W. PÜTTMANN[2], S. ABRAMOVICH[3], A.ALMOGI- LABIN[4], S. FEINSTEIN[3]

[1]Karlsruhe Institute of Technology (KIT), Germany (peter.illner@kit.edu)
[2]J.W. Goethe Universität, Frankfurt am Main, Germany
[3]Ben GurionUniversity of the Negev, Beer Sheva, Israel
[4]Geological Survey of Israel, Jerusalem, Israel

In the Negev, the transition from latest Campanian to early Maastrichtian is marked by organic- and phosphate-rich sediments deposited in a high productivity regime induced by coastal up-welling along the southern margin of the Tethys. The study aims at tracing small scale fluctuations in the depositional conditions in this coastal upwelling system, by exploring the isotopic composition of different forms of sulphur in a ca. 50 m thick sequence, encompassing the top of the Phosphate Unit (PU) of the Mishash Formation and the Oil Shale Member (OSM) of the Ghareb Formation.

Different sulphur compounds, including acid soluble sulphates (ASS), acid volatile sulphides (AVS), chromium reducible sulphur (CRS), organic sulphate (OS) and organic bond reduced sulphur (ORS) were separated according to the protocol suggested by Mayer and Krouse [1] and were characterized for their isotopic composition.

In oil shales most of the sulphur (up to 94%) is bond to the organic fraction, decreasing gradually toward the top of the OSM to 40-60% of the sulphur present in sediment. Pyrite-S (CRS), which is the second most common form of sulphur, is low in the basal, most organic rich part of the OSM (<10%), but it can represent up to 40-50% of sulphur in the central part of the section. In the PU and in the marls that top the oil shales, sulphate-S (gypsum, apatite-bond-S) becomes the dominant S-species (>80% of total).

The $\delta^{34}S$ values of the reduced organic sulphur vary throughout the section in a relatively close range between -6 and +1‰, and are always considerably higher than the much more scattered values recorded for the pyrite-S. Sulphur in pyrite is typically strongly depleted in ^{34}S (-43 to -34‰), except in the PU and in the lowest, most organic-rich part of the OSM where the $\delta^{34}S$-values can be as high as -16‰.

The incorporation of sulphur into sedimentary pools with distinct isotopic composition is interpreted in terms of depositional conditions/ primary environmental signals (e.g., availability of reactive iron and degradable organic matter, sulphate diffusion, bottom water oxygenation, sedimentation rate) which were in part overprinted by late/ post diagenetic effects.

The chemical nature of Titan's organic aerosols; constraints from spectroscopic and mass spectrometric observations.

HIROSHI IMANAKA[1*]

[1]University of Arizona, Lunar and Planetary Laboratory, Tucson, USA, himanaka@lpl.arizona.edu (* presenting author)

Introduction

The Cassini-Huygens observations greately extend our knowledge about Titan's organic aerosols. The Cassini INMS and CAPS observations clearly demonstrate the formation of large organic molecules in the ionosphere. The VIMS and CIRS instruments have revealed spectral features of the haze covering the mid-IR and far-IR wavelengths. This study attempts to speculate the possible chemical nature of Titan's aerosols by comparing the currently availabe observations with our laboratory study.

Results and Conclusion

We have conducted a series of cold plasma experiment to investigate the mass spectrometric and spectroscopic properties of laboratory aerosol analogs [1, 2]. Titan tholins and C_2H_2 plasma polymer are generated with cold plasma irradiations of N_2/CH_4 and C_2H_2, respectively. Laser desorption mass spectrum of the C_2H_2 plasma polymer shows a reasonable match with the CAPS positive ion mass spectrum. Furthermore, spectroscopic features of the the C_2H_2 plasma polymer in mid-IR and far-IR wavelegths qualitatively show reasonable match with the VIMS and CIRS observations. These results support that the C_2H_2 plasma polymer is a good candidate material for Titan's aerosol particles at the altidues sampled by the observations.

B-Sr-U isotope systematics and ^{14}C dating of groundwaters from southwestern France.

C.INNOCENT[1*], E. MALCUIT[2], C. FLEHOC[1], C. GUERROT[1], W. KLOPPMANN[1], E. PETELET-GIRAUD[1] AND P. NEGREL[1]

[1]BRGM – MMA, Orleans, France, c.innocent@brgm.fr
[2]BRGM – SAR/SGR-AQI, Pessac, France, e.malcuit@brgm.fr

The Eocene sands aquifer has been extensively studied for its hydrology, hydrogeochemistry, and also for stable isotopes and groundwater residence time using ^{14}C [1, 2]. Recently, in the framework of the CARISMEAU project, groundwaters have been in addition characterized for B, Li, Sr and U isotopes (Négrel et al., 2008).

The second step of the CARISMEAU research project is aimed at studying the restricted "Entre-Deux-Mers" area, where Eocene groundwaters displays high sulfate and fluorine contents that exceed the regulation limits for drinking water use. B and Sr isotopes have been measured in 18 water samples. The isotopic signal of these groundwaters emphasize the influence of carbonate and evaporitic sources, and also of clay lithologies in some samples, as indicated by B isotopes.

Uranium activity ratios are also available for 18 waters samples (which do not match those analyzed for B and Sr). U activity ratios are in any case higher than the equilibrium value, ranging from 2.9 to 8.6. Such high values confirm those previously measured in Eocene groundwaters during the first step of the project [4].

Finally, ^{14}C activity has been measured in 2009 on 30 groundwaters. The calculated residence times are compared when possible to ^{14}C dates obtained during the 90's on water samples recovered from the same sites. New dates are surprizingly much younger. In addition, a slight shift in $\delta^{13}C$ is observed between the 90's data and those obtained in 2009. The significance of these new ^{14}C data is discussed in the light of both groundwater sampling procedures and the impacted status of this aquifer due to overpumping.

The Paleoproterozoic Lomagundi $\delta^{13}C_{carb}$ excursion between 2.22 and 2.06 Ga corresponds to the most significant period of atmospheric oxygenation and is referred to as the "Great Oxidation Event" (GOE). Large $\delta^{13}C_{carb}$ excursions are often followed by periods of accelerated biological evolution, suggesting that rocks deposited immediately after 2.06 Ga might preserve changes in environmental chemistry and microbial communities after the GOE. The poorly studied rocks of the Belcher, Nastapoka, and Richmond Gulf Groups, along the northwestern margin of the Superior Craton, Canada, have been dated between 2.03 and 1.870 Ga (Chandler and Parrish, 1989; Hamilton et al., 2009), and thus represent ideal rocks to investigate the evolution of microbial communities and of the carbon cycle in a higher redox state. These Paleoproterozoic successions contain exceptionally well-preserved carbonates with abundant and diverse stromatolites. The Belcher Group preserves three successive transgressions of a drowning carbonate platform between two major volcanic episodes (Ricketts and Donaldson, 1989). Progressive transitions from green/gray to red argillites/mudstones and the development of beds of carbonate concretions indicate a progressive oxidation of fine-grained marine sedimentary rocks and organic matter near the end of the second and third megacycles (Tukarak and Costello-Laddie Fms.). Data from the McLeary and Kasegalik Fms. in the Belcher Group show uniform $\delta^{13}C_{carb}$ values around +0.1‰ and $\delta^{13}C_{org}$ values between -26.1‰ and -22.1‰. Current work is focused on completing the carbon isotope chemostratigraphies to establish geochemical correlations between the entire Belcher Group and the correlative Richmond Gulf and Nastapoka Groups.

Degrees, depth, settings and age of partial melting

A major reason why various models for the formation of cratonic mantle continue to be debated [1] is that the modal and chemical composition of initial melting residues, hence melting conditions, remain poorly constrained. Spl harzburgite xenoliths (Mg# 0.92-0.93) from the Udachnaya kimberlite in the central Siberian craton, unlike most published data on cratonic peridotites, form clear trends on major oxide plots and based on experimental results [2] are residues of 35-40% fractional partial melting of upwelling fertile mantle over a broad depth range (7-1 GPa). By contrast, the majority of garnet peridotites from Udachnaya show metasomatic enrichments in Fe, Ti etc. relative to the residual harzburgites. Dunites (melting degrees >40%) are extremely rare.

Unmetasomatized spl harzburgites yield isochron Lu-Hf age of 1.8 Ga and Sm-Nd age of 2.0 Ga [3]. The early Proterozoic formation of the Siberian lithospheric mantle is also indicated by Re-depletion ages for coarse peridotites from this study [4] that range from 1.5 to 2.6 Ga (av. 1.8 Ga). The Re-Os age range may reflect metasomatic overprinting rather than prolonged craton creation. Garnet peridotites yield Hf- and Nd-isotope WR-isochron ages of 0.7 Ga, apparently dating a major metasomatic event [3].

O-isotope data and the origin of opx-rich peridotites

We report laser-fluorination O-isotope data for olivine and opx from 32 Udachnaya peridotites. Average δ18O for the olivines is 5.18 ± 0.26‰ (2σ), i.e. identical to the mantle olivine average of 5.18 ± 0.28‰ [5]; the opx are on average 0.5‰ heavier than coexisting olivine. Calculated bulk compositions are similar for spl and coarse and sheared garnet peridotites (~5.3‰) and show no relation to modal or major oxide abundances. A sub-group of Udachnaya spl harzburgites have too much opx (31-43% vs. 7-22% in 'normal' harzburgites) to be melting residues. The high opx in Siberian and other cratonic peridotites are commonly attributed to hydrous melting or post-melting silica enrichments in subduction zones. Bulk O-isotope compositions of the opx-rich spl harzburgites are similar to those for all other Udachnaya peridotites. There is no evidence that processes producing opx-rich (or metasomatized) cratonic peridotites impart distinctive O-isotope characteristics; their links to subduction settings remain unsupported by chemical or isotope data. The opx-rich rocks could form by mineral segregation in unconsolidated residues, crystallization of pockets of trapped residual melt etc. We find no evidence that intitial melting residues were dunites later refertilized to harzburgites in subduction zones.

The use of $^{87}Sr/^{86}Sr$ ratios is a powerful tool in the field of analytical ecogeochemistry, above all for the investigation of migration, mobility and movement due to its outstanding properties of regional difference and Sr abundance in nature. Only recently, variation of the $^{86}Sr/^{88}Sr$ ratio due to natural fractionation processes induced by weathering and temperature effects were reported, as well.

Laser ablation coupled to multiple collector inductively coupled plasma mass spectrometry (LA-MC-ICPMS) stands out due to its attributes as a semi-invasive means for the fast and direct investigation of Sr isotope ratios and marginal sample preparation required. However, direct stable Sr isotope ratio measurements in calcium phosphates and carbonates suffer from significant matrix-related interferences such as molecular ions, e.g. $(^{40}Ca\text{-}^{31}P\text{-}^{16}O)^+$, $(^{40}Ar\text{-}^{31}P\text{-}^{16}O)^+$, $(^{43}Ca\text{-}^{44}Ca)^+$ as well as in many cases concomitant atomic ions, e.g. $^{87}Rb^+$, $^{174}Hf^{2+}$. Interferences on Sr isotopes analyzed by LA-MC-ICPMS have been subject to numerous debates and discussions among scientists during the last couple of years. Interpretations of generated data are highly diverse regarding the trustworthiness of LA-MC-ICPMS, as corrections are approached in different ways and diverse sources of interferences are presumed. The major part of observations report trends towards higher $^{87}Sr/^{86}Sr$ ratios for LA-MC-ICPMS compared to solution-nebulisation based MC-ICPMS when analyzing apatite matrices and lower ratios in case of calcium carbonate matrices.

This study is dedicated to the systematic investigation of the effect of interferences and instrumental mass discrimination on Sr isotopic investigations using LA-MC-ICPMS and the assessment and validation of possible correction strategies. This includes evaluating the potential of the implementation of externally added elements (e.g. Zr) for mass bias correction.

The major focus was set on analyzing human tooth samples, fish hard parts and geological carbonates. Laser ablation data and corresponding data established using solution nebulisation based approaches were compared and potential sources of interferences identified by e.g. using high resolution ICPMS. The combined corrections of interferences and adequate mass bias correction procedures lead to accurate data even though increased uncertainties have to be taken into account. The obtained results are discussed along with coexisting approaches for data correction in laser ablation analysis.

Speciation and Localization of Cd in the Hyperaccumulator Plant *Arabidopsis halleri* Grown in the Field and in Controlled Conditions by XAS Techniques

Some higher plants naturally grow on metal contaminated soils due to their ability to cope with metal toxicity. They can be used in phytoremediation to extract (phytoextraction) or stabilize (phytostabilization) metals accumulated in soils. These techniques can be an alternative to invasive physico-chemical remediation techniques. However, to develop phytoremediation, it is necessary to understand the mechanisms involved in metal accumulation, and particularly the way that plants transfer and store metals. These mechanisms have not been elucidated yet [1]. In this context, synchrotron radiation based techniques, and particularly micro-focused X-Ray Fluorescence (μXRF), and X-ray Absorption Spectroscopy (XAS) appear as powerful tools to determine the localization and the chemical forms of metals in plants, and thus the mechanisms involved in the metal accumulation capacity [2, 3]. In this study, we have investigated the Zn, Cd hyperaccumulator *Arabidopsis halleri*, which naturally develops on some contaminated soils in Europe. This work presents the application of μXRF and Cd μXANES to determine the distribution and speciation of Cd in *Arabidopsis halleri*, in combination with bulk Cd EXAFS/XANES spectroscopy. We particularly compared *Arabidopsis halleri* collected on the field and in various controlled conditions. Results show that Cd is mainly located in veins and mesophyll of leaves and that hot spots are found in trichomes (epidermal hairs), although this compartment is not a major compartment of storage for the metal. The speciation of Cd varies with the various conditions of Cd treatments but also differs from the plants originated from the site. This study highlights the difficulty to extrapolate the laboratory experiments to the field in a remediation context.

Search for Early Archean mantle lacking the late-veneer component

AKIRA ISHIKAWA[1,2*], MASANORI SHIMOJO[1], KATSUHIKO SUZUKI[2], KENNETH D. COLLERSON[3] AND TSUYOSHI KOMIYA[1]

[1] Earth Science and Astronomy, The University of Tokyo, Tokyo 153-8902, Japan, akr@ea.c.u-tokyo.ac.jp (*presenting author)

[3]Earth Sciences, Univ. Queensland, Brisbane Qld 4072, Australia

The overabundance of highly siderophile elements (HSEs) in the modern terrestrial mantle, relative to predicted composition is frequently attributed to the late influx of chondritic materials (late veneer) after the efficient stripping of HSEs to the metallic core. Although this model is not universally accepted due to insufficient knowledge of metal-silicate partitioning under high P-T conditions, broadly chondritic ratios of HSEs in fertile peridotites from a variety of tectonic settings provide strong support for the late veneer model.

A recent discovery of ^{182}W enrichments in ~3.8 Ga crustal rocks from Isua, West Greenland suggests that this area of Earth's surface has escaped addition of the late veneer, and remained unaffected by subsequent replenishment [1]. Furthermore, possible secular increase of HSE abundances for the komatiite source has been attributed to the progressive pollution of the HSE-poor deep mantle by the late veneer component between 3.5 and 2.9 Ga [2]. These studies raise the possibility that ~3.8 Ga ultramafic rocks from West Greenland and Labrador, Canada, can be used to establish HSE abundances of the Earth's mantle before the arrival of the late veneer.

We present HSE abundances and Re-Os systematics for a set of ultramafic rocks from Saglek-Hebron area of northern Labrador. Based on field and geochemical data, they were classified into two suites: residual peridotites occurring as tectonically-emplaced slivers of lithospheric mantle, and metakomatiites comprising mostly pyroxenite layers in supracrustal units. The samples analysed here have been investigated previously for Sm-Nd and Pb-Pb systematics, supporting their >3.8 Ga formation [3, 4]. Thus, the primary aim is to test whether the meta-peridotites and komatiites record peculiar HSE signatures of the early Archean shallow and deep mantle, respectively.

The two suites display contrasting HSE patterns that are consistent with their inferred protoliths. The harzburgitic to dunitic metaperidotites are typically marked by depletion of Pt, Pd and Re relative to Os, Ir and Ru, resulting from extensive melt extraction. In contrast, metakomatiites show smooth patterns with gentle positive slopes (except for Re). Overall, in terms of HSE patterns and abundances, both suites do not differ from their late Archean equivalents, such as the harzburgitic to dunitic xenoliths from North Atlantic Craton [5] and the 2.7 Ga Belingwe/Abitibi komatiites [6]. Moreover, a rare lherzolitic sample shows a very similar HSE pattern to that of PUM estimate [7]. These observations suggest that 3.8 Ga mantle has been influenced by the late veneer. We will discuss the possible reasons for the decoupling between W isotope evidence from crustal rocks and HSE signatures in mantle materials.

Coupling between separative techniques and inductively coupled plasma mass spectrometry for lanthanides separation and on-line isotope ratio measurements

ISNARD H. [1*]., GOURGIOTIS A.[1]., MIALLE S.[1], BOURGEOIS M.[1], VIO L.[1], NONELL A.[1], CHARTIER F.[2]

[1] Commissariat à l'Energie Atomique, DEN/DPC/SEARS/LANIE, 91191 Gif-sur-Yvette Cedex, France, helene.isnard@cea.fr
[3] Commissariat à l'Energie Atomique, DEN/DPC, 91191 Gif-sur-Yvette Cedex, France

The precise lanthanide (Nd, Sm, Eu) isotope composition is of major interest in geosciences (geochronology, erosion studies, paleo-circulation reconstruction…) as well as in nuclear industry (determination of nuclear fuel burn-up, management of the spent fuel nuclear fuel…). Direct determination of lanthanides by mass spectrometry is hampered by isobaric interferences and so previous chemical separations are then required before mass spectrometric measurements. In most cases isotope ratio are determined off-line after chemical separation processes.

We would like to present here the simultaneous online determination of some lanthanides (Nd, Sm, Eu) isotopic composition in nuclear samples by the hyphenation of two separative techniques with inductively coupled plasma mass spectrometry.

The first one is the coupling between liquid chromatography and ICPMS [1]. The LUNA SCX column which includes benzene sulfonic acid group and 2-hydroxy-2-methylbutyric acid as a complexing agent in eluent solution were used for the separation. The column has been directly coupled to ICPMS. Data acquisition and correction of mass bias by different approaches are discussed.

The second one present the development and conception of a microchip for the lanthanides separation. This microchip is based on the isotachophoresis (ITP) separation of lanthanides and was directly coupled to an MC-ICPMS for the on-line measurements of Nd and Sm isotopic ratio [2]. This is the first time that such a coupling is performed and the feasibility is demonstrated in this study. These on-line methods are a great challenge related to the limited signal duration [3] but a very attractive approach to decrease the sample size and the sample preparation time. Such a coupling and further applications could be envisaged for geochemical applications.

Concentrations and chemical forms of trace metals in coastal seawater in coral reefs and their relationship to coral mucus

AKIHIDE ITOH[1*] AND SHOKO GANAHA[1]

[1]University of the Ryukyus, Science education, Okinawa, Japan, akihide@edu.u-ryukyu.ac.jp (* presenting author)

Coastal seawater in coral reefs near Okinawa Island in Japan, which is in oligotrophic conditions, has a diverse and unique ecosystem. It is possible that nutrient salts and trace metals, classified into nutrient type, are effectively supplied to marine phytoplankton and zooxanthellae from seawater. However, the concentrations and chemical forms of trace metals in coastal seawater in coral reefs have been scarcely reported so far. In addition, it is reported that the coral mucus plays an important role as a nutrient supply to fishes and other animals, and scavengers of suspended particles [1]. In the present study, firstly, the characteristics of the concentrations and chemical forms of trace metals in coastal seawater in coral reefs were investigated according to seasonal variation. Secondly, the relationship between concentrations of trace metals in seawater in coral reefs and in coral mucus were discussed.

A monitoring investigation of the coastal seawater in coral reefs, located near the northern part of Okinawa Island, was carried out once every month from Sep. 2010 to Aug. 2011. After the chemical species in the seawater were separated into dissolved, acid-soluble particulate, and ionic ones, an analytical method using a chelating resin disc and a disposable syringe was employed for desalination and preconcentration of trace metals. After that, trace metals in the concentrated solutions were measured by ICP-MS. On the other hand, coral mucus was sampled from *Acropora nasuta* exposed to sunlight and then analysed by ICP-MS.

As a result, 10 elements in the dissolved form of each sample could be determined. The average concentrations (unit: $\mu g\ L^{-1}$)for all samples were as follows: Mo:10.8, U: 3.2, V:1.6, Mn:0.14, Ni:0.16, Zn:0.13, Cu:0.070, Pb:0.023, Co:0.0022, Cd:0.0019. The concentrations for most trace metals were close to ones at the surface of open seawater in the North Pacific Ocean, but the concentrations of Co, Ni, Cu, Zn, and Cd, classified into nutrient type, were significantly lower than ones in other coastal seawater. These results suggest that the coastal seawater in coral reef ecosystems were in oligotrophic conditions. The most of Mo, V, and U exist in dissolved forms, while most Fe exists in acid-soluble form. 50–70 % of Cu, Zn, Pb, and Co and 21–42 % of Cd, Mn, and Ni existed in acid-soluble particles. These results suggest that some trace metals in the nutrient type exist as biogenic particulate matter. As for their relationship to coral mucus, the concentrations of Mn, Fe, Co, Ni, Zn, Cd, and Pb in coral mucus were 10-150 times larger than those dissolved in coastal seawater in coral reefs, while those of Na, Mg, K, V, and U in coral mucus were almost the same as the dissolved forms. The elements which showed high concentration for acid-soluble particles in June and January were almost the same as those in coral mucus. Therefore, the concentrations of trace metals in acid-soluble particles in June and January may be affected by coral mucus, which combined with sediment and was lifted by tidal flows.

Can Nd tell us about Mediterranean Outflow Water?

RUŽA IVANOVIĆ[1*] MARCUS GUTJAHR[2], RACHEL FLECKER[3], PAUL VALDES[4], TANJA KOUWENHOVEN[5], JÖRG RICKLI[6], ROB ELLAM[7], ANDRIA NICODEMOU[8]

[8] University of Bristol, Bristol, UK

Although εNd is a well established water provenance tracer for deep ocean circulation, there remains some debate over the practicability of Neodymium (Nd) isotopes at intermediate water depth on the continental-margin. Using the method of Vance and Burton (1999), we intend to answer some of the questions on how useful Nd can be for tracking Mediterranean Outflow Water (MOW), and whether or not Nd isotopes (expressed as ε_{Nd}) measured in foraminfera from this setting represent a true water-column signal, or a post-depostional one.

We have measured ε_{Nd} in 90 foraminiferal samples (each containing 400-900 individuals) and fish-remains samples in order to assess whether or not Nd extracted from these palaeo archives can elucidate on the evolution of MOW at high temporal resolution. We examined Late Quaternary samples, to make direct comparisons between our data, other Quaternary MOW reconstructions[e.g.2] (including different phases from the same samples) and modern observations[e.g.3]. We also analysed samples from the Late Miocene, 8-6 Ma, when progressive tectonic restriction of the Betic-Rif region caused Mediterranean-Atlantic water exchange to fluctuate dramatically, making the period a good test-case for MOW extremes. We further interpreted our ε_{Nd} record within the context of more finely resolved Sr and foram assemblage records, including data we obtained from the same samples as the Nd.

From these results, we propose that ε_{Nd} in foraminifera and fish teeth can tell us about MOW evolution. For example, we clearly detect changes in water provenance, indicative of marine shallowing events and corridor 'closure'. Furthermore, our data suggest that foraminfera-hosted Nd is not diagenetic and thus our planktic Nd indeed appears to be a 'true' water-column signal. However, questions remain over whether or not boundary exchange[4] and localised riverine inputs have confused the extracted ε_{Nd} signal, and although our Sr and benthic assemblage data do present some clues to the answers, these are by no means exhaustive tests. In short, there remain significant challenges in fully understanding this continental-margin ε_{Nd} record, and we advise that although Nd can provide valuable information about changes in MOW, a multi-proxy approach is essential for making robust interpretations of the data.

Rock boring fungi in subseafloor basalts

MAGNUS IVARSSON[1*]

[1]Swedish Museum of Natural History, Department of Palaeozoology, Stockholm, Sweden, magnus.ivarsson@nrm.se (* presenting author)

Fossilized fungal hyphae in subseafloor basalts bear witness of extensive weathering and tunneling in vein and vesicle filling secondary mineralisations (carbonates and zeolites). The minerals have been chemically dissolved and penetarted by the fungal hyphae, which have produced and occur in complex mycelium-like networks within the minerals. The hyphae frequently branch and anastomoses between branches occur, a mechanism that is not fully understood. Rock boring hyphae in subseafloor basalts have been observed from two separate locations: the Emperor Seamounts, Pacific Ocean, and the volcaniclastic apron of Gran Canaria, Atlantic Ocean, thus, it is not an isolated phenomenon [1]. Selection towards Fe-rich carbonates (siderite) over Fe-poor carbonates (calcite) indicates a possible trophic strategy in a few samples. Otherwise, the strategy of tunnelling probably is due to migration through the system or acquiring of habitable space. Subseafloor, hydrothermal settings are dynamic environments characterised by extreme shifts in, for example, temperature or pH, thus, the tunneling can be a response mechanism to environmental stress. Fungi are known as a powerful geobiological agent in terrestrial environments that promotes mineral weatherin and decomposition of organic matter. It is probable to assume that fungi would play a similar role in the ocean crust and mediate weathering and mobilization of elements.

XAFS investigation for sorption mechanism in As(V) coprecipitation with ferrihydrite

SAYAKA IZAWA[1*], CHIHARU TOKORO[2], YUJI ODA[3], DAISUKE HARAGUCHI[4], AND SHUJI OWADA[5]

[1]Waseda University, Tokyo, Japan, izasaya@ruri.waseda.jp
[2]Waseda University, Tokyo, Japan, tokoro@waseda.jp
[3]Waseda University, Tokyo, Japan, my-happy-ending@ruri.waseda.jp
[4]Waseda University, Tokyo, Japan, d.haraguchi@aoni.waseda.jp
[5]Waseda University, Tokyo, Japan, owadas@waseda.jp

Coprecipitation method using ferrihydrite has been commonly applied to remove As(V) from acid mine drainage. However, the mechanism in coprecipitation is unclear. Therefore, it is demanded to clarify how coprecipitation of As(V) with ferrihydrite occures in acid mine drainage.

In the previous paper, we investigated the sorption mechanism of dilute As(V) with ferrihydrite using three kinds of experimental studies for an artificial wastewater in which the ion strength was 0.05 and pH was 5; (i) sorption isotherm formation, (ii) zeta potential mesurment and (iii) XRD analysis. We already confirmed that As(V) was formed a simple two-dimentional adsorption onto the surface of ferrihydrite when the initial As/Fe molar ratio was less than 0.4, whereas a surface precipitation of amorphous ferric arsenate was formed when the initial As/Fe molar ratio was more than 0.4 [1]. In this study, XAFS analysis was conducted to know more detail mechnism of As(V) sorption to ferrihydrite in coprecipitation proess. Additionaly, the effect of ionic strength to As(V) sorption mechanism with ferrihdyrite in coprecipitation process was also discussed.

Both of XANES and EXAFS analysis on K-edge of As showed As(V) coprecipitates with ferrihydrite was mixture of As(V) adsorbed ferrihydrite and amorphous ferric arsenate. When the ion strength was 0.05 in an artificial wastewater containing As(V), estimated weight ratio of amorphous ferric arsenate in As(V) coprecipitates became above 0.5 when the initial molar ratio of As/Fe≥0.5 was used. These results corresponded with results by XRD analysis. EXAFS analysis assuming one surface complex for As-Fe bond showed the coordination number of As to Fe in As(V) coprecipitates increased with increasing the initial molar ratio of As/Fe. Moreover, EXAFS analysis assuming three kinds of surface complexes for As-Fe bond showed the coordination number for 2.85 Å of As-Fe bond increased and it for 3.24 Å of As-Fe bond decreased with increasing the initial As/Fe molar ratio. All experimental data obtained in this study showed As(V) co-precipitation mechanism shifted gradually from As(V) complexation to the surface of ferrihydrite toward amorphous ferric arsenate.

On the other hand, when the ion strength was 0.5, the sorption density of As(V) to ferrihydrite obtained from coprecipitation process was lower than it at ion strength of 0.05. Results of XRD and XAFS analysis revealed that the formation of surface precipitation was prevented when the ion strength was high, whereas simple two-dimentional adsorption of As(V) onto the surface of ferrihydrite was not so prevented by the higher ion strength.

Silica, Al and Pb in atmospheric PM10 and in human lungs in Upper Silesia,Poland

JABLONSKA MARIOLA [1], JANECZEK JANUSZ[1], LESNIOK MIECZYSLAW [2] LUCYNA LEWIŃSKA-PREIS[1]

[1]University of Silesia, Department of Geochemistry, Mineralogy and Petrology; Sosnowiec, Poland
mariola.jablonska@us.edu.pl;
janusz.janeczek@us.edu.pl
[2]University University of Silesia, Department of Climatology,Sosnowiec, Poland,

Upper Silesia (US) is the most densely populated (>1600 people/km^2) and the most polluted region of Poland. Annual average of PM10 concentration is still higher then national standars set by the regulators at 40 μg/m^3. That situation poses a high risk to human health as evidenced by the medical data. In this study silica, aluminium and lead were determined in atmospheric PM10 and in human lung tissues. Silica occurs as quartz and amorphous phase, whereas aluminium is in clay minerals, feldspars, amorphous alumino-silicates etc. Lead occurs in the form of galena, lead chloride and lead oxide. All of those mineral particles are abundant in respirable fraction of PM10 and in ultrafine particles.

Fifteen samples of PM10 and 34 samples of lung tissues from autopsy donors from US (13 female and 21 male) were analysed. Silica was determinated by colorimetry, and aluminium and lead were determined using inductively coupled plasma-atomic emission spectrometry (ICP-AES).

The concentration of silica in PM10 is the range of 1,00 – 34,98 wt. % (the average is 12,11±5,19 wt. %). In human lung tissues the average concentration of silica is 3,03±0,84 wt. % (the minimum value is 0,37 wt. % and the max. 5,65 wt. %). The concentration of aluminium in PM10 ranges from 0,58 wt.% to 2,78 wt. %. The average concentration of Al of 1,69±0,42 wt. % is distinctly higher than the average of Al in human lungs (0,197±0,08 wt. %). The lead content in PM10 ranges from 45 ppm to 1473 ppm, with the average 296±92 ppm. In human lungs the content of lead is 13±3 ppm, (min. 2 ppm, max. 47 ppm).

The presence of abundant Si, Pb, and Al in ultrafine particles is particularly worrisome as it is known, that particles with a diameter less than 0.5 μm immediately infiltrate into blood circulation system similarly to gases [1]. 100% of Pb hosted by ultraparticles is absorbed by lung tissues [2].

It is believed that no single mechanism can account for the full amplitude of past CO_2 variability. But although multiple synergistic processes may be involved, intensified isolation of deep-water masses from the atmosphere has emerged as a central mechanism for low glacial CO_2. This could have resulted from increased oceanic density stratification, increased sea ice cover, or a decrease wind-driven vertical mixing. Recent evidence is consistent with the existence of a poorly ventilated, carbon-rich water mass in a large portion of the glacial Pacific and Southern Oceans. However, the mechanisms by which this water mass dissipated upon glacial terminations remains a subject of debate.

Here, we present a compilation of sedimentary redox-sensitive trace metal records from the subarctic Pacific and the Southern Ocean to reconstruct changes in deep ocean oxygenation – and, by inference, respired carbon storage - across the last glacial termination.

Our results suggest that the abyssal Pacific and Southern oceans were depleted in oxygen during the last glacial maximum, though they were not anoxic. The large and abrupt increase in sedimentary opal accumulation observed in the Southern Ocean at approx. 18 kyr is accompanied by a decrease in authigenic uranium concentrations suggesting better oxygenation at the depth of the core site. Enhanced mixing within the Southern Ocean, driven by stronger winds and/or changes in the density profile of the water column, would have invigorated circulation at depth, The increase in the rate of nutrient supply to the surface would have enhanced the strength of the Southern Ocean High Nutrient Low Chlorophyll (HNLC) region, and increased the leakage of nutrients into intermediate and mode waters of the southern hemisphere. Simultaneously, the decrease in nutrient-poor NADW to the deep sea, caused by the freshwater forcing associated with Heinrich Event 1, allowed nutrient-rich AABW to dominate the deep ocean. Both of these mechanisms would have increased global preformed nutrient concentrations, previously shown to contribute to higher atmospheric pCO_2, and could have explained the large-scale transfer of carbon from the deep ocean to the atmosphere between 18 and 15 ka. In the subarctic Pacific, the arrival of well-oxygenated abyssal waters appears to have taken place at the onset of the Bolling/Allerod, 14.7 ka, accompanying the reinvigoration of North Atlantic Deep Water, which increased the overall rate of deep ocean ventilation, even as it contributed to an overall decrease in the preformed nutrient load of the global ocean. The fact that atmospheric pCO_2 stopped increasing at this time is consistent with this interpretation. Our results suggest that this stepwise reinvigoration of deep water circulation, resulting from the buffeting of ocean density structure by large inputs of freshwater, was responsible for driving carbon out of the abyssal ocean during the melting of the large continental ice sheets.

Helium solubility in ring site bearing minerals and implications for noble gas recycling

COLIN R.M. JACKSON[1*], SIMON P. KELLEY[2], STEPHEN W. PARMAN[1]. REID F. COOPER[1]

[1]Brown University, Providence, United States colin_jackson@brown.edu (* presenting author)
[2]The Open University, Milton Keynes, England

Noble gas solubility in minerals is generally assumed to be low, leading to the assumption that noble gases are not recycled back in to the mantle (e.g. 1). However, applicable experimental data remain scarce. To explore possible mechanisms of noble gas recycling, we conducted a series of experiments defining He solubility in a suite of amphiboles and cyclosilicates using an externally heated, gas-pressure-medium apparatus. Analysis was conducted using by laser-ablation mass spectrometry. Helium was the pressure medium in all experiments. Pressures and temperatures ranged from 50 to 170 MPa and 650 to 800°C, respectively. Helium solubility in both cyclosilicates (tourmaline, beryl, cordierite) and amphibole (richterite, paragasite, actinolite) is remarkably high and correlates with the density of vacant (i.e., unoccupied by a cation) ring sites. Helium is >1,000x more soluble in vacant ring rich cordierite, beryl, and actinolite than in olivine.

The concentration of He dissolved into cordierite and beryl is linearly dependent on P_{He}, demonstrating Henrian behaviour, and thus applicable to natural systems. Depth profiles were completed on each phase investigated and showed that He concentrations are homogenous. This indicates a close approach to equilibrium and an absence of inclusions affecting the analysis. The observed solubilities are independent of experimental duration (7-27 hrs) and temperature (650 to 800°C).

The ring site is a lattice structure constituting six $Si/AlO_4^{4-/5-}$ tetrahedra linked in a hexagonal ring. It is large, hosting alkali cations, and has no net charge when vacant. Following lattice strain theory, the ring site is an energetically favorable environment for noble gas dissolution. Excess argon is commonly observed in natural samples of ring-bearing minerals (amphibole, mica, cyclosilicates) (2, 3), corroborating our conclusion that noble gas solubility can be associated with ring sites.

Ring-site-bearing minerals, including mica, serpentine, talc, and amphibole, are common in recycled lithologies (4) and may provide a possible mechanism for widespread recycling of noble gases back into the mantle. Moreover, ring-site bearing minerals are the major minerals responsible for recycling water and halogens. Thus, water and halogen recycling may be mineralogically linked to noble gas recycling.

Trace element composition of a non-chondritic Earth: Potential solutions and geodynamic implications

MATTHEW G. JACKSON[1*], A. MARK JELLINEK[2]

[1] Boston University, Department of Earth Sciences, Boston, MA, 02115, USA (jacksonm@bu.edu)
[2] Department of Earth and Ocean Sciences, University of British Columbia, Vancouver, British Columbia, V6T 1Z4, Canada (mjallinek@eos.ubc.ca)

The bulk composition of the silicate part of the Earth (BSE) has long been assumed to be tied to chondrites, where refractory, lithophile elements like Sm and Nd are thought to exist in chondritic relative abundances in the Earth. However, recent work exploring the $^{142}Nd/^{144}Nd$ systematics of modern terrestrial samples identifies ratios that are 18±5 ppm higher than the chondrite reservoir that challenges the traditional BSE model [1]. Here we investigate a hypothesis that this terrestrial ^{142}Nd excess is related to a Sm/Nd ratio 6% higher than chondritic. We develop a non-chondritic BSE trace element model in which the elevated Sm/Nd requires a shift of BSE $^{143}Nd/^{144}Nd$ from 0.51263 to 0.51300 that demands, in turn, corresponding changes to $^{87}Sr/^{86}Sr$ and $^{176}Hf/^{177}Hf$, as well as the associated parent-daughter ratios—Rb/Sr, Lu/Hf. These modified parent-daughter ratios define a normalized trace element pattern, or spidergram, that is depleted in highly incompatible elements relative to the chondrite-based BSE. We use the ^{40}Ar abundance of the atmosphere, crust and depleted mantle to constrain the minimum K in the Earth (155 ppm), and anchor the spidergram to this K concentration to determine the concentrations of the other geochemically important incompatible elements, such as U and Th. An upper limit (170 ppm K) is estimated by assuming that abundances of the least incompatible elements (e.g., Lu) do not exceed chondrite-based BSE concentrations. This non-chondritic BSE trace element model requires that >78% of the mantle mass contribute to the formation of continental crust. The reduced concentrations in heat-producing elements U, Th and K in our new BSE compositional model implies a ~30% reduction in the current rate of radiogenic heating and, thus, a proportional increase in the heat flow delivered to Earth's surface by plate tectonics, the implications of which we explore in parameterized thermal history models.

Shale gas and its environmental footprint

R.B. JACKSON[1*], A. VENGOSH[2], N.R. WARNER[3], AND S.G. OSBORN[4]

[1]Duke University, Nicholas School of the Environment and Center on Global Change, Durham, NC, 27708, USA, jackson@duke.edu (* presenting author)
[2]Duke University, Nicholas School of the Environment, Durham, NC, 27708, USA, vengosh@duke.edu
[3]Duke University, Nicholas School of the Environment, Durham, NC, 27708, USA, nathaniel.warner@duke.edu
[4]Cal Poly Pomona, Department of Geological Sciences, Pomona, CA, 91768, USA, sgosborn@csupomona.edu

The Marcellus shale is one of the largest natural gas reservoirs in the United States and, like other shale gas reserves, has been developed through advances in drilling technologies and production strategies. Concerns over potential environmental impacts have accompanied natural gas extraction around the country. We have sampled shallow groundwater systems of >200 homeowners in NE Pennsylvania and New York for brines, dissolved gases, and other attributes of water quality for the last two years. In particular, we have exampled possible relationships between water quality and distance to natural gas wells.

In our first study publishd in May of 2011 [1], we found no evidence of increase salt concentrations or fracturing fluids with distance to gas wells, but dissolved methane concentrations were 17 times higher on average for water wells found within 1km of them. Higher chain hydrocarbons (ethane, propane, and butane) were detected more often in active areas (21, 8, and 3, respectively) compared to non-active areas (3, 0, and 0, respectively), indicating a more thermogenic methane character. The carbon isotope values of methane (δ^{13}C-CH4), in active extraction areas were on average less negative (-37±7 ‰) than non-active extraction areas (-54±11‰). We conclude from these, and newer follow-up results, that there are important differences in methane concentration, natural gas composition, and δ^{13}C-CH_4 values in some shallow groundwater wells near natural gas extraction areas. Furthermore, the dissolved gas geochemistry nearer gas wells appears to be consistent with a more thermally mature source of organic matter. New results from additional sampling in 2011 will be presented.

Mapping element concentrations and Ce^{4+}/Ce^{3+} ratios in zircon by LA-ICP-MS

SIMON E. JACKSON[1*] AND JOHN B. CHAPMAN[1]

[1]Geological Survey of Canada, Ottawa, Ontario, Canada, simon.jackson@nrcan-rncan.gc.ca (* presenting author); john.chapman@nrcan-rncan.gc.ca

A LA-ICP-MS procedure has been developed for simultaneously generating element, element ratio and isotope ratio maps of individual zircon grains. The instrumentation used was a Photon Machines Analyte.193 laser ablation system and Agilent 7700 quadrupole ICP-MS with addition of a second rotary interface pump that doubles instrument sensitivity. The procedure involves performing lines of individual spot ablations, resulting in true spot size-limited spatial resolution. Each spot ablation is preceded by several laser cleaning pulses and a short period of flushing to remove surface contamination (from condensation and other sources). For each element, signals for each individual spot are integrated into single readings, then calibrated using an external standard (NIST 612) and an internal standard (SiO_2) for element concentration measurements, and against a zircon (GJ-1) for Pb-U isotope ratio measurement. The concentration or ratio data are then presented as colour pixel maps by assigning colours according to concentration (or ratio) using a choice of different colour assignment schemes (linear, logarithmic, percentile)

Zircon ($ZrSiO_4$) is an abundant accessory mineral in granitoid igneous intrusive rocks that are associated with porphyry and other magmatic-hydrothermal mineral deposits. Using spot sizes as small as 7 microns in diameter, Ce and the REE from Nd-Lu, Pb, Hf, Th and U can be detected routinely in zircons. Measurement of this suite of REE allows, by extrapolation, calculation of Ce^{4+}/Ce^{3+} ratios, which are a proxy for oxidation state of the source magma which has been linked to its fertility for generation of porphyry-style Cu (±Au±Mo) mineralization [1]. Distribution maps for key trace elements and Ce^{4+}/Ce^{3+} ratios in single zircons thus allow the geochemical evolution of the magmatic system, including oxidation state, to be visually documented.

The procedure is been applied to zircons from a suite of Jurassic and Cretaceous granitoid intrusions from the Canadian Cordillera, including samples from igneous host rocks to porphyry-style deposits, to determine whether systematic differences exist in the geochemical trends between mineralised and non-mineralised intrusions. Pb/U ratio and age maps for the zircons are also being generated, allowing identification of inherited cores and, potentially, multiple crystallisation ages for zircons that have had a protracted crystallisation history. Also being evaluated is whether zones with anomalous ages can be identified and whether these correlate with the chemistry of the REE, or other elements, as has been proposed [2].

High concentrations of atmospheric ClO_4^-, ClO_3^-, and NO_3^- occur in the Atacama Desert where dry and oxic conditions allow oxyanions to accumulate near the surface over long periods. We collected sediment samples from vertical profiles (~1-3 m depth) over a 1000 km longitudinal transect along the central depression in the Atacama. ClO_4^-/NO_3^- molar ratios (350-3,500) and NO_3^- stable isotopes were relatively consistent both with depth and along the longitudinal transect except for locations receiving >2 cm of annual precipitation. ClO_4^-/ClO_3^- molar ratios were similar for most sites (~1). In contrast, ClO_4^- exhibited substantial variation in its stable isotopic composition ($\delta^{18}O$ and $\Delta^{17}O$) with respect to location along the longitudinal transect. In addition, the $\delta^{18}O$ and $\Delta^{17}O$ of O in ClO_4^- were strongly correlated (r^2=0.89). Elevated $\Delta^{17}O$ values indicate ClO_4^- formed largely by O_3 mediated oxidation of Cl, possibly in the stratosphere. However, substantial variation in $\delta^{18}O$ (-25 to -3 per mil) and $\Delta^{17}O$ (+4 to +10 per mil) of ClO_4^- is intriguing given the long salt accumulation times (~10^6 years). This isotopic variation may indicate some unknown process is controlling deposition over a large area for long time periods, atmospheric ClO_4^- isotopic composition has varied in geologic time, or some surface process (generation or alteration) that varies spatially is affecting the ClO_4^-isotope composition by transformation, exchange, or dilution. Insights from our work are relevant to models of oxyanion production and accumulation in areas with little biologic activity.

Enstatite Chondrites and the Composition of the Earth

STEIN B JACOBSEN[1*], MICHAIL PETAEV[1] AND SHICHUN HUANG[1]

[1]Department of Earth and Planetary Science, Harvard University, jacobsen@neodymium.harvard.edu (*)

The nearly identical O isotopic compositions of the enstatite chondrites (EC), Earth's mantle, and Moon were used [1] to argue that the EC provide the best Solar System material for estimating the chemical composition of the Earth. A possible link between the EC and Earth is further supported by recent observations that EC and Earth have the same isotopic compositions for both major and minor elements (O, Ca, Ti, Cr) which exhibit substantial variations among different chondrite groups [e.g., 2-4], with Si being the only exception.

However, there is a huge mismatch in chemical compositions between the EC and Earth. For example, the EC have much too high Rb/Sr and K/U ratios and are depleted in FeO and refractory lithophile elements compared to the composition of Earth's mantle deduced from terrestrial rocks. This discrepancy could be resolved by assuming that the Earth and EC had a common nebular precursor but they have experienced different chemical evolution. Such an assumption is supported by the mineralogy and O isotopic data for the most primitive EH3 chondrites.

The abundant FeO-bearing silicates, compositionally similar to those in other classes of chondrites, are well documented in ECs [5-8], with most silicates having O isotopic compositions of the bulk EC values [7-8]. Recent studies [9-11] showed that the chalcophile behaviour of Ca, Mg, Na, and other elements in EC is due to secondary processing of FeO-bearing silicates in an H-poor environment with high f_{S2} (Fe-FeS buffer) and f_{O2} close to the CO-CO_2 buffer.

We propose that the nebular reservoir that produced the precursor material for EC has also produced the building blocks for the Earth, chemically similar to the widely accepted Earth's composition of [12]. Interestingly, the Nd isotope variations in the Earth and EC are consistent with a bulk mantle-crust system that followed the CHUR evolution curve [13].

Investigating cloud absorption effects I and II: Global and Arctic absorption properties of black carbon and tar balls in clouds and aerosols

MARK Z. JACOBSON[1*]

[1]Stanford University, Stanford, U.S.A., jacobson@stanford.edu (* presenting author)

This is a study to understand better Cloud Absorption Effects I and II, which are the effects on cloud heating of absorbing inclusions in hydrometeor particles and of absorbing aerosol particles interstitially between hydrometeor particles at their actual relative humidity (RH), respectively [1]. The GATOR-GCMOM model was used to study these effects as well as optical properties and the mixing states of black carbon (BC) and tar balls (TB) in clouds and aerosols. The globally- and annually-averaged modeled 550-nm aerosol mass absorption coefficient (AMAC) of externally-mixed BC was found to be 6.72 (6.3-7.3) m^2/g, within the laboratory range (6.3-8.7 m^2/g). The global AMAC of externally- plus internally-mixed (IM) BC was 16.2 (13.9-18.2) m^2/g, less than the measured maximum at 100% RH (23 m^2/g). The resulting AMAC amplification factor due to internal mixing was 2.41 (2-2.9), with highest values in high RH regions. The global 650-nm hydrometeor mass absorption coefficient (HMAC) due to BC inclusions within hydrometeor particles was 17.7 (10.6-19) m^2/g, ~9.3% higher than that of the IM-AMAC. The 650-nm HMACs of TBs and SD were half and $1/190^{th}$, respectively, that of BC. Modeled aerosol absorption optical depths were consistent with AERONET and OMI data. In column tests, BC inclusions in low and mid clouds (CAE I) gave column-integrated BC heating rates ~200% and 235%, respectively, those of interstitial BC at the actual cloud RH (CAE II), which itself gave heating rates ~120% and ~130%, respectively, those of interstitial BC at the clear-sky RH. Globally, cloud optical depth increased then decreased with increasing aerosol optical depth, consistent with boomerang curves from satellite studies. Thus, CAEs, which are largely ignored, heat clouds significantly.

[10]LBNL, Berkeley, USA, KHWilliams@lbl.gov

Stimulating microbial reduction of soluble U(VI) to less soluble U(IV) is a promising strategy for remediating uranium contaminated groundwater. Little is known about optimizing the electron donor for promoting this process, nor what fraction of the electron donor is utilized by the target microbial population. Results presented here focus first on the effect of several electron donors on the microbial community and the overall uranium removal efficiency, and then on the specific utilization of acetate by target microorganisms.

Acetate and lactate, as well as more complex and commercially used donors such as a hydrogen-releasing compound (HRC) and vegetable oil were examined in terms of their effect on uranium removal and the microbial community, using flow-through column experiments. The composition of the microbial communities was evaluated with quantitative PCR probing specific 16S rRNA genes and functional genes, phospholipid fatty acid analysis, and clone libraries. For equivalent amounts of donor in terms of total organic carbon, acetate was least effective in U(VI) removal, while vegetable oil and HRC were most effective.

Utilization of acetate was examined closer by utilizing C-13 labeled acetate to determine which microorganisms take up acetate during biostimulation, and how the uptake of acetate by specific organisms, especially *Geobacter sp.*, changes over time during a long-term (~ several months) biostimulation experiment. A biostimulation experiment was performed, operating eight columns in parallel under continuous flow conditions, amended with 3 mM C-12 acetate. At regular time intervals, C-12 acetate flow into a column was switched to C-13 acetate for 36 hours before that column was sacrificed for detailed geochemical and microbiological analyses. Phospholipid fatty acid analysis (PLFA) and stable isotope probing (SIP) were used for the microbial characterization and to differentiate between the biomass that incorporated C-12 vs. C-13. Results showed that the *Geobacter* population remained fairly constant throughout the duration of the experiment (pre and post sulfate reduction), and that of the total amount of acetate incorporated into the overall biomass, about 40% was incorporated into the *Geobacter* biomass throughout the duration of the experiment.

The final experiment to be discussed shows that a very large fraction of acetate supplied for the biostimulation is utilized by methanogens, and that for very long biostimulation times and sufficiently high acetate levels to reduce all available sulfate, methane bubbles will form in the porous medium, which has implications for the system's permeability.

The differentiation of continental crust in arcs

OLIVER JAGOUTZ[1]*, MAX W SCHMIDT[2], ANDREAS ENGGIST[2]

[1]Dep. Earth Atmos. Planet. Sciences, MIT, Cambrige, USA, jagoutz@mit.edu (* presenting author)
[2]Dep. Earth Sciences, ETH Zurich, Switzerland

Processes resulting in the chemical stratification of the continental crust have since long been studied but, limited information is available on the extend and origin of stratification of the initial juvenile continental crust formed in arcs. This lack of knowledge renders the quantification of secondary reworking processes in the continental crust difficult. Here we present an extended dataset documenting the magnitude and nature of chemical stratification of the juvenile Kohistan arc crust. The Kohistan arc (NE Pakistan) is the only complete exposed arc section preserved in the geological record, ranging from upper mantle peridotites and ultramafic cumulates at the bottom to unmetamorphosed sediments at its top. The bulk composition of the Kohistan arc, formed during intra oceanic subduction, is andesitic and similar to the bulk continental crust [1]. As postcollisional secondary reworking processes in Kohistan are negligible, the chemical stratification observed of the Kohistan arc represents the best available initial stratification state of the juvenile continental crust formed in arcs.

We used in total ~60 own and published geobarometric results (Al-in-hbl and various net-transfer reactions) to constrain the (re)crystallisation depth of the different plutonic rocks of the entire Kohistan arc. The calculated (re)crystallisation pressures coincide well with inferred intrusion depths of the different units based on magmatic phase relationships and form a regionally consitent pattern of increasing pressures from the unmetamorphosed sediments in the north to the upper mantle peridotites in the south. We thus interpret the geobarometric results to generally reflect magmatic emplacement pressures. Based on these results, we used standard krigging methods to approximate the intrusion depth of > 200 sample for which geochemical whole rock compositions exist. The result is a profound chemical stratification between the lower and upper crust. Whereas the upper part of the crust is internally only weakly stratified and compositional rather homogenous the lower arc crust section is compositionally strongly stratified and complementary to the upper crust. This indicates that the juvenile continental crust formed in arcs inherits a strong primary compositional stratification before secondary (e.g. remelting) processes may set in.

Multi-tool dating for polymetallic deposits (Antimony Line, RSA)

JUSTINE JAGUIN[1*], MARC POUJOL[1], PHILLIPE BOULVAIS[1], GILLES RUFFET[1], LAURENCE ROBB[2], VALERIE BOSSE[3] AND JEAN-LOUIS PAQUETTE[3]

[1]Laboratoire Géosciences Rennes,UMR CNRS 6118, France justine.jaguin@univ-rennes1.fr
[2]Department of Earth Sciences, University of Oxford, UK
[3]Laboratoire Magmas et Volcans, UMR CNRS 6524, France

The 3.09-2.97 Ga Murchison Greenstone Belt is one of several Archean volcano-sedimentary belts within the Kaapvaal Craton in southern Africa [1]. It hosts a variety of ore deposit types: VMS style Cu-Zn mineralization [2], pegmatite related emerald and orogenic-style Sb-Au deposits along the Antimony Line (AL), the latter an unusual Precambrian Sb-dominant set of deposits located in a major quartz-carbonate altered ductile structure. Various models (magmatic, volcanogenic-derived, orogenic-gold…) have been proposed for the AL, which emphasize its overall complexity.

The Malati Pump mine, at the eastern end of the AL, hosts Au-Sb mineralization in the cupola of one of a number of granodiorite plugs intrusive into the belt. Its U-Pb (Zircon) dating and Pb-Pb dating of the Au-Sb-related sulphides yield an age of 2.97 Ga, identical to the age of the VMS Cu-Zn and the emerald deposits. Thus the granodiorites emplacement was probably the main trigger for this polymetallic metallogenic system at different crustal levels (Fig).

The AL is also clearly related to hydrothermal fluid circulation. Albitites run along the AL and were developed at the expense of a granodioritic protolith. Their systematic enrichment in Sb highlights a genetic link between the Sb mineralization and the albitization process. U-Pb data on hydrothermal monazites spread along the Concordia from 2.8 down to ca 2.0 Ga. Chemical analyses on the dated monazite allow us to interpret the data as a Discordia (combination of a major fluid circulation at 2.8 Ga followed by a thermal/fluid event at ca 2.0 Ga) rather than as a multi-events system.

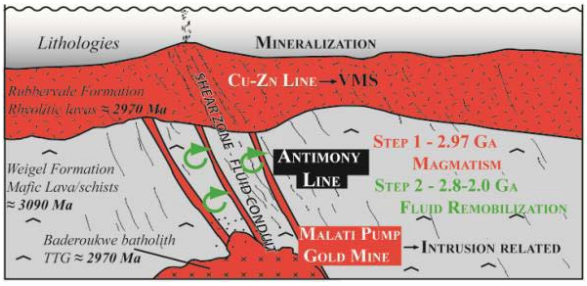

Figure: Model for the AL deposit formation and evolution.

Fluid dating is rather complex as is the AL system as a whole. This study illustrates that a combination of conventional U-Pb zircon dating to accurately identify the emplacement ages of the major meta-igneous host rocks, with Pb-Pb dating of sulphide minerals and U-Pb dating of monazites to date stages of mineralization, plus mineral chemistry studies of the various dated phases combined with $^{40}Ar/^{39}Ar$ geochronology represents a useful methodology for uncovering the history of metallogenically complex regions.

Shear deformation of olivine at high pressures and temperatures: An atomic scale perspective

SANDRO JAHN

GFZ German Research Centre for Geosciences, Telegrafenberg, 14473 Potsdam, Germany, jahn@gfz-potsdam.de

Olivine, $(Mg,Fe)_2SiO_4$, is assumed to be the most abundant mineral of the Earth's upper mantle. The knowledge of its physical properties in the relevant range of pressures and temperatures therefore provides important constraints on the dynamic behavior of the upper mantle. Plastic deformation of olivine has been investigated for a long time but recent experimental [1] and computational [2] studies suggest a pressure and strain rate dependence of the dominant olivine dislocation slip system from [100] slip at low pressures and low strain rates to [001] at high pressure and high strain rates.

Here, an atomic scale modeling approach is used to investigate the pressure and temperature dependence of the shear deformation mechanism of the magnesium end member, Mg_2SiO_4 forsterite. The simulations combine classical molecular dynamics with metadynamics using the scaled simulation cell box matrix as dynamic variables [3]. The particle interactions are described by an advanced polarizable ion potential [4]. Pressure was varied between atmospheric and 20 GPa, temperature between 1000 K and 2000 K. At high pressures (> 5 GPa), the dominant shear is observed in [001], which is consistent with the experimental studies. The dominant shear plane changes from (100) to (010) with increasing pressure and temperature. At lower pressures (< 5 GPa), both shear in [100] and combined shear in [001] and [100] are observed.

Besides identification of shear plane and direction, insight into the atomic scale mechanism of shear is obtained. The most interesting observation is a change of shear mechanism in [001](010) from a two-step process at lower pressure, in which SiO_4 tetrahedra remain intact and the stacking order of oxygens unchanged, to a three-step process, which involves breakage of Si-O bonds and changes in the stacking order of the oxygen sublattice. The latter mechanism is observed at the highest pressure, where the free volume needed for the other shear mechanism becomes energetically too expensive. Finally, possible relations between shear deformation and high pressure phase transitions of single crystal forsterite will be discussed.

The shear deformation observed in these simulations does not describe the process of dislocation creep but it provides useful guidelines and insights that are not available otherwise. The method used in this study may therefore complement other efforts to understand the rheological behavior of mantle minerals, including the very promising multiscale simulation method presented very recently [5].

Mineralogical controls on arsenic bioaccessibility in mine waste and body fluids

HEATHER JAMIESON[1*], MACKENZIE BROMSTAD[1], SUZETTE MORMAN[2], AND GEOFFREY PLUMLEE[2]

[1]Queen's University, Geological Sciences and Geological Engineering, jamieson@geol.queensu.ca (*presenting author)
[2]U.S. Geological Survey, gplumlee@usgs.gov, smorman@usgs.gov

Arsenic associated with ores is typically hosted in arsenopyrite and/or arsenical pyrite. In mine waste, arsenic mineralogy is much more complicated as a result of weathering, ore processing and the ability of As to be incorporated as As(V), As(III) or reduced As in a wide range of secondary minerals. Gastric to intestinal extraction tests indicate decreasing As bioaccessibility from Ca Fe arsenate > lead arsenate > arsenic trioxide > amorphous iron arsenate > As-bearing Fe oxyhydroxide > arsenical pyrite > As sulfide (realgar) > arsenopyrite.. There are likely to be additional factors affecting As uptake in the gastro-intestinal system including changes in pH, redox conditions and availability of Fe and S to combine with dissolved As.

Field and laboratory observations of the stability of As secondary minerals in mine waste may provide insight into the anticipated complexities and As phase transformations in the gastro-intestinal system. Arsenopyrite (FeAsS) is typically coarse-grained relative to secondary minerals, explaining why it does not react during bioaccessibility tests which involve exposure to gastric fluids for only an hour or so. Scorodite ($FeAsO_4 \cdot 2H_2O$) forms as a oxidation product of arsenopyrite (Fe/As = 1 for both minerals) and is stable in low pH environments which explains why it releases little As to acid gastric fluids, even when the starting solid is nanocrystalline [1]. As pH increases, scorodite is transformed to hydrous ferric arsenate (Fe/As>1), which may explain why more As is released to circum-neutral pH intestinal fluids. Tooeleite ($Fe_6(AsO_3)_4(SO_4)(OH)_4 \bullet 4H_2O$) has been recognized only rarely in mine waste but precipitates readily when As(III) is combined with Fe(III) under acid conditions (pH<4) [2] suggesting that if sufficient Fe is available (Fe/As=.66), this phase may form under gastric conditions and limit As bioaccessibility. Arsenic trioxide (As_2O_3) is a product of ore processing which is stable over a wide range of pH and, in some contaminated soils, persists for many decades. In other situations, arsenic trioxide combines with Fe(III) to form scorodite in acid drainage [3] or with reduced S to form secondary As sulfides [4]. It is possible that similar transformations may occur in the body, both of which would reduce As bioaccessibility. Finally, Ca-Fe arsenate minerals (e.g. yukonite $Ca_7Fe_{12}(AsO_4)_{10}(OH)_20 \bullet 15H_2O$) have Fe/As>1 form under pH-neutral conditions where carbonate minerals are stable. These minerals are soluble in acid fluids and exhibit high As bioaccessibility in gastric solutions.

Laboratory results indicate that As bioaccessibility can actually be higher per mass in simulated lung fluids than gastric, but the overall dose is smaller due to the lower amounts that reach the lung.

Chromium isotope fractionation during reduction of Cr(VI) under saturated flow conditions

JULIA H. JAMIESON-HANES[1*], BLAIR D. GIBSON[1], MATTHEW B.J. LINDSAY[1,2], YEONGKYOO KIM[3], CAROL J. PTACEK[1], AND DAVID W. BLOWES[1]

[3]Dept. of Geology, Kyungpook National University, Korea, ygkim@knu.ac.kr

Chromium (VI) is a pervasive groundwater contaminant that poses a considerable threat to human health. Remediation techniques have focused on the reduction of the highly mobile Cr(VI) to the sparingly soluble Cr(III) species. Reduction has been shown to produce significant Cr isotope fractionation, characterized by an enrichment in the $^{53}Cr/^{52}Cr$ ratio in the remaining Cr(VI) pool [1]. Chromium isotopes are promising indicators of Cr(VI) reduction in groundwater; however, the influence of transport on fractionation has not been fully examined.

A laboratory column experiment was conducted to evaluate isotopic fractionation of Cr during Cr(VI) reduction under controlled flow conditions. Simulated groundwater containing 20 mg L^{-1} Cr(VI) was pumped through a saturated column containing quartz sand with 10% (v/v) organic carbon. Isotope measurements were performed on both effluent and profile samples. Dissolved Cr(VI) concentrations decreased while $\delta^{53}Cr$ increased, indicating that reduction of Cr(VI) occurred. Solid-phase analysis by scanning electron microscopy (SEM) and X-ray absorption near edge structure (XANES) spectroscopy confirmed the presence of Cr(III) on the surface of the organic carbon. The $\delta^{53}Cr$ data followed a linear regression equation yielding a fractionation factor (α) of 0.9979, whereas previous studies of batch experiments under similar geochemical conditions demonstrated Rayleigh-type isotope fractionation. Both the results of the solid-phase Cr and isotope analyses suggest a combination of Cr(VI) reduction mechanisms, including reduction in solution, and sorption prior to reduction [2]. The linear characteristic of the current $\delta^{53}Cr$ data may reflect the contribution of transport on Cr isotope fractionation.

Mechanisms of reaction driven porosity and permeability generation

BJØRN JAMTVEIT[*], OLIVER PLÜMPER, ANJA RØYNE AND ANDERS MALTHE-SØRENSSEN

Physics of Geological Processes, University of Oslo, P.O. Box 1048, Blindern, N-0136, Oslo, Norway (bjorn.jamtveit@geo.uio.no)

The evolution of the Earth's lithosphere is, to a major extent, affected by reactions in which magmatic or metamorphic rocks consume fluid components such as H_2O and CO_2. Examples include serpentinization of the oceanic lithosphere and weathering of continental rocks. The progress of such reactions, as well as many other replacement processes that depend on the presence of a fluid phase, requires that porosity is maintained to keep fluid in contact with reactive solid surfaces.

As most volatilization reactions lead to a reduction in rock density, and thus an increase in the volume of solid, the initial pore volume will tend to become filled with new mineral phases during such processes, in the absence of porosity-generating processes. However, observations at scales ranging from nanometer to outcrop scales, indicate that a variety of porosity generating processes are operating. For example, replacement reactions mediated by dissolution-reprecipitation mechanisms have been observed to produce micro-porous products in a variety of systems [1], while reactions associated with a significant volume increase often lead to fracturing [2]. However, the detailed mechanisms of these porosity- producing processes have been poorly understood.

In this contribution, we review examples of reaction driven fracturing, and propose a new model for how stress is generated at reacting olivine surfaces during serpentinization. This model emphasizes the role of interface coupled dissolution-reprecipitation processes in producing the surface roughness required to generate stress concentration and associated fracturing at the reactive surface. This process results in the hierarchical fracture network [3] represented by the characteristic mesh-structure of partly serpentinized olivine grains. Similar patterns are also observed in a variety of other systems.

The relationship between PM10 and meteorological conditions in Sosnowiec (Poland) in view of potential health hazard

JANECZEK JANUSZ[1*], JABLONSKA MARIOLA[1],
LESNIOK MIECZYSLAW[2],

[1]University of Silesia, Department of Geochemistry, Mineralogy and Petrology; Sosnowiec, Poland
janusz.janeczek@us.edu.pl; mariola.jablonska@us.edu.pl
[2]University University of Silesia, Department of Climatology,Sosnowiec, Poland,
mlesniok@op.pl

The aim of this study was to determine concentrations and chemistry of PM10 in one of the major cities in densely populated and industrial region of Upper Silesia, SW Poland, in relation to meteorological conditions. Meteorological conditions and atmospheric circulations play an important role in dispersion of air pollutants [1].

Both concentrations of PM10 and meteorological parameters were monitored from June to December 2011. In addition, the collected PM10 was investigated by analytical scanning and transmission electron microscopies (SEM, TEM). The identification of phases in PM10, their morfology, chemical compositions, structure and particle size enabled the precise pinpointing of the emission sources.

The abundant ultraparticles occur in the PM10 fraction. Those ultraparticles are carriers of heavy metals inluding Pb, Zn, Cd, U and others. The most common constituent of PM10 is soot. A large number of nano-sized particles containing toxic elements adhered to the soot surface and together with respirable soot particles can be inhaled by the humans.

Quartz, iron oxides, amorphous and crystalline alumino-silicates are also abundant in PM10 and in ultraparticles. Regardless of their size they may have a negative impact on human health as suggested by medical data for this part of Poland. All of the observed mineral phases in PM10 are typical of fossil fuels combustion and of car exhausts.

As expected, the highest concentrations of PM10 was observed during the prevalence of anticyclonic conditions, at low speed winds, and the lack of precipitation. The extremaly high concentrations of PM10 were associated with the thermal inversion. The presence of some mineral phases in PM10 (e.g. Zn, Pb, Cd-sulfides, Sn alloys) combined with back-tracing of air flow allowed precise location of particular sources of dust emissions.

Authigenic neodymium isotopes recording change in Arctic Ocean circulation

KWANGCHUL JANG[1*], YEONGCHEOL HAN[1], YOUNGSOOK HUH[1], SEUNG-IL NAM[2]

[1]Seoul National University, Seoul, Korea, wkdrhkd3@snu.ac.kr (* presenting author), hanlove7@snu.ac.kr, yhuh@snu.ac.kr
[2]Korea Polar Research Institute, Incheon, Korea, sinam@kopri.re.kr

We analyzed neodymium isotope ratios of Fe-Mn oxide coatings in sediments from the Mendeleev Ridge collected during RV Polarstern Expedition ARK-XXIII/3. According to our age model constructed using AMS ^{14}C ages (n=4) and by correlating $\delta^{18}O$ and $\delta^{13}C$ with neighbouring cores 94B16 [1] and 0503-8JPC [2], the record extends to MIS 5a. The average ε_{Nd} value (n = 39) was -10.2, which is quite similar to the present-day water column values of the Canada and Makarov basins [3]. Two significant deviations from the average ε_{Nd} were observed. Middle MIS 3 displayed unradiogenic ε_{Nd} accompanied by decreases in $\delta^{18}O$ and $\delta^{13}C$ of planktonic foraminifera (*N. pachyderma* sin.) and an increase in $\%CaCO_3$. The unradiogenic dissolved Nd of the Mackenzie River [4] and carbonate-rich lithology of the Canadian Archipelago suggest that the melting of the Laurentide Ice Sheet (LIS) was mainly responsible. Additionally, the pinkish carbonate layer observed at this depth interval is reported to be derived from Banks and Victoria islands of the Canadian Archipelago [5]. The radiogenic ε_{Nd} peak during Late MIS 4–Early MIS 3 period coincided with decreases in $\delta^{18}O$ and $\delta^{13}C$ values and low $\%CaCO_3$. The radiogenic dissolved Nd of the Ob and Yenisei rivers [6] and the carbonate-poor lithology of western Siberia suggest that outburst of ice-dammed lakes from this region could have affected the western Arctic Ocean [7].

The two contrasting sources mentioned above imply that the water circulation pathway has changed. During the Mid-MIS3, transport via the Beaufort Gyre may have expanded and water from the Canadian Archipelago bathed the southern Mendeleev Ridge. On the other hand, during the Late MIS 4–Early MIS 3 period, the Beaufort Gyre may have weaked and water from western Siberia dominated on the southern Mendeleev Ridge. According to Morison et al. [8], the strength of the Beaufort Gyre is modulated by the Arctic Oscillation (AO). Consequently, our results suggest that the negative mode of AO is associated with the warmer Mid-MIS3 and the positive mode with the colder Late MIS 4-Early MIS 3.

A Physiochemical Analysis of the Transport and Retention of Technetium in Unsaturated Hanford Formation Sediments

DANIELLE P. JANSIK[1,2*], DAWN M. WELLMAN[1], JONATHAN ISTOK[2], JIM SZECSODY[1], KENT PARKER[1], ELSA CORDOVA[1]

[1]Pacific Northwest National Laboratory, Richland, United States, Danielle.Jansik@pnnl.gov

[2]Oregon State Univeristy, Corvallis, United States

The transport of Tc, like many other radionuclides, is of interest due to the potential for human exposure and impact on ecosystems. Specifically, Tc is a contaminant of concern at several DOE facilities including the Hanford, Oak Ridge, Paducah, Portsmouth, and Savannah River Sites.

Current conceptual models do not fully explain the distribution and persistence of technetium in vadose zone environments such as the Hanford site, Eastern Washington. In an oxic environment with low organic content the residence time of technetium in the soil would be expected to be low, due to its low sorption and high mobility. While $Tc^{VII}O_4$ can be reduced, it is also readily oxidized, so temporary reducing environments are not expected to alter the general rapid Tc migration in the subsurface. Inexplicably, nearly 50 years following the release of contamination into the site, a significant fraction of Tc has persisted in the subsurface in the 200 Area.

In these experiments we examined the unsaturated transport of pertechnetate at very low water content using an Unsaturated Flow Apparatus (UFA) to evaluate breakthrough curve behavior and the potential impact of immobile domains, anion exclusion and sorption on the transport and retention of technetium. The analysis confirmed that Tc was transported at pore water velocity and that transport was not altered by the presence of immobile domains, anion exclusion, or sorption. The experimental dispersivity increased with decreasing saturation.

Using borehole sediments from the Hanford site 200 Area where Tc was co-disposed with a variety of chemicals and has been in contact with the sediment for decades, a series of sequential extractions was conducted to evaluate the mineral associations of technetium in natural Hanford sediments. The sequential extractions targeted the Tc associated with the ion exchange layer, carbonate minerals, aluminosilicate minerals and iron oxides. The analyses indicated that while most Tc was associated with an aqueous extractable phase, some Tc was associated with oxalic acid and nitric acid extractable phases. The preliminary results indicate a portion of the Tc may be less mobile than originally indicated. EXAFS and XANES will be used to identify Tc surface phases, as the surface Tc may be incorporated in minerals or coated by non-Tc precipitates. Results from extractions and additional geochemical analysis will be presented.

Saline groundwater discharges in the Athabasca oil sands region: a chemical mass balance

S. JASECHKO[1*], J.J. GIBSON[2,3], S.J. BIRKS[2,4], Y. YI[2,3], A. MARANDI[5]

[5]Institute of Geology, Tallinn Technical University, Tallin, Estonia

Quantifying water quality impacts of oil sands developments in western Canada will require decoupling natural contributions of organic and inorganic contaminants from potential releases from tailings ponds, oil sands mining, and in-situ bitumen production. Here, we quantify natural saline groundwater contributions to the Athabasca River by applying a chemical mass balance (Cl^-) to monthly chemical and discharge data collected between 1987 and 2009, using data available from the Long Term River Network.

The results of the chemical mass balance indicate that saline springs are an important control on the chemistry of the Athabasca River, despite comprising <3% of the river's discharge. The impact of these discharges on the chemistry of the Athabasca River is greatest during periods of low river flow. The shift in chloride concentrations measured between Fort McMurray and the Peace Athabasca Delta can only be explained if saline groundwater along this stretch are in the range of 500 to 3400 L/s. This finding is supported by the subcrop exposure and known seepage of Devonian- and Cretaceous-aged aquifers bearing saline fluids along this reach of the Athabasca River. While this study does not exclude the possibility that tailings discharge to the Athabasca River could be occurring, the observed increase in chloride measured between Fort McMurray and the Peace-Athabasca Delta cannot be accounted for using tailings pond seepages alone. The range of chloride concentrations reported for a wide range of tailings ponds are very low in comparison with the groundwater seeps entering the river and the total increase in chloride along this stretch cannot be reconciled using just mixing with tailings pond water.

Given the important role discharges of saline groundwater from Cretaceous and Devonian formations appears to play in the geochemical evolution of the Athabasca River, a more comprehensive evaluation of regional groundwater flowpaths and groundwater surface water interactions is warranted. These results suggest that any future water quality monitoring efforts for the Athabasca River should try to better quantify the contribution of groundwater inflow to changes in river water quality.

Historical atmospheric deposition of PAHs in lakes east of the Athabasca oil sands operations

JOSUÉ JAUTZY[1*], JASON M. E. AHAD[2], CHARLES GOBEIL[1], AND MARTINE M. SAVARD[2]

[1]INRS Eau Terre Environnement, Québec City, Canada, Josue.Jautzy@ete.inrs.ca (* presenting author), Charles.Gobeil@ete.inrs.ca

[2]Geological Survey of Canada, Natural Resources Canada, Québec City, Canada, Jason.Ahad@nrcan.gc.ca, MartineM.Savard@nrcan.gc.ca

The growth of bitumen mining activities in northeastern Alberta poses significant environmental challenges. One of the main concerns is a potential increase in emissions of harmful organic contaminants such as polycyclic aromatic hydrocarbons (PAHs). PAHs are widespread in the environment and result from incomplete organic matter combustion (kinetic process) or maturation (thermodynamic process), which makes them good markers of pyrogenic or petroleum input.

In order to understand the impact of oil sands-related mining activities to the environment it is essential to examine PAH emissions in the context of variability in natural background levels. Here we report geochronological records of PAH atmospheric deposition fluxes over the last century in two headwater lakes located approximately 50 km downwind from the main area of oil sands operations. Assessing PAH levels over the last 100 years allowed us to differentiate the deposition fluxes prior to the modern period of bitumen mining activities (i.e., pre-1970). Concentrations of the 16 EPA priority PAHs in addition to coronene, retene, perylene and 6 alkylated groups were measured in dated cores from both lakes. PAH molecular diagnostics ratios were used in order to discriminate preliminary sources and their variation over time.

Results and conclusion:

Our results showed an increase of parent and alkylated PAHs (2-fold for alkylated PAHs and 0.5-fold for 16 EPA priority PAHs) in both lakes over the past decade. Alkylated PAHs are generally related to petroleum sources. A possible explanation for this increase may be the expansion of open mine pit area resulting in greater sensitivity to wind erosion and transport. PAH molecular diagnostics ratios revealed two distinct groupings using two different sets of ratios: a pre-1980s combustion dominated type, and a post-1980s petroleum dominated one. These results point to an increasing contribution from recent oil sands mining activities, though it should be noted that overall PAH levels in these lakes are relatively low. In light of these results, and taking into consideration the future expansion plans of bitumen mining activities, it is possible that PAH fluxes in this region may continue to rise. Further insight into PAH source apportionment is expected from ongoing work involving compound-specific isotope analysis.

Meridional distribution of the atmospheric $^3He/^4He$ isotopic ratio

P. JEAN-BAPTISTE[1*], E. FOURRE[1]

[1]LSCE, CEA-CNRS-UVSQ, Gif/Yvette, France, pjb@lsce.ipsl.fr

Due to the release of crustal helium by natural gas and oil production and by coal mining with a low $^3He/^4He$ ratio, the atmospheric $^3He/^4He$ ratio may be decreasing with time. The direct detection of this change is problematic due to the difficulty in finding well preserved ancient air samples and has led to conflicting results. Most of the He release occur in the northern hemisphere, therefore it may create an interhemispheric gradient in the atmospheric $^3He/^4He$ ratio, as already observed for other anthropogenic gases such as CH_4, CFC or ^{85}Kr. We performed precise helium isotope measurements on air samples collected at various latitudes going from 82°30'N (Alert Station) to 78°38'S (Vostok Station). The mean helium isotope ratio (relative to our Saclay air standard) are identical for both hemisphere : 1.0004 ± 0.0005 for the northern hemisphere and 1.0004 ± 0.0009 for the southern hemisphere respectively, thus showing no detectable meridional gradient. However, as shown in Fig. 1, $^3He/^4He$ values are very homogeneous from the northermost latitudes to 20°S but the two southernmost data points show diverging trends. Therefore, additional data are needed south of 20°S.

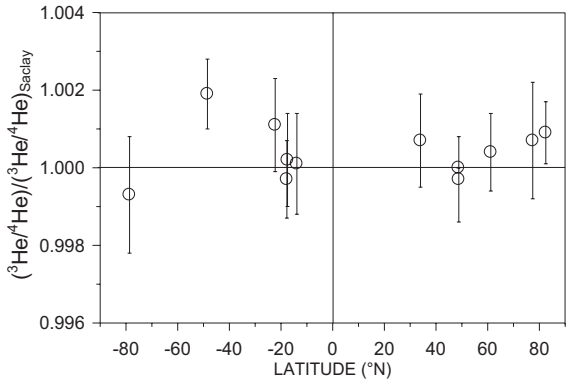

Figure 1: Meridional distribution of the helium isotopic ratio of air

The lower value for Vostok could be due either to the high elevation (3500 m) or to the relative isolation of the air masses over the Antarctic interior. If we consider this latter data point as an outlier, the mean $^3He/^4He$ value for the southern hemisphere becomes 1.0006 ± 0.0009. The two mean values, $^3He/^4He = 1.0004$ for the northern hemisphere and $^3He/^4He \leq 1.0006$ for the southern hemisphere, can be used to estimate the value of the anthropogenic helium flux using a simple two-box model of the atmosphere with an interhemispheric mixing time of about 1 year [1-2] and a anthropogenic helium input function proportional to the world release of fossil carbon since 1850. Model results indicate that the He/C molar ratio may be $\leq 2\times10^{-4}$, with a decrease of the atmospheric $^3He/^4He$ ratio $\leq 0.7\%$ over the industrial period.

[2]Montana State University, Chemical and Biological Engineering, Bozeman, Montana, United States of America.

[3]Pacific Northwest National Laboratory, Richland, Washington, United States of America.

Introduction and Approach

Ferric oxyhydroxide microbial mats in acidic high-temperature springs of Norris Geyser Basin, Yellowstone National Park (Wyoming, USA) are inhabited by an environmentally constrained consortia of archaea. These extreme environments are ideal sites to study microbial interactions in natural communities where gradients in temperature and oxygen occur over spatially resolvable distances. The goal of this study was to generate a stoichiometric metabolic model as an incremental step in describing the microbial ecology within these chemotrophic systems. We obtained a metagenome of a ferric oxyhydroxide mat community in One Hundred Springs Plain via Sanger sequencing (DOE-Joint Genome Institute). *De novo* assemblies were obtained using the Celera (J. Craig Venter Institute) assembler and evaluated using nucleotide word frequency-principal components analysis. These communities are comprised of several dominant populations including chemolithoautotrophic *Metallosphaera yellowstonensis*, as well as heterotrophic Thermoproteales, Desulfurococcales, and a novel, deeply rooted archaeon (NAG1). *De novo* assemblies corresponding to these populations were annotated and *in silico* stoichiometric metabolic models were created for each organism focusing on mass and energy fluxes within and between community members.

Results and Conclusion

Multiscale metabolic systems analysis was used to predict possible modes of microbial interaction where autotrophic metabolism of *M. yellowstonensis* supports Thermoproteales, Desulfurococcales, and NAG1 growth via metabolic exchange of co-factors as well as different types of reduced carbon. These metabolite exchanges suggest autotroph-heterotroph relationships constrained by fluxes of major electron donors/acceptors and sources of carbon. This work provides a rational, *in silico* framework for understanding the microbial ecology within a thermophilic ferric oxyhydroxide mat community.

Enhanced soil remediation by microwave irradiation with sodium hydroxide and iron powder

SANGJO JEONG[1,*] AND HANG-DEUK KIM[1]

[1]Korea Military Academy, Department of Civil Engineering and Environmental Sciences, sangjo.jeong@gmail.com

Abstract

Thermal treatment is one of the fast and effective methods to remediate highly contaminated soils with organic contaminants such as gasoline, diesel fuel, and organic solvents, etc. However, the energy efficiency of thermal treatment is relatively low, compared to other soil remediation techniques. In this study, microwave irradiation was applied for contaminated soils to efficiently desorb and degrade organic contaminants. The effects of additives such as iron powder and sodium hydroxide (NaOH), activated carbon on desorption and degradation of organic contaminants in soils were investigated.

The modified microwave oven (2,450 MHz, 800W) was used as a reactor. Tetrachloroethylene (PCE) and hexachlorobenzene (HCB) were selected as representative organic contaminants. Sandy soil, clay soil, *and* zeolite were used as adsorbents. Each soil sample was intentionally contaminated with organic contaminant which was dissolved in methanol, respectively, and dried in the fume hood. The contaminated soils were located in the microwave reactor and irradiated with microwave for 9 minutes in nitrogen condition. About 10% of additives and 20% of water were also mixed with the contaminated soils and treated with the same method for contaminated soils. During microwave irradiation, effluent gas was collected with methanol. After microwave irradiation, residual organic contaminants were extracted from soils with by methanol. Desorbed and residual organic contaminants were analyzed with both gas chromatography (GC, Shimadzu GC 2014) with electron capture detector (ECD) for mass balance and GC with mass spectrometry (Agilent 5795C VL MSD) for degradation products. The chloride ions were extracted from soils after microwave irradiation and analyzed with ion chromatography (Dionex ICS-2000) to investigate the degradation of chlorinated organic contaminants.

The results of chloride ion analysis showed that chlorinated organic contaminants in soils were degraded by microwave irradiation with iron powder and NaOH. Desorption of organic contaminants from soils was enhanced by the addition of water. Microwave irradiation for 9 minutes with additives (e.g., 10% Fe / 5% NaOH, 10% activated carbon) removed most of the contaminant from PCE contaminated sandy soils. However, it was not sufficient for HCB contaminated sandy soils. Later on, the properties of pyrolyzed organic contaminants will be investigated using zeolite and the differences of soil remediation properties between sandy and clay soils will also be examined. These results will contribute to develop more energy efficient soil remediation techniques, which is applicable to highly contaminated soils with organic contaminants.

Geochemical characteristics of suspended matters and sediments in a small watershed of the central Guizhou province and its weathering implications

JI HONGBING[1, 2*], JIANG YONBIN[1, 2], ZHAO XINGYUAN[1]

[1] The College of Resource Enviroment and Tourism, Capital Normal University, Beijing 100048, China
[2] School of Civil and Environmental Engineering, University of Science and Technology Beijing, Beijing 100083, China (*correspondence: hongbing.ji@yahoo.com)

Southwest China is one of the three biggest karst areas in the world. Over the past few decades, land use changes in this area have resulted in a series of severe ecological and environmental problems. This paper presents data on trace elements and C, N isotopes of suspended matters and sediments collected from the Qianzhong watershed in the central Guizhou province, Southwest China. Results showed that the contents of trace elements are different between rivers and lakes, also between suspended and sedimentary phases; the spatial and temporal distribution of OC contents, $C_{organic}/N_{total}$ and $\delta^{13}C$ in total suspended matter (TSM) and sedimentary matter showed different variation, indicating the transfer and arrival of allochthonous organic matter and the ecosystem changes during past sedimentary period. $\delta^{15}N$ ratios reflected the combined results of information of sources and a series of biogeochemical processes. Although $\delta^{15}N$ ratios could provide limited information of sources, it can be used to trace some special biogeochemical processes. The conclusion was testified the element characteristics and material conveying status in chemical weathering and physical erosion processes in the small watershed, And by the analysis of end members. C_3 plant debris and soil organic matter from decomposition of a mixture of C_3 and C_4 plant debris are the dominant sources for SED-OC, and aquatic plants for POC. The fractionation of $\delta^{13}C$ caused by decomposition of organic matter or diagenesis was minor. There are two models for the relationship between physical erosion and chemical weathering there: the co-promotion model for regions which have serious anthropogenic effects, and the increase and decrease model for regions where anthropogenic input is less significant. Both models would likely to be occurring in global scale.

From schwertmannite to natrojarosite: aging processes involving precipitation and dissolution reactions

AMALIA JIMÉNEZ[1*], ANGELES FERNÁNDEZ-GONZÁLEZ[1], ANA HERNÁNDEZ[1] AND MANUEL PRIETO[1]

[1]University of Oviedo, Spain, amjimenez@uniovi.es*

Introduction

Minerals of the jarosite group ($MFe_3(SO_4)_2(OH)_6$) are involved in different mineralogical and geochemical processes ocurring in the environment (acid mine water drainage, chemical weathering). Here, the objective is studying the genesis of natrojarosite during aging processes at ambient temperature. For this purpose, a set of experiments was carried out by mixing $Fe_3(SO_4)_2$ (0.5N) and NaOH (0.5N) parent solutions which were kept at constant agitation for specific reaction periods (1 hour to 50 days). Similar experiments were performed using 1N concentration of parent solutions. Composition and crystallinity were determined by X-ray powder diffraction (XRD) using the computer program X'Pert Plus (Panalytical). The aqueous solution composition was analysed by ICP-OES, and the pH was monitored at the beginning and end of the experiments. Speciation and aqueous solution modeling was carried out using PHREEQC code [1].

Results and Conclusion

XRD results reveal that schwertmannite ($Fe_8O_8(SO_4)(OH)_6$) precipitate in the early stages of the experiments, regardless of the initial concentration. In the case of the experiments carried out with 0.5 N parent solutions, schwertmannite remains during the entire aging process. In contrast, using 1N parent solutions, schwertmannite evolved to form natrojarosite ($NaFe_3(SO_4)_2(OH)_6$). The main XRD reflections (012, 021 and 113) of natrojarosite become more apparent and undergo a progressive decrease of widthness (FWHM) and an increase of intensity which indicate an increasing degree of crystallinity at the end of the aging process. The analysis of the aqueous solution shows that there is a virtually complete removal of Fe due to the precipitation of schwertmannite. In the experiments performed with 1N parent solution, the evolution of the aqueous composition is consistent with the initial precipitation of schwertmannite and subsequently, the precipitation of natrojarosite with increasing of crystallinity. The reactions takes place in acidic conditions (pH~2.2) in all experiments. Although PHREEQC considers many other phases susceptible to precipitate, any of these were identified in the diffractograms.

A set of reactions, including precipitation of schwertmannite and its transformation into natrojarosite takes place simultaneous in a highly supersaturated aqueous medium for both phases.

Towards a unifying theory of geomicrobial kinetics

QUSHENG JIN[1*]

[1]Department of Geological Sciences, University of Oregon, Eugene, OR, USA, qjin@uoregon.edu (* presenting author)

Geomicrobial kinetics studies how fast microbial metabolism proceeds in natural environments – a key question of low-temperature geochemistry [1]. It differs from microbial kinetics by considering wide spectra of tempertaures, pHs, availibilities of energy sources and growth nutrients, and other environmental factors. Geomicrobial kinetics also differs from geochemical kinetics in that it accounts for life's essential functions, including energy conservation, growth, and maitenance, and considers how thermodynamics impacts reaction rates.

Geomicrobial rates can be predicted on the basis of rate laws that applicable to natural environments [2]. These rate laws carry relatively large numbers of kinetic and thermodynamic parameters in order to account for various environmental and microbial factors. But application of the rate laws present a special challenge – how to assign values for the parameters.

Jin and Roden propose a best-choice approach to assign parameter values [1]. In theory, microbial parameters can be seperated into two groups, extant and intrinsic [3]. Extant parameters describes how rates are influenced by microbial adaptation to the environments, and include half-saturation constants for electron donor oxidation, acceptor reduction, and nutrient consumption, and specific maitnenance rate. These parameters vary with the availability of energy and nutrient sources, and should be determined directly using samples from the environment.

Intrinsic parameters describe the dependence of microbial rates on cellular enzymes and pathways, and include rate constant, growth yield, ATP yield, phosphorylation energy, and average stoichiometric number. These parameters bear the relationships determined by microbial physiology. Taking anaerobic respiration as an example, ATP yield and average stoichiometric number vary with electron donors and acceptors, and can be determined on the basis of respiratory pathways. Also, because microbial growth depends on ATP synthesis, growth yield increases linearly with ATP yields. As a result, we can taken intrinsic parameters as constants of microorganisms, and extraploate the values determined for pure cultures directly to the environment.

Taking the simulation of microbial sulfate reduction and methanogenesis as examples, I demonstrate how to select parameter values that are consistent with our current knowledge of microbial physiology and relavant to the environment of interest. I then apply the parameter sets and simulate microbial metabolism in batch reactors of mixed culture, flow-through sediment columns, and lake sediments. The results demonstrat that the best-choice approach reduces the task of parameter fitting and ensures the quality of simulation.

Experimental study on carbonation of Portland cement in sodium chloride solutions

HWANJU JO[1*], HO YOUNG JO[1], AND YOUNG-NAM JANG[2]

[1]Korea University, Earth and Environmental Sciences, Seoul, Republic of Korea, chohwanju@korea.ac.kr (*presenting author)

[2]Korea Institute of Geoscience and Mineral Resources, CO_2 sequestration Research Department, Daejeon, Republic of Korea

Carbonation behavior of cement has been extensively studied because cement carbonation affects the conrete stength and corrosion resistance of the steel reinforcement. Various factors can affect the carbonation of cement. This study presents the influence of salinity on the carbonation behaviors of cement material.

The leaching and carbonation tests were conducted on ordinary Porland cement(OPC) using a Teflon reacter at various NaCl concentrations (0 ~ 2.0 M) under ambient temperature and pressure conditions. For the carbonation tests, CO_2 gas (99.9%) was injected in the slurry, which was obtained by mixing the soluiton and OPC.

For the leaching tests, the slurry pHs increased to 12.0 ~ 12.9, regardless of the NaCl concentration, after 24-hours leaching due to dissolution of $Ca(OH)_2$. The electrical conductivities (ECs) of the slurries increased steadily during the leaching test at low NaCl concentrations (< 1.0 M), whereas decreased at high NaCl concentrations (> 1.0 M). The Ca concentration in the slurry increased with increasing the NaCl concentration. After the leaching tests, dissolution of C_3S and $Ca(OH)_2$ and formation of C-S-H and Friedel's salt were indentified by XRD, SEM-EDX, and TGA analysis. The NaCl concentration affected the extent of the C-S-H formation during the leaching tests. The C-S-H content in the reacted OPC was the highet at the 1.0 M NaCl solution. During CO_2 injection, the pH decreased due to the dissolution of CO_2 and the carbonation reaction. Precipitation of well-crystallized calcite ($CaCO_3$) and halite (NaCl) in the reacted OPC obtained after the carbonation tests were identified by XRD, SEM-EDX, and TGA analysis. The C-S-H content decreased but the $CaCO_3$ content increased with incresing the NaCl concentration after the carbonation tests. Theses results sugesst that the presence of NaCl enhances the dissolution of $Ca(OH)_2$ in the OPC during hydration and the precipitation of $CaCO_3$ by the elevated dissolution of C-S-H during CO_2 injection.

Combined silicon, oxygen isotope and trace element microanalysis of giant spicules of the deep-sea sponge *Monorhaphis chuni* for paleoclimate research

KLAUS PETER JOCHUM[1*], XIAOHONG WANG[2], JAN A. SCHUESSLER[3], BÄRBEL SINHA[1], BRIGITTE STOLL[1], ULRIKE WEIS[1], MEINRAT O. ANDREAE[1], AND WERNER E.G. MÜLLER[4]

[1]Max Planck Institute for Chemistry, Mainz, Germany, k.jochum@mpic.de (* presenting author)

[3]German Research Centre for Geosciences GFZ, Potsdam, Germany
[4]Universitätsmedizin Mainz, Germany

The deep-sea sponge *Monorhaphis chuni* forms giant spicules, which can reach lengths of 3 m and diameters of 10 mm [1]. Because of the long lifespan of this sponge (several thousands years), the spicules offer a unique opportunity to record environmental change of past oceanic and climatic conditions [2]. To get a detailed time-resolved record over the lifetime of the sponge, analyses at a high resolution in the nm to µm range were performed. We investigated several giant spicules from the East and South China Sea along center-to-surface segments by determining Si isotopes with UV fs-LA-MC-ICP-MS at GFZ, and O isotopes with NanoSIMS and trace elements with LA-ICP-MS at MPI. No clear trend in Si isotope variability outside external analytical reproducibility (±0.2 ‰, 2SD) could be identified in the spicule MC from the East China Sea; average δ^{29}Si and δ^{30}Si values relative to NBS 28 were -0.67±0.21 and -1.30±0.35 (2SD), respectively. According to [3], the Si isotope fractionation is influenced by seawater Si concentration with lower isotope ratios being associated with sponges collected from waters high in Si. This implies that no significant change in Si concentration in the ambient seawater occurred during the lifetime of the sponge. Average δ^{29}Si values for the specimen SCS-3 and Q-E from the South and the East China Sea, respectively, are different: -0.43±0.22 (SCS-3) and -1.28±0.23 (Q-E) indicating different Si contents of the seawater. In contrast to these measurements, oxygen isotope data and Mg/Ca ratios of the spicule MC show a small trend in $\delta^{18}O_{VSMOW}$ from about 36±1 (rim) to 38.5±0.5 (core) and Mg/Ca from 0.062 (rim) to 0.055 (core), which can be interpreted as an increase in seawater temperature of about 3 °C during the lifespan of this specimen, similar to the results of the giant spicule QB [2].

Gold, Gilding and gilded marble sculpture in Antiquity: new methods, new results.

PHILIPPE JOCKEY[1*]

[1]Aix-Marseille Université, Centre Camille Jullian, Aix-en-Provence, France, philippe.jockey@univ-amu.fr

Gilding marble statues in Antiquity was rather a common practice, as testified both by ancient literary and epigraphical sources. However, for a long time, scholars showed some reluctance to admit it, due to the lack of archaeological evidence. Today, on the contrary, new scientific methods of surveying, evidencing and analysing marble surface treatments, by combining for instance videomicroscopy and X-ray fluorescence spectroscopy, confirm without any doubt the success of gilded marble statues in ancient Greece as in Rome[1]. They also give informations about gilding an regilding processes, documenting gold leaf thickness as well as the techniques of applying it on the marble layer by layer. By crossing archeological and archeometrical evidence, it becomes then possible to reconsider both ancient taste and gilded statues functions. For instance, a bright white marble hellenistic copy of the Famous classical Greek sculptor Polycletes, found in Delos [Figure 1] at the beginning of the 20th century was originally wholly gilded [Figure 2], leading to new conclusions as regards the status and functions of such a work[2]. But at the present time, some decisive information remain unknown, as for instance the provenance of the gold itself, a central historical and economic topic for Historians and Archaeologists. We need to find the missing link between antique gold mines and gilded or gold artefacts. The present talk aims also at arousing new collaborations focused on this topic.

Sources of organic matter fueling As mobilization in groundwaters of West Bengal, India: Evidence from reactive transport modeling

KAREN H. JOHANNESSON[1*], SAUGATA DATTA[2], T. JADE MOHAJERIN[1], KATHERINE TELFEYAN[1], NINGFANG YANG[1], CHRISTOPHER D. WHITE[3] AND BRAD E. ROSENHEIM[1]

[1]Department of Earth and Environmental Sciences, Tulane University, New Orleans, LA, USA, kjohanne@tulane.edu (* presenting author)

[2]Department of Geology, Kansas State University, Manhattan, KS, USA, sdatta@k-state.edu

[3]Department of Petroleum Engineering, Louisiana State University, Baton Rouge, LA, USA, cdwhite@lsu.edu

It is generally agreed that microbial reduction of Fe(III) oxides/oxyhydroxides coupled to organic matter (OM) oxidation is an important mechanism by which arsenic (As) is mobilized to groundwaters within the Bengal Basin of Bangladesh and West Bengal, India. Nonetheless, the source of the OM driving the respiratory processes remains contentious [1]. Some researchers argue that recently constructed perennial ponds are a major source of recharge waters, and hence dissolved organic matter (DOM) to the As affected groundwaters, whereas others maintain that the sediments contain sufficient OM to fuel microbial respiration [2, 3]. Here we employ reactive transport modeling to simulate transport of DOM in aquifers from the Murshidabad district of West Bengal, India. The goal was to assess the possibility that OM originating in surface ponds could be transported to depth in the local sediments where As is chiefly being mobilized (i.e., ~ 30 m below ground surface). A one-dimensional advective-dispersive transport code was linked to the generalized, two-layer surface complexation model (SCM) for Fe(III) oxides/oxyhydroxides to evaluate DOM transport within local sediments. We present the results of different scenarios that include variable aquifer heterogeneity, DOM lability, and different potential surface water sources (i.e., river Bhagirathi and constructed perennial ponds). The model runs indicate that transport of pond-derived and river-derived DOM to depths in the underlying aquifer where As mobilization is greatest is unlikely to be significant over time scales consistent with the estimated ages of groundwater at these depths (e.g., ~ 50 years). Instead, DOM from surface waters would require at least 1000 years to reach the top of the As affected aquifers in Murshidabad. Results of the modelling support an *in situ*, sediment source for the DOM.

A triple-proxy approach to reconstrucing seawater $\delta^{18}O$

CÉDRIC M. JOHN[1*], ANNA JOY DRURY[1], ANNE-LISE JOURDAN[1]

[1]Department of Earth Science and Engineering, Imperial College London, London SW7 2AZ, United Kingdom. cedric.john@imperial.ac.uk (* presenting author), a.j.drury10@imperial.ac.uk, a.jourdan@imperial.ac.uk

Reconstructing changes in the oxygen isotopic composition of seawater ($\delta^{18}O_{seawater}$) through geologic times is a high-value target as this proxy informs us on the evolution of Earth's crysophere (waxing and wanning of ice sheets), changes in ocean currents (with subtle differences in $\delta^{18}O_{seawater}$) and salinity effects related to the amount of evaporation of surface waters (the lighter ^{16}O isotope being preferentially fractionated in the water-vapor phase during evaporation). Unfortunately, geologic samples of biogenic marine calcite ($\delta^{18}O_{calcite}$) record the combined effects of changes in $\delta^{18}O_{seawater}$ and changing water temperature. For instance, a phase of expended high-latitude ice sheets during a glaciation will result in heavier $\delta^{18}O_{seawater}$ (due to ^{16}O preferrentially stored in the continental ice) but would also be associated with a global cooling of the ocean, thus further increasing the $\delta^{18}O_{calcite}$ values. This makes assessing the relative impact of each mechanism on $\delta^{18}O_{calcite}$ difficult, and hinders quantitative assessments of changes in $\delta^{18}O_{seawater}$.

The paleoceanography community has tried to come around this limitation by pairing $\delta^{18}O_{calcite}$ with other temperature proxies independent of $\delta^{18}O_{seawater}$. One of the most succesful proxies to date is the Mg/Ca ratio of benthic foraminifers. Foramiferal Mg/Ca ratio has been shown to be temperature dependent for many species, and the Mg/Ca ratio of seawater is thought to be conservative on the timescale of 1 million years. However, on timescales greater than a million year the Mg/Ca ratio of seawater is likely to change, implying that this proxy is a good proxy for relative temperature changes, but that it cannot unambiguously resolve absolute seawater termperatures for periods older than the Pleistocene. Furthermore, the concentration of carbonate ions seem to impact Mg/Ca intake in benthic foraminifers, and thus changes in carbonate ion concentrations in the ocean could impact on the temperature estimates from foraminiferal Mg/Ca.

This review talk will highlight how adding a third, novel proxy (clumped isotopes) could resolve some of the issues at hand. The "Clumped isotope paleothermometer" is based on thermodynamics, and thus is independent of $\delta^{18}O_{seawater}$. Calibrations have shown that clumped isotopes are independent of nearly all changes in ocean chemistry, though some exceptions occur (for instance, in hypersaline conditions). Clumped isotopes suffer from their own set of limitations, notably because the measurements require a significant amount of time and sample material (up to 25 mg if three replicates are made). However, we will show through some preliminary data what strategies can be put in place to overcome this limitation, and how a "triple-proxy" approach based on high-resolution $\delta^{18}O_{calcite}$ measurments, medium resolution foraminiferal Mg/Ca measurements and low-resolution clumped isotope mesurements could help resolve some of the issues currently faced by the paleoclimate community.

The role of nano-components in contaminated mine water outflow crossing a redox boundary

CAROL A. JOHNSON[1*], GINA FREYER[2], KIRSTEN KÜSEL[2], MICHAEL F. HOCHELLA JR[1]

[1]Department of Geosciences, Virginia Tech, Blacksburg, VA, USA, cjohns49@vt.edu (* presenting author), hochella@vt.edu

[2] Institute of Ecology, Friedrich-Schiller University, Jena, Germany, gina.freyer@uni-jena.de, kirsten.kuesel@uni-jena.de

Especially in the last 15 years, Earth scientists have been exploring the role of nano-sized materials in a number of environment-related processes, including the transport and transformation of organic and inorganic contaminants. In this study, with both the geochemistry and microbiology in mind, we chose to study a highly dynamic environmental system (Ronneburg Mining District, Germany) where groundwater outflow from a former uranium mine is negatively impacting the downstream environment. The outflow contains high amounts of Fe(II) and, upon exposure to air at pH 5.8-6.0, iron oxyhydroxide particles form. Our principal goal was to determine the role that nanoparticulate formation has on the (bio)geochemistry of this complex and dynamic system. From June to October of 2011, water and sediment was carefully collected at four sites along portions of the flow path of greatest interest: at the groundwater outflow point, at rust-colored terraces where the outflow water flowed over a creek bank, from the creek adjacent to the terrace, and from the creek about 1 km downstream. A multi-scale approach was used to analyze the samples including XRD, ICP-MS, SEM and analytical TEM (HR-TEM, EDS, and SAED).

The first indication of nanocrystalline particles comes from the broad XRD peaks of the sediment samples, many of which match goethite and akaganeite. XRD of suspended particles shows even broader diffraction maxima that cannot readily be indentified, but do indicate the predominance of nano- and/or very poorly crystalline or amorphous particles. TEM corroborates this to a point, but also reveals very important details. For example, suspended particles (40-300 nm) in terrace and creek sites tend to be roughly spherical, and found in aggregates of amorphous iron oxyhydroxides intimately mixed with and sometimes coated by amorphous silica. Various types of nanocrystalline phases were found in the sediment samples as well, including nanoneedles of goethite growing from 100-300 nm spherical particles, and even smaller and smoother spherical particles that are clearly mixtures of amorphous silica and the very earliest stages of iron oxyhydroxide crystallization manifested by uniform lattice fringes that can be traced over only 2 to 5 nanometers. Interestingly, in the groundwater outflow, suspended nanometer-thin ferrous sulfate pseudo-hexagonal platelets (containing small amounts of Zn) were discovered. We have tentatively identified these as the mineral rozenite using electron diffraction analysis.

As these rozenite particles in the outflow become unstable, they are an important source of Zn, which is the metal with the fourth-highest concentration downstream. Zn and Ni were not primarily associated with larger suspended particles (> 0.1 μm), unlike the metals at trace concentrations (U, Cu, Cr, and Pb). Interestingly, Sn oxide oval-shaped nanoparticles (5-20 nm) were found multiple times in terrace site water samples, and their significance is presently being investigated.

In this ongoing study, we have shown again why knowledge of the formation, transformation, reactivity, and dissolution of the nano-components are important in understanding the behavior and evolution of the entire system.

From mineral interfaces to 200 million tons per year: A geologic perspective of the surface-catalyzed iron redox cycle

CLARK M. JOHNSON[1,*]

[1]Department of Geoscience, University of Wisconsin, Madison, USA, clarkj@geology.wisc.edu

Evidence for redox-driven reactions at the mineral-fluid interface of iron oxides may be found in the largest iron deposits on Earth, banded iron formations (BIFs), which were largely deposited in the Neoarchean and Paleoproterozoic. The insights gained by detailed, mechanistic studies of mineral-fluid reactions demonstrate that the major volume of BIF deposits was not formed by "passive" accumulation of iron oxide minerals on the seafloor but instead record an extensive redox history during formation and early diagenesis prior to lithification. Redox-driven reactions are the fundamental process that inhibits iron oxides from behaving as "inert" particles, and, in fact determine not only the isotopic compositions of redox-sensitive elements such as Fe, but also the O isotope compositions through breakage of Fe-O bonds. In addition, the structural changes that occur in iron oxides upon subsitution of Si, an important component in marine environments in the Precambrian, produce signficant changes in stable isotope compositions. Redox-driven reactions between aqueous Fe(II) and Fe(III) oxides that are catalyzed by biology may produce signficiantly different end products and elemental mass balance than abiologic Fe(II)-Fe(III) oxide interactions, and this contrast may be expressed as distinct isotopic compositions. In the case of BIFs, the isotopic fingerprints of microbially-catalyzed redox cycling is expressed in fine-scale isotopic heterogeneity that produces compositions out of equilibrium with ambient seawater. Importantly, the end product of extensive biological reduction of Fe(III) oxides are not mixed Fe(II)-Fe(III) minerals such as magnetite, which are produced at moderate extensts of reduction, but Fe(II)-bearing carbonates (siderite, ankerite). Although perhaps not imemdiately obvious, iron carbonates actually contain the best evidence for the magnitude of microbially-catalyzed redox cycling of iron oxides in BIFs, and C, O, and Fe isotope compositions clearly indicate biological Fe(III) reduction. The C, O, and Fe isotope compositions of the largest BIFs, the 2.5 Ga Brockman (Pilbara craton, Australia) and Kuruman (Kaapvaal craton, South Africa) iron formations, indicate that virtually all of the Fe in these deposits has been cycled by microbes. These BIFs provide the majority of the world's iron, in economic deposits that reflect later hydrothermal mobilization, oxidation, and deposition. These BIFs are mined at a rate of ~200 million tons per year in the Pilbara craton alone, an impressive testament to the importance of surface-catalyzed redox cycling.

[4]University of New South Wales, Sydney, Australia
[5]Alfred-Wegener Institut, Bremerhaven, Germany

The West Antarctic Ice Sheet is thought to be inherently unstable and has the potential to contribute up to 3.3 metres to sea level rise. Recent years have seen dramatic rates of thinning of major ice streams flowing into the Amundsen Sea, and in particular Pine Island Glacier. Onshore measurements of these changes are restricted to decadal timescales and in particular the satellite era, which makes it difficult to judge their significance and whether such changes are unprecedented. One way to place these events in a longer-term context is to study the geological record of past ice sheet change. This approach also provides data that are critical for building reliable ice sheet models that will predict the magnitude and timing of sea level change.

Recent advances in exposure dating afford new approaches for dating Holocene ice sheet thinning: we present the first study combining precise ^{10}Be and in-situ ^{14}C surface exposure ages from Antarctica. We used glacially-transported erratic cobbles as a vertical 'dipstick' for tracing past fluctuations in thickness of the West Antarctic Ice Sheet, focusing on the lower elevations of three nunataks in the Hudson Mountains (immediately north of Pine Island Glacier and close to its present-day grounding line). Exposure ages from the lowermost 100 m of two nunataks (Mt Moses and Maish Nunatak) suggest that rapid thinning was sustained there over a few hundred years in the early- to mid-Holocene, and brought the ice sheet surface close to its present elevation by ~6 ka. We also report exposure ages from within 40 m of the modern ice surface at Meyers Nunatak.

Formation of the Si-rich layer on olivine surfaces during carbonation under *in-situ* conditions

NATALIE C. JOHNSON[1,*], BURT THOMAS[2], KATHERINE MAHER[3], DENNIS K BIRD[3], ROBERT J.ROSENBAUER[2], GORDON E. BROWN, JR.[1,3,4]

[*]nataliej@stanford.edu

Olivine dissolution releases divalent cations (Mg^{2+}, Fe^{2+}) into solution and in the presence of dissolved CO_2 will result in the precipitation of carbonate minerals. This process, known as mineral carbonation, has the potential to safely store CO_2 in the subsurface over geologic time. Although the reaction is thermodynamically favored and occurs naturally, the kinetics are typically slow at temperatures < 100°C and thus limit industrial applications of the process. Previous results from this group and others have shown that the dissolution rate of olivine drops over two orders of magnitude as the reaction solution approaches saturation with respect to amorphous silica (a by-product of metal silicate carbonation). This study aims to understand why and how the rate drop occurs, using a series of batch reactions in a three-phase system (water, solid, and supercritical CO_2) at conditions relevant to in-situ carbonation (60°C, 100 bar P_{CO2}). Analysis of the mineral reaction products indicates the formation of a Si-rich, Mg-depleted layer on the olivine surface as soon as 2 days after reaction is started and before the bulk solution reaches silica saturation. Ion probe analysis of olivine grain surfaces produced by reaction with a ^{29}Si-spiked, CO_2-containing aqueous solution suggests that a Si-rich layer up to 1.5 μm deep forms on the grain surfaces, and that after 2 weeks of reaction this layer is primarily due to preferential removal of cations (leaching) rather than re-precipitation of silica. At t<20 days and pH<5, the Si-rich layer appears to control the rate of olivine dissolution. After 20 days, the layer no longer controls the dissolution rate, the rate increases, and carbonation occurs. Although Mg-carbonate precipitation requires significant oversaturation with respect to magnesite, the overall rate-limiting step for olivine carbonation as measured in our experiments involves the formation and subsequent break-down of the Si-rich layer. Current work is aimed at preventing the formation of the leached layer.

Interrogating the mechanisms controlling sulfur isotope fractionation during sulfate reduction

DAVID T. JOHNSTON*, WILLIAM D. LEAVITT, MARIAN SCHMIDT, SCOTT D. WANKEL, ALEX S. BRADLEY AND PETER R. GIRGUIS

Harvard University, Dept. of Earth and Planetary Sciences, Cambridge, MA, USA, johnston@eps.harvard.edu (*presenting author)

The sedimentary sulfur isotope record represents a unique opportunity to learn about Earth's environmental history. This great interpretability is related to the fact that the sulfur cycle captures the interplay of numerous redox sensitive biological processes and preserves an extraordinary geological signal, both of which are accessible with a multiple isotope system. The precision with which we can tell these stories, however, rests with the quality of our calibrations. To date, isotopic calibrations have targeted microbial sulfate reduction; an anaerobic metabolism that is both the dominant contributor to the preserved sulfur isotope variability and provides the tight, quantitative links between the sulfur, oxygen and carbon cycles. Decades of classic batch experiments with whole cells of sulfate reducers underpin our understanding of the fractionation capacity of this metabolism, coarsely linking cellular and volumetric rates of reduction to the inverse of the magnitude of $^{34}S/^{32}S$ fractionation (*1*). Although informative, it is possible to both place tighter quantitative constraints on this relationship, as well as to develop a more fundamental understanding of the physiological mechanisms driving the observed fractionation patterns. With this level of calibration, and through the inclusion of minor isotope fractionation patterns, a more refined picture of Earth surface evolution is possible.

In what follows we present data from a suite of continuous culture experiments with two pure *Desulfovibrio* strains of sulfate reducer: *D. vulgaris* Hildenborough and *D. alaskensis* G20. Through these experiments we varied sulfate concentrations from 1-100% of modern values and modulated the electron delivery rate over an order of magnitude in order to induce varying degrees of limitation in electron availability. These experiments thus target the two primary controls on sulfate reduction – electron donation rate (lactate flux) and reception (sulfate availability) – and map onto distinct geological questions. For example, in the case of sulfate availability, the difference in isotopic composition between Proterozoic sulfates and sulfides is often inferred as related to $[SO_4^{2-}]$; our experiments directly address this assumption as they span the presumed $[SO_4^{2-}]$ for that time interval (0.5-5 mM). Our entire data set presents fractionation that in $^{34}S/^{32}S$ range from the ordinary (< 25‰) to the extraordinary (> 50‰), and can be contoured by electron consumption rates. When paired with the minor isotope data, the flux of sulfur through a bacterium can be more specifically solved for. This is in part because of the steady-state character of the experiments and through additional insight gained from oxygen isotope geochemistry. In the case of the oxygen isotope work, we lean on new experimental calibrations of the sulfite-water isotope equilibrium conducted over a range of temperatures and pH (data presented herein). Together with an updated metabolic model (*2*), this study allows for the internal operation of the metabolism to be solved.

Through the tight constraints allowed by our experimental design, and with the direct measurement of all sulfur bearing phases present in the reactor at each time point (satisfying elemental and isotopic mass-balance), we link electron utilization to isotopic fractionation (*3*) in a manner that allows for geological records to be more fully interpreted. This work also helps to open the 'black box' of large fractionations produced by sulfate reduction through solid physiological and geochemical constraints. The sum of the information gained through this work will allow Proterozoic and Phanerozoic oxidant budgets to become more accessible.

Bacterial resistance to heavy metals is controlled by metal-responsive transcriptional regulators. For example, bacterial resistance to inorganic and organic mercury compounds is conferred by the *mer* operon, which is typically located on transposons or plasmids [1,2]. These proteins are involved in Hg(II) import, proteolysis of organomercurials and Hg(II) reduction to Hg(0). Expression of the *mer* operon genes is controlled by the transcriptional repressor-activator MerR.

How Hg(II) binding affects the changes in the conformation of MerR, which in turn propagate through DNA contacts to its operator DNA (MerOP) is unknown. In this study we investigate Hg(II)–induced conformational changes of MerOP in complex with its regulator MerR to reveal the transcription control mechanism conferred by MerR. Experimentally, we purified MerR and prepared a complex with a 23bp MerOP dsDNA construct. In vivo, MerR tightly binds to MerOP in a region of dyad symmetry between the -10 and -35 RNA polymerase recognition sites. In the absence of Hg(II), RNA polymerase binds to its promoter and forms a stable pre-initiation complex with dimeric MerR acting as a repressor preventing RNA polymerase from accessing the -10 recognition site. In the experiments, we examined the MerR-MerOP complex in the presence and absence of Hg(II) using small-angle neutron scattering (SANS) (Fig. 1). A contrast variation series allowed us to detect changes in the conformation of MerR and MerOP, respectively. Homology modeling and molecular dynamics simulations were used to generate atomic resolution models to interpret the data. The results provide insights on the allosteric change in MerR triggered by Hg(II), which causes a reorientation of the -10 recognition site and ultimately initiation of transcription by RNA polymerase [3].

Variations in climatic cycle during different periods often affect various aspects in the earth, especially it shows more diversity in the aquatic region. Our study focuses mainly on the geochemical aspects of river sediments from River Amajac, Panuco and its lagoons which are located in the north eastern part of the Mexico. The whole system runs through the Sierra Madre Oriental in Central part of Mexico and finally drains into the Gulf of Mexico. The difference in the weathering pattern in the sediments of the river basin could be related to the changes in the climatic cycle in the region [1-2]. The results also clearly indicate that the decrease in rainfall events during the last three decades have affected the farming land and has resulted in deforestation and subsequently it has resulted in erosion of finer particles into the aquatic system. The analysis of major, trace elements and the calculated weathering pattern results suggest that the region is frequently vulnerable to erosion. The concentration and distribution pattern of the geochemical elements also indicate that the higher concentration of toxic elements is mainly anthropogenic, which can be related to the industrialization of the region.

The Transvaal Supergroup in South Africa hosts one of the most pristine Archean sedimentary successions known, with largely flat lying strata and sub-greenschist metamorphism [1]. The relevant section of this unit records an intertidal carbonate platform deepening upward to a basinal iron formation. The carbonates from the platform, especially the Lower Nauga formation, have relatively high Mn concentrations, but more limited Fe. We propose that this resulted from surface sea waters containing substantial Mn and a paucity of Fe, based on the ideal partitioning coefficients of Mn and Fe into calcite and dolomite lattices [2].

Fe speciation data from deep basin sediments indicate deposition under anoxic, ferruginous conditions, implying that the water column was stratified with manganous surface waters overlying ferruginous bottom waters. Surface sea waters could be devoid of Fe^{2+} for a number of reasons, including photic zone oxygen production, anoxygenic phototrophic Fe^{2+} oxidation, or sulfide scavenging of Fe^{2+}. Dissolved Mn^{2+} can persist through all of these scenarios; however, pervasive oxygenation could be expected to oxidize Mn as well. Had Mn been deposited as oxide, the $\partial^{13}C$-CO_3 should move to more negative values, reflecting the $\partial^{13}C$ composition from the organic matter used during dissimilatory reduction. Platform carbonates of the Campbellrand Subgroup from the intertidal to the lagoonal to the shelf margin have previously been shown to have $\partial^{13}C$-CO_3 compositions around -0.5 ‰ [3], a signal indicative of water column carbonate precipitation. The speciation of Fe present on the carbonate platform also indicates anoxic surface water. The vertical extent of the depositional environments of these Mn rich carbonates from the intertidal zone to the shelf margin together with the roughly 600 m of elevated Mn:Fe ratios in the carbonates suggest a substantially thick manganous surface layer above the more reducing (mostly ferruginous) deep basin.

Field evidence of Sr exchange between particulate material and seawater in estuaries

The reactivity of riverine particulate material upon arrival in the oceans is an important consideration for global element cycles, as this flux dominates for the majority of elements [1]. A small amount of particulate dissolution in saline water would have a noticeable impact on land-to-ocean fluxes of key elements such as Ca, Mg and Sr. A recent study showed significant dissolution and/or exchange of strontium between riverine particulate material and seawater in laboratory conditions [2]. If replicated in the natural environment, the calculated Sr release upon arrival in estuarine waters would be of a similar order of magnitude to hydrothermal exchange at mid-ocean ridges. To date, no study has found evidence of Sr exchange in field studies, potentially because the concentrations of Sr in seawater are high and there is experimental evidence for contemporaneous precipitation of Sr-bearing phases [2].

This study focuses on the Borgarfjörður estuary in western Iceland. The basaltic lithology of the catchment and the shallow depth of the fjord make this site ideal for detecting any interaction between solid and liquid phases, as this should equate the most easily weathered material and the highest sediment to water ratio in the natural environment. Two independent field trips collected water, suspended material and bedload samples in transects along the fjord, and subsequently analyzed for major element concentrations and $^{87}Sr/^{86}Sr$ values. While dissolved Sr concentrations are controlled by the extent of mixing with saline water, the $^{87}Sr/^{86}Sr$ values of both the dissolved and suspended load display evidence that unradiogenic Sr is liberated from solid particles upon first contact with saline water. Bedload samples show a systematic increase in $^{87}Sr/^{86}Sr$ values along the length of the estuary. These analyses represent the first *in situ* evidence of considerable Sr exchange between riverine particulate material and seawater, and demostrate that particulate material can play an important role in defining the chemistry of coastal waters. These findings have important consequences for global Sr budget calculations and the general use of isotopes as tracers of biogeochemical processes.

Subduction erosion, magmatism and continental crust formation in the southern Central Andes

ROSIE JONES[1*] LINDA KIRSTEIN [1], RICHARD HINTON[1], SIMONE KASEMANN[2], BRUNO DHUIME[3] AND TIM ELLIOTT[3]

Subduction zones, such as the Andean convergent margin, form large recycling systems and are the main producers of new continental crust. The subduction of continental material through either tectonic subduction erosion or sediment cycling is an important component when estimating the mass flux through an active margin over time. Suduction erosion in particular has been highlighted as an important process along certain parts of the Andean continental margin, especially to the west of the Central Andes [1, 2].

It has been suggested that the rate of subduction erosion along the north-central Andean margin has varied over time with constant, fast rates between 150 and 20 Ma and slower rates during the Neogene [3]. A near constant rate of subduction erosion between 150 and 20 Ma suggests a continuous supply of continental material into the subduction zone, during this time.

We have combined high resolution, U-Pb dating, isotope geochemistry, and major and trace element analyses, from a suite of magmatic rocks sampled from the southern Central Andes (28º to 32ºS), in order to investigate source contamination by subducted continental material between the late Cretaceous and the late Miocene.

The results of new, in-situ U-Pb dating of magmatic zircons by SIMS place further constraints on the presence of a widespread period of reduced arc magmatism in the southern Central Andes during the late Eocene to late Oligocene (35 - 26 Ma). Oxygen and hafnium isotopic analysis, of the same magmatic zircons (by SIMS and LA-ICPMS respectively), reveal variations in $\delta^{18}O_{(VSMOW)}$ of between 9.78 ± 0.21‰ and 3.59 ± 0.21‰ and in εHf of between 10.4 ± 1.3 and -4.4 ± 0.8. This new data, when combined with the results of whole rock, major and trace element analysis, provides increased constraint on the amount of continental material being subducted to depth and recycled to the continental crust via arc magmatism during this key time in the evolution of the Andes.

Size-dependent surface charging of TiO_2 nanoparticles

CAROLINE M JONSSON*, JENNY PEREZ HOLMBERG, ELISABET AHLBERG, MARTIN HASSELLÖV, JOHAN BERGENHOLTZ, AND ZAREEN ABBAS

University of Gothenburg, Department of Chemistry and Molecular Biology, Gothenburg, Sweden
caroline.jonsson@chem.gu.se (* presenting author), perezj@chem.gu.se, ela@chem.gu.se, martin.hassellov@chem.gu.se, jbergen@chem.gu.se, zareen@chem.gu.se

Metal oxide nanoparticles show variations in their structure relative to corresponding larger microparticles of the same material, often with new unexpected features occurring in the nanoscale size range. Generally, nanoparticles have increased roughness and curvature of the surface, large specific surface area and high abundance of active binding sites; thus are very reactive. The surface charge is highly affected by the surrounding media, which in turn affects the colloidal stability of nanoparticles.

This study focuses on the size-dependent surface charging of TiO_2 (anatase) nanoparticles. TiO_2 nanoparticles with well-defined particle sizes (<30 nm) and without any coatings or surfactants were synthesized using low-temperature hydrolysis of $TiCl_4$. Temperature during synthesis reaction, dialysis and storage was found to strongly influence the particle size and crystal structure, according to [1]. The nanoparticles were extensively characterized using several techniques and were found to have a sphere-like shape. In order to study the size-dependence on the pH_{PZC} (point of zero charge), potentiometric titrations were used to determine the surface charge of the TiO_2 nanoparticles at 25 °C, and at varying ionic strengths obtained with NaCl as background electrolyte. Further, zeta potential measurements were performed under similar conditions.

The experimentally determined size-dependent surface charging behavior of TiO_2 nanoparticles are compared with the corresponding surface charge densities calculated by classical surface complexation models, as well as by the Corrected Debye-Hückel (CDH) theory [2].

Biomineralization and fate of the Fe^{II}-Fe^{III} hydroxy salt green rust *vs.* magnetite

JORAND FRÉDÉRIC*, ZEGEYE ASFAW, SERGENT ANNE-SOPHIE, REMY PAUL-PHILIPPE, LARTIGES BRUNO AND HANNA KHALIL

University of Lorraine LCPME UMR 7564 CNRS –, Jean Barriol Institute, 405 rue de Vandoeuvre, 54600 Villers-lès-Nancy, France (*correspondence: frederic.jorand@univ-lorraine.fr)

It is well known that iron oxide reduction by *Shewanella* spp. bacteria promotes the formation of Fe^{II} bearing minerals, such as the mixed Fe^{II}-Fe^{III} hydroxysalt green rusts (GRs), in anaerobic conditions. Although the microbial-promoted generation of GRs is widely demonstrated, the mechanisms and factors governing the GR formation as the main secondary iron mineral at the expense of other products in lab-scale investigations or environmental systems are largely unknown. As GR is an effective reductant for several contaminants the mechanism controlling the formation routes of GR merit investigation, from both the environmental and engineering points of view.

Some factors such as cellular material (i.e. autoclaved cells and/or bacterial polymers), synthetic anionic polymers or oxyanions have been identified to control the route of the GR mineralization as secondary mineral at the expense of other products such as magnetite.

The arrangement mode of the heterogeneous aggregates resulting from the interactions between bacterial cells, iron oxide particles and polymers was suggested to influence the routes of formation of secondary iron minerals by limiting the diffusion of reactive species and thus creating favorable microenvironment for GR formation. In these aggregates, the electron transfer from cells to iron oxides is supported by organic electron shuttles.

On the other hand, anionic polymers, colloidal and aqueous silicates were found to also influence the nature of the secondary iron minerals through the stabilization of the GR crystals.

These results indicate clearly that the bacterial cells drive indirectly the nature of the secondary Fe^{II}-bearing mineral. Moreover, they give new insights into the understanding of the mechanisms of « biogenic » mineral formation based on the electron transfers from bacteria towards iron oxides. Finally, this work contributes to our understanding of the processes leading to green rust formation in environmental systems, such as soils or aquatic systems biofilms, in which a very high cell density can be found at a micro-scale level, associated to exo-cellular polymers and natural silica mineral composites.

Soil vapour characterization and intrusion to indoor air: a reactive transport modelling approach

P. JOURABCHI[1*], I. HERS[2], S. MOLINS[3], AND M. LAHVIS[4]

[1]Golder Associates Ltd., Burnaby, Canada, pjourabchi@golder.com (* presenting author)
[2]Golder Associates Ltd., Burnaby, Canada, ihers@golder.com
[3]Lawrence Berkeley National Lab, Berkeley, USA, SMolins@lbl.gov
[4]Shell Global Solutions, Houston, USA, Matthew.Lahvis@shell.com

Introduction

Vapour intrusion to indoor air often represents a significant exposure pathway for risk assessment at sites contaminated by volatile petroleum hydrocarbons. While the importance of biodegradation processes on the fate and transport of petroleum hydrocarbon vapours is well established [1; and references therein], fewer studies have investigated site specific factors such as source concentration and location with respect to the building, pressure conditions, and soil properties, all of which have been shown to impact the potential for vapour intrusion [e.g., 2-4]. In this numerical modelling study, site specific factors are evaluated using the multi-component reactive transport code MIN3P-DUSTY [5-6]. The model includes the key processes of hydrocarbon volatilization, gas- and aqueous-phase diffusion, gas-phase advection, aerobic biodegradation (using dual-Monod kinetics formulation) and sorption in a domain comprising the subsurface and the building foundation. Benzene and iso-octane are used as surrogates of the aromatic and aliphatic compounds of the gasoline vapours. Initially, a sub-model for transport through concrete and within foundations cracks was developed and benchmarked against an analytical solution. The model was calibrated based on a high quality data set for an unoccupied research house located above a petroleum hydrocarbon plume (located in North Battleford, Saskatchewan, Canada), and then used to predict the hydrocarbon vapour distribution for a range of observed and hypothetical conditions.

Results & Conclusion

For the observed site conditions, the calibrated model indicates soil vapour transport is dominated by diffusion and aerobic biodegradation, and that building pressures and soil gas advection have little influence on soil vapour concentrations. Comparison of wetter (spring) and drier (winter) conditions indicate that the vadose zone oxygen concentrations above the contamination source area are lower for wetter spring conditions because of the reduced diffusion through relatively wet surface soils. For most scenarios simulated, there is rapid attenuation of benzene within approximately 1 m of the source; however, less attenuation of iso-octane is predicted, consistent with site data. For a shallow NAPL scenario, a concrete foundation slab resulted in an oxygen shadow and increase in benzene and iso-octance concentrations below the building.

Clumped isotope Vs. fluid inclusion thermometry in crystals from Oman.

A.-L. JOURDAN[1*], CÉDRIC M. JOHN[1], SIMON DAVIS[1] AND VEERLE VANDEGINSTE[1]

[1]Department of Earth Science and Engineering, Imperial College London, London SW7 2AZ, United Kingdom. a.jourdan@imperial.ac.uk (* presenting author), cedric.john@imperial.ac.uk, s.davis@imperial.ac.uk, v.vandeginste@imperial.ac.uk

Clumped isotopes are a new exciting tool in the domain of paleothermometry. The "clumped isotopes carbonate paleothermometer" has been tested and used as a new temperature proxy for paleoclimate studies during the last few years. Indeed, clumped isotopes (Δ47) appear to be a great proxy since they are based on the degree of association of ^{13}C and ^{18}O into the carbonate ions, a function of thermodynamics. Therefore, measuring Δ47 allows the determination of the formation temperature of the carbonate material independent of the isotopic composition of the precipitating fluid. Furthermore, unlike other proxies, Δ47 seems insensitive to potential 'vital effects'.

However, there is still a lot to unravel in this field of geochemistry, and some improvement and development are necessary. Some processes, such as kinetic fractionation, need to be identified and better understood in order to apply this proxy in the most precise way possible. Studies need to include comparisons between clumped isotopes and other temperature proxies.

Here we intend to compare data from both fluid inclusions microthermometry and clumped isotopes measurements carried out on the same material. Our focus has been placed on calcite crystals sampled in the carbonate carapace of a salt dome at Jebel Madar, Oman, where preliminary data suggest a low temperature precipitation.

As carbonates are very reactive minerals, diagenesis and metamorphism could re-order the isotope clumping configuration in the carbonate and the measurements would reflect the equilibrium temperature of recrystallisation. Hence, careful consideration needs to be given to sampling strategies. Calcite crystals were sampled in fractures showing multiple pulses of opening, and the crystals themselves show evidence for growth zoning and fracture healing. We focus our study on deciphering and understanding the processes and effects of diagenesis on the reliability of the carbonate clumped isotope paleothermometer.

The project is part of the Qatar Carbonate and Carbon Storage Research Centre (QCCSRC), funded jointly by Qatar Petroleum, Shell and the Qatar Science and Technology Park.

Sources and processes identification for Zn cycling in the Seine river, France

DELPHINE JOUVIN[1*], ALEXANDRE GÉLABERT[2], PASCALE LOUVAT[2], GUILLAUME MORIN[3], FARID JUILLOT[3], AND MARC F. BENEDETTI[2]

[1]IDES UMR 8148, Université Paris Sud - CNRS, Orsay, France (*delphine.jouvin@u-psud.fr)
[2]Univ. Paris Diderot – Sorbonne Paris Cité - IPGP, Paris, France (gelabert@ipgp.fr, louvat@ipgp.fr, benedetti@ipgp.fr)
[3]IMPMC CNRS UMR7590, UMPC, Paris, France (guillaume.morin@impmc.upmc.fr, farid.juillot@impmc.upmc.fr)

An accurate determination of the ecological status of the Seine River (flowing through greater Paris, France) is required as it is one of the most severely damaged European rivers. However, important evaluation limitation still exists, partly because the metal cycling in this system is not fully understood, with for instance half the Seine river Zn not having clearly identified sources[1]. Along with Zn isotopic measurements, this study proposes to use XAS (X-ray Absorption Spectroscopy) to determine precisely the speciation of Zn complexes, and thus to define the proportion of water mixing vs. processes for Zn transfer in the watershed. A geographical sampling transect has been performed downstream Paris, where the contamination is maximum – 5 samples from the Seine River and 3 tributaries.

Significant isotopic signature variations are observed, varying from $\delta^{66}Zn$ = 0.04 to 0.14 ± 0.05‰ in the particulate phase, and from $\delta^{66}Zn$ = -0.23 to 0.10 ± 0.06‰ for the dissolved phase. These results are in line with previous work by Chen et al.[2] on the Seine River, but as we focus on the most polluted downstream part of the river, the $\delta^{66}Zn$ variation range in both dissolved and suspended loads is much narrower. The XAS analysis performed on the suspended load samples at the Zn K-edge confirmed however a real heterogeneity by showing different speciations with a major contribution of sulfides, iron oxides, amorphous silica and organic ligands.

The dissolved phase displays systematically lower isotopic signatures than the particulate phase, resulting from adsorption processes [3, 4]. A significant discrepancy was observed between summer and winter for the dissolved phase, with higher values in winter high-water stages, reflecting a bigger contribution of natural sources ($\delta^{66}Zn$ is 0.88‰ for chalk [2]) than during summer low-water stages dominated by anthropogenic sources.

The regional major wastewater treatment plant (WWTP) in Achères (shortly after Paris) brings significantly heavier Zn to the Seine River particulate material. This change in $\delta^{66}Zn$ follows a change in Zn speciation, with a strong decrease in sulfides contribution after Achères. This WWTP impacts both dissolved and particulate phases on concentration, speciation and isotopic signatures. Comparison with Chen et al.[2] indicates a significant variability of the WWTP Zn signal that needs further investigation.

Geochemical Assessment of the Metallogenic Potential of Proterozoic LIPs of Canada

S. M. JOWITT[1], AND R. E. ERNST[2*]

[1]School of Geosciences, Monash University, Melbourne, VIC3800, Australia, simon.jowitt@monash.edu
[2]Dept. of Geology, Carleton University and Ernst Geosciences, 43 Margrave Avenue, Ottawa, Ontario, Canada K1T 3Y2, richard.ernst@ernstgeosciences.com (* presenting author)

The lithogeochemistry of eight Proterozoic Large Igneous Provinces (LIPs) within Canada has been studied to determine the Ni-Cu-PGE prospectivity of these major magmatic events. Three of the LIPs discussed here, the 1.87 Ga Chukotat, 1.27 Ga Mackenzie and the 2.49-2.45 Ga Matachewan LIPs, host known magmatic Ni-Cu-PGE sulphide mineralisation; in addition, the 0.72 Ga Franklin LIP may be associated with the coeval and mineralised Dovyren intrusion in Siberia and several Franklin-related Ni-Cu-PGE prospects are known within northern Canada. The other four LIPs, the 1.14 Ga Abitibi, 0.59 Ga Grenville, ~1.25 Ga Seal Lake and 1.24 Ga Sudbury (distinct from the Sudbury impact event) LIPs, have no known Ni-Cu-PGE mineralisation.

The mineralised Chukotat, Mackenzie and Matachewan LIPs are characterised by basalts with Ti/V ratios below 50, Gd/Yb ratios close to primitive mantle values and variable La/Sm ratios. The magmas that formed these LIPs assimilated significant amounts of crustal material and samples representing both chalcophile depleted and undepleted magmas are present within these LIPs. This suggests that the magmas that formed these LIPs were fertile and S-undersaturated when they left the mantle and subsequently underwent a S-saturation event, forming immiscible magmatic sulphides. The close relationship between chalcophile element depletion and crustal contamination evident in the geochemistry of these LIPs suggests that S-saturation was caused by assimilation of crustal material, most likely by assimilation of crustal sulphides. The magmatic sulphides produced during this event were presumably segregated from silicate magmas and were deposited in cogenetic mafic-ultramafic sills and intrusives associated with these LIPs.

The Grenville and part of the Franklin LIPs have similar magma source characteristics to LIPs with known Ni-Cu-PGE mineralisation. However, although magmas from both LIPs were fertile and assimilated crustal material, the Grenville LIP did not undergo a S-saturation event prior to emplacement, whereas the Franklin LIP may have; the timing and location of this S-saturation event may be a useful guide during exploration for Ni-Cu-PGE mineralisation. The Abitibi, Sudbury and Seal Lake LIPs are alkaline, dominated by alkali basalts and are characterised by high Gd/Yb ratios, a wide range in La/Sm ratios and Ti/V ratios higher than 50. All samples from the Abitibi, Seal Lake and Sudbury LIPs are chalcophile element depleted, suggesting that these magmas left residual sulphide within the mantle during partial melting, and indicating that these LIPs are probably unprospective for Ni-Cu-PGE sulphide mineralisation.

Sulfate adsorption at buried mineral/solution interfaces probed via vibrational surface spectroscopy

AARON M. JUBB[1] AND HEATHER C. ALLEN[2*]

[1]The Ohio State University, Columbus, USA, ajubb@chemistry.ohio-state.edu

[2]The Ohio State University, Columbus, USA, allen@chemistry.ohio-state.edu (* presenting author)

Introduction

Understanding the structure and energetics of adsorbed ions at the buried mineral/solution interface has great importance to the geochemical and atmospheric chemistry communities. Vibrational spectroscopy is a powerful tool for the study of mineral/solution interfaces as these techniques can be applied *in situ*, are sensitive to surface structures, and are generally non-destructive. Sulfate (SO_4^{2-}) adsorption at buried mineral (fluorite, silica, hematite)/sulfate-solution interfaces was studied using either vibrational sum frequency generation spectroscopy (VSFG), which is inherently interface specific, or total internal reflection (TIR) Raman spectroscopy. Sulfate is a simple, inorganic anion whose behavior is important to understand as it is ubiquitous in the environment being the third most prevalent ionic species in seawater by weight [1].

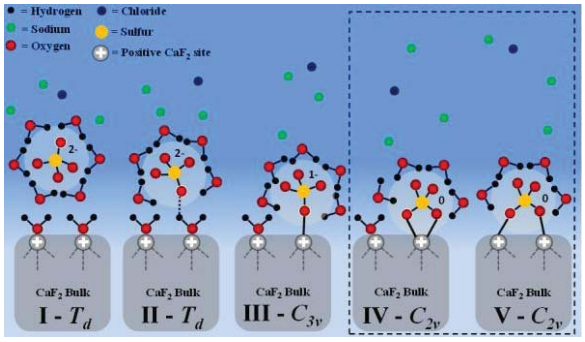

Figure 1: Idealized possible sulfate adsorption complexes at fluorite surface.

Results and Conclusions

The use of VSFG and TIR-Raman allows for the spectral resolution of anion adsorption complex structure, i.e. inner-sphere versus outer-sphere adsorption, Figure 1, at the mineral surface. Utilizing VSFG the sulfate anion is observed to adsorb with a bidentate inner-sphere structure at the fluorite surface with a surface free energy of adsorption of -33 ± 2 kJ/mole for pH 7 solutions at 298 K. The use of TIR-Raman spectroscopy to examine sulfate behavior at silica and hematite surfaces, which feature differing surface charges at pH 7, allows for the direct observation of anion adsorption behavior as a function of the model oxide mineral surface charge.

Use of in vivo and in vitro assays for refining human health exposure assessment for As-contaminated soil

ALBERT JUHASZ[1,2*], EUAN SMITH[1,2], JOHN WEBER[1,2] AND RAVI NAIDU[1,2]

[1]Centre for Environmental Risk Assessment and Remediation, University of South Australia, Adelaide, Australia, Albert.Juhasz@unisa.edu.au

[2]Cooperative Research Centre for Contamination Assessment and Remediation of the Environment, Adelaide, Australia

Introduction

When quantifying exposure to arsenic (As) for human health risk assessment calculations, As bioavailability is assumed to be 100% which presumes that all of the As has been solubilised in the gastrointestinal tract and absorption into systemic circulation has occurred. In reality, a fraction of the soil-borne As may only be bioavailable and as such this assumption may overestimate the chemical daily intake thereby influencing risk assessment [1]. In order to refine risk calculations by adjusting the default bioavailability value, reliable assays are required that can quantitatively measure site specific bioavailability.

In this study, As bioaccessibility and As relative bioavailability was assessed in contaminated soils using a variety of *in vitro* and *in vivo* assays. In vitro results were compared to in vivo relative As bioavailability data (swine assay) to determined which methodologies have the potential to act as surrogates for in vivo assays.

Materials and Methods

Contaminated soils used in this study were collected from regional areas where the soil type, source of As and As-soil residence time varied. Arsenic bioaccessibility was determined using SBRC [2], IVG [3], PBET [1], DIN [4] and UBM [5] assays while in vivo As relative bioavailability was determined using a swine model according to Rees et al. [6].

Results and Conclusions

Comparison of in vitro and in vivo results demonstrated that the in vitro assay encompassing the SBRC gastric phase provided the best prediction of in vivo relative As bioavailability (r^2 = 0.75, Pearson correlation = 0.87). However, As relative bioavailability could also be predicted using gastric or intestinal phases of IVG, PBET, DIN and UBM assays but with varying degrees of confidence (r^2 = 0.53-0.67, Pearson correlation = 0.73-0.82).

Light is an active contributor to vital effect in coral skeleton proxies

ANNE JUILLET-LECLERC[1*], STEPHANIE REYNAUD[2], DELPHINE DISSARD[1,3], GUILLAUME TISSERANT[2] AND CHRISTINE FERRIER-PAGES[2]

[1]LSCE, Gif sur Yvette, France
Anne.Juillet@lsce.ipsl.fr (*presenting author)

sreynaud@centrescientifique.mc
[3]School of Earth and Environment, Crawley, Australia

Biologists emphasize the Light Enhanced Calcification (LEC) for a long time, although the interaction between light and calcification in coral skeleton formation remains not understood. $d^{18}O$, Sr/Ca and Mg/Ca are regarded as temperature tracers. However, we have no information concerning potential light influence on proxies.

Symbiotic colonies of the coral *Acropora* sp. were cultured, under constant conditions, in a factorial design of three temperatures (21, 25 and 28°C) and two light intensities (200 and 400 □mol photon m^{-2} s^{-1}). Metabolic, growth and geochemical measurements ($d^{18}O$, $d^{13}C$, Sr/Ca and Mg/Ca) were conducted on 6 colony sets representing each environmental (light temperature) condition. The experiment intended firstly to identify the separated influences of temperature and light on metabolism and calcification rates and secondly to compare them with corresponding skeletal $d^{18}O$, $d^{13}C$, Sr/Ca and Mg/Ca variations.

Metabolic parameters responded as biologists could expect: photosynthesis increased with temperature, being always higher at high light. When colony was maintained at low light zooxanthellae (coral symbionts) density was higher at 25 and 28°C than under high light, illustrating the coral capability of shadow-adaptation. Calcification rate was also positively correlated to temperature, the quantity of deposited aragonite being always higher under high light. In opposite, surface expansion (equivalent to linear extension) did not show straightforward behavior. In addition, mean (for each data set) photosynthetic activity was related to mean calcification rate following logarithmic relationship.

Proxy responses showed huge scattering especially under high light and high temperature, exceeding by several °C the value calculated by using conventional calibrations, thus compromising the robustness of commonly admitted temperature tracers. The average assessed by the 6 values of $d^{13}C$, Sr/Ca and Mg/Ca measured on the 6 nubbins of each set were correlated to averaged calcification rates, following logarithmic relationship. Furthermore, they seemed to obey to the temperature-light synergy. In □opposite, correlation between $d^{18}O$ and calcification rate strongly depended on the light intensity, although $d^{18}O$ seemed the most relevant temperature tracer. Examination of isotopic micro-measurements confirmed that isotopic fractionation could differ following light intensity. By considering individual values measured on each colony developed under high light, we underlined that photosynthetic activity, covering the total measured amplitude, was strongly related to symbiotic algae density, regardless temperature value, such as individual proxy values showed strong correlation with calcification rate according to light intensity, regardless temperature value. We deduced that in these conditions the high scattering that we observed could be due to the light effect, at least under high light.

No coral proxy is dependent on the sole temperature and no temperature calibration could be regarded as a universal law.

Distribution of vanadium in a basaltic aquifer of Jeju Island, Korea: effects of geochemical reactions and hydrological mixing

HEE-WON JUNG[1*], SEONG-TAEK YUN[1], BERNHARD MAYER[2], KYOUNG-HO KIM[1], YOUNG-HWA GO[1], SANG-SIL OH[3], AND KYUNG-GOO KANG[4]

[1]Korea University, Green School and the Department of Earth and Environmental Sciences, South Korea, indra832@korea.ac.kr (* presenting author)
[2]University of Calgary, Geoscience, Canada
[3]Jeju Special Self-Governing Province Institute of Environment Research, Jeju, South Korea
[4]Jeju Special Self-Governing Province Development Corporation, Jeju, South Korea

Hydrochemistry data (i.e., major cations and anions, and trace metals such as Fe, Mn, V, As, Mo and U) of 25 groundwater samples from the Gosan area at the southwestern part of Jeju volcanic island, South Korea, were examined to investigate physico-chemical factors controlling the spatio-temporal distribution of vanadium in a basaltic aquifer. The study area is comprised of a wide coastal agricultural land with hills with moderate slopes in the northeast. Groundwater sampling was conducted in May 2009 and October 2010. Groundwater in the study area usually contains high concentrations of V with an average of 12.2 μg/L (max. 28.8 μg/L). Except for two samples that were influenced by seawater intrusion, as indicated by higher concentrations of Cl, Mg and SO_4 and elevated $\delta^{34}S$ values (14.5~18.9 ‰), groundwater in the study area is clustered into two major hydrochemical types: 1) a Mg-Cl-NO_3 type and 2) a Na-HCO_3 type. The latter type is characterized by higher pH values (8.2~8.9, avg 8.6), compared to water type 1 (pH: 6.9~8.3, avg 7.3). The concentrations of V are strongly correlated with pH (γ^2 = 0.89) and are higher in the Na-HCO_3 type water. In addition, positive correlations were observed between pH and Cl-normalized concentrations of Na (γ^2 = 0.79), K (γ^2 = 0.49), and HCO_3 (γ^2 = 0.64). These observations indicate that water-rock interactions during southwestward regional groundwater flow in the basaltic aquifer largely control the observed hydrochemical changes and increasing V concentrations. However, V concentrations also tend to decrease in samples with higher concentrations of NO_3 characteristic for Mg-Cl-NO_3 type waters. Examination of relationships between concentrations and $\delta^{15}N$ and $\delta^{18}O$ values of nitrate in the study area revealed that nitrate is mainly derived from synthetic fertilizers (~3 to 4 ‰ $\delta^{15}N_{NO3}$) applied to agricultural fields. During infiltration of rainwater into the aquifer, agricultural nitrate is locally attenuated by partial denitrification to low nitrate levels (~8 ‰ $\delta^{15}N_{NO3}$). These observations suggest that there are two major paths of groundwater recharge in the study area: 1) regional flow accompanying water-rock interactions with V leaching from basalts, and 2) local flow dominated by direct infiltration of rainwater through agricultural land, accompanyed by nitrate loading. We suggest that V concentrations of groundwater will decrease with increasing nitrate concentrations at times of increased local recharge.

Fate of Metallic Silver Nanoparticles in a Sewer System

RALF KAEGI[1*], ANDREAS VOEGELIN[1], BRIAN SINNET[1], HARALD HAGENDORFER[2] AND CHRISTOPH ORT[1]

[1]Eawag: Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland, ralf.kaegi@eawag.ch (* presenting author)

[2]Empa: Swiss Federal Institute of Materials Science and Technology, Dübendorf, Switzerland, harald.hagendorfer@empa.ch

The biocidal properties of Ag^+ ions have led to the incorporation of metallic Ag nanoparticles (Ag-NP) in a wide range of industrial and commercial products. Therefore, the emission of Ag-NP to the aquatic environment seems inevitable, most likely occuring via urban water systems. However, the understanding of the transport behavior of Ag-NP in urban water systems is still incomplete. It has been shown that Ag-NP are readily transformed to Ag_2S during wastewater treatment [1] and based on laboartory studies, Liu et al. [2] speculated that the transformation might already occur in the sewer system. To assess whether Ag-NP sorb to and are retained by the sewer biofilm and to investigate the physical-chemical changes during the transport in a sewer line, we conducted experiments in a 5-km sewer stretch (no exfiltration, no confluents).

The wastewater flow rate for our experiment was adjusted to 30 l/sec. Over 30 seconds, we spiked 1g of Ag-NP (15 nm diamter) to the wastewater. Subsequntly, wastewater samples were collected at three locations 500 m, 2.4 km, and 5 km downstream. The transit times for unretarded Ag-NP at the respective locations were derived from tracer experiments and equalled 10 min, 60 min, and 120 min, respectively. Around these times, forty wastewater samples were collected at each location and immediately acidified for analysis of total Ag contents. Additional samples were prepared for transmission electron microscopy (TEM) and X-ray absorption spectroscopy (XAS) to assess changes in Ag-NP aggregation state and speciation along the sewer stretch.

Between 95 and 105% of the spiked Ag were recovered at all sampling stations, indicating that Ag retention by the sewer biofilm was negligible, which was also confirmed by Ag contents in the biofilm before and after the experiment. TEM revealed that the Ag-NP did not aggregate amongst themselves but were dominately attached to other colloids. Energy dispersive X-ray analysis indicated that the Ag-NP were partially transformed into Ag_2S already after 500 m (10 min), consistent with high acid-volatile sulfide levels of 0.15mM in the raw wastewater. The quantitative Ag speciation will be determined in XAS measurements scheduled for March 2012.

Zinc isotope fractionation during metabolic uptake by bacteria

FOTIOS-CHRISTOS KAFANTARIS[1*] AND DAVID M. BORROK[1]

[1]University of Texas at El Paso, El Paso, Texas, USA., fkafantaris@miners.utep.edu (* presenting author), dborrok@utep.edu

Zinc is a trace metal responsible for the normal operation of living organisms but can be toxic at elevated concentrations. The biogeochemical processing of Zn in microorganisms may be reflected in changes in the ratios of stable Zn isotopes. If so, the isotopic signatures of Zn might be used as a tool to learn more about cellular metal processing and toxicity. Despite pioneering work on how Zn isotopes are fractionated during interaction with diatoms and plants, Zn isotopes in bacterial systems remain largely unexplored.

In this study, we conducted a series of metabolic uptake experiments with bacteria using different concentrations of Zn-citrate. Experiments were conducted using the Gram-negative bacteria, *Pseudomonas mendocina* and *Escherichia Coli*, as well as with a natural consortium of desert soil bacteria. Each experimental system was sampled as a function of time/cell growth and the elemental and isotopic compositions of Zn were determined for both the bacterial cells and the solution.

When exposed to 2 ppm of Zn, the growth curves for both *E. coli* and the natural consortium were similar in that the stationary phase occurred 8 days after inoculation. The stationary phase for *P. mendocina* occurred at 6 days after inoculation. However, when *P. mendocina* cells were exposed to 20 ppm of Zn, there was a time lag and the populations reached stationary phase 9 days after inoculation. Cell counts also suggested that fewer bacteria grew under the elevated Zn concentrations. In the 2 ppm experiments, *E. coli, P. mendocina* and the natural consortium incorporated a maximum of 17, 16 and 29 ppm of Zn, respectively. In contrast, when exposed to 20 ppm of Zn in the growth solution, *P. mendocina* incorporated 509 ppm of Zn. Zn isotopes, reported as $\Delta^{66}Zn_{bacteria\text{-}solution}$, for the 2 ppm Zn experiments varied as a function of the growth phase. A separation factor of +0.22‰ was measured for the log phase of *E. coli*, but this decreased to slightly negative values during the death phase. In contrast, *P. mendocina* showed the most negative $\Delta^{66}Zn_{bacteria\text{-}solution}$ during the log phase of its growth (-0.4‰). When *P. mendocina* cells were exposed to 20 ppm of Zn, the $\Delta^{66}Zn_{bacteria\text{-}solution}$ was positive, ranging from +1.02 to +1.5‰. The largest values were again found in the log phase of growth. The natural bacterial consortium did not substantially fractionate Zn isotopes ($\Delta^{66}Zn_{bacteria\text{-}solution}$ = -0.04 to +0.05‰) when exposed to 2 ppm of Zn.

Despite some broad similarities, our experiments demonstrate that the bacterial species, growth phase, and the dosage of Zn all impact the Zn isotopic composition of bacteria. This may suggest that Zn isotopes could be used as a chemical tool for understanding Zn homeostasis within cells. The observation of a dose-dependent fractionation further suggests that Zn isotopes might serve as a tool for understanding toxicological impacts on these microorganisms. However, because of these same complexities, the use of Zn isotopes as a possible biological marker in natural systems deserves further scrutiny.

Estimation of S, F, Br and Cl Fluxes at Mid Ocean Ridges

T. KAGOSHIMA[1*], Y. SANO[1], N. TAKAHATA[1], J. JUNG[1], H. AMAKAWA[2], AND H. KUMAGAI[3]

[1]Atmosphere and Ocean Research Institute, the University of Tokyo, Chiba, Japan (*correspondence: kagoshima@aori.u-tokyo.ac.jp)
[2]National Taiwan University, Department of Geoscience, Taipei, Taiwan
[3]JAMSTEC, Kanagawa, Japan

Introduction

It is known that superficial volatile elements of the Earth have been accumulated mainly by degassing from the solid Earth. Studies that used noble gases as tracers have been conducted to investigate the degassing history of the Earth, which suggests that the significant degassing occurred in the early Earth [1, 2]. Carbon and nitrogen fluxes were well documented in literatures, and they provided other constraints on the hypothesis of degassing history [3, 4]. It is important to study the degassing history of the Earth from the mantle based on the other volatile elements, thus we measured sulfur (S), fluorine (F), bromine (Br) and chlorine (Cl) concentrations trapped in vesicles in mid-ocean ridge basalts (MORBs) and back-arc basin basalts (BABBs) and compared them with helium-3 (^{3}He) concentrations to estimate their fluxes from the mantle.

Analysis

Approximately 1 g of fresh glassy aliquots were picked up from MORB and BABB glasses and were put in a stainless-steel crusher with 1-2 cm^3 of distilled aqueous sodium hydroxide (1-4 mol/L) and a stainless-steel ball. The alkali solution was frozen at the temperature of liquid nitrogen (77K). When the crusher was shaken up and down, the glassy aliquots were crushed together with the frozen solution by the stainless-steel ball. Highly reactive elements including S, F, Br and Cl were extracted from vesicles of glasses by mechanical fracturing and immediately dissolved into a small portion of melted alkali solution. While helium (He), not dissolved into the solution, was introduced into a vacuum line and purified, then helium-4 (^{4}He) intensity and ^{3}He/^{4}He ratio were measured by a VG5400 mass spectrometer. S, F, Br and Cl concentrations in the alkali solution were measured by ion chromatography (Dionex-320).

Results and Discussion

Concentrations of volatile elements trapped in vesicles were (4 – 31) × 10^{-15} mol/g for ^{3}He, (20 – 430) × 10^{-9} mol/g for S, (60 – 5000) × 10^{-9} mol/g for F, (5 – 1300) × 10^{-9} mol/g for Br and (160 – 450) × 10^{-9} mol/g for Cl. Under an assumption that the samples in this study represent typical MORBs, global fluxes of S, F, Br and Cl were estimated using mole ratios X/^{3}He of the samples and the ^{3}He flux of 1060 mol/yr from the mantle [5]. These estimated fluxes from mid ocean ridges will be discussed in comparison with those from volcanic arcs.

Magnetotactic bacteria (MTB) synthesize chains of intracellular, membrane-bound, single crystals of magnetite or greigite in the 30-80 nm size range, an exquisite example of biomineralization. We used Scanning Transmission X-ray Microscopy as a chemically and magnetically sensitive probe to investigate the magnetism of individual magnetosomes and thereby study the mechanism of magnetosome biomineralization. The Fe $L_{2,3}$ X-ray magnetic circular dichroism (XMCD) of cultured cells of *Candidatus* Magnetovibrio blakemorei (MV-1) has the same shape and intensity as abiotic magnetite indicating that the magnetic moment of the magnetosomes is nearly saturated (Fig. 1) [1,2].

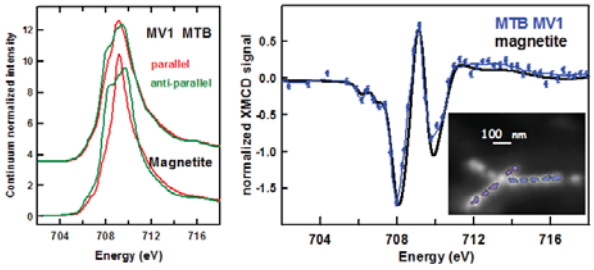

Figure 1: (Left) Fe L_3 and **(Right)** Average XMCD spectrum of magnetosome chains (dots) from two magnetosome chains (see inset) compared to the XMCD of magnetically saturated abiotic magnetic (black). The average magnetosome magnetic moment is 3.6(2) μB [2], 0.93(6) of that of magnetite [3].

Many cells of MV-1 show characteristic gaps between magnetosome chains that occasionally yield intracellular chain orientation reversals. In these gaps there is a reasonably strong Fe L_3 signal very similar to that of magnetite, but without XMCD. These are possibly the result of incomplete or defective magnetite biomineralization and thus may provide insights into the mechanism of chain formation and alignment as well as biogeochemical factors affecting magnetosome chain growth. We will report our recent XMCD-STXM findings of this phenomena and the implications with respect to the mechanism of chain formation.

The Meso- and early Neoproterozoic deep ocean REE issue

BALZ S. KAMBER[1*], ELIZABETH C. TURNER[2], SEAN P. O'HARE[2], GEOFFREY J. BALDWIN[2] AND KATHERINE HAHN[2]

[1]Trinity College Dublin, Department of Geology, Dublin, Ireland, kamberbs@tcd.ie (* presenting author)

[2]Laurentian University, Department of Earth Sciences, Sudbury, ON, Canada, eturner@laurentian.ca, sp_ohare@ laurentian.ca, gj_baldwin@laurentian.ca, kx_hahn@laurentian.ca

The sulphidic deep ocean model for the post-1.85 Ga Proterozoic elegantly combines several lines of evidence and reasoning, including: release of sulphate from land into the ocean; the increase in extent of S-isotope fractionation; the lack of significant Mo enrichment in black shales; and the absence of BIF. However, sediment redox proxies for the latest Neoproterozoic have more recently suggested that the deep ocean might have reverted from a sulphidic to a ferruginous state many 10 Ma before the Sturtian BIF deposition. In addition, little direct sedimentological or other geological evidence exists for the proposed sulphidic nature of Proterozoic deep ocean sedimentary rocks.

The present work aims to add to this debate from a rare earth element (REE) perspective. Archaean and Palaeoproterozoic hydrogenous sediments show very pronounced positive Eu anomalies. This well-established aspect of the seawater REE chemistry reflects the fact that the REE from high temperature hydrothermal fluids were not scavenged onto Fe-oxyhydroxides. In other words, hydrothermal vents were a significant source of dissolved REE to the ocean. By contrast, Phanerozoic seawater proxies consistently have either no or a slight negative Eu anomaly. The expectation from these observations for a sulphidic deep ocean, in which hydrothermal Fe combined with S (from sulphate) to form pyrite, is that the positive Eu anomly would persist. Pyrite cannot accommodate Eu in its lattice and the post-1.85 Ga deep ocean could thus be expected to still carry a strong Eu excess.

New data from the ≤711 Ma Rapitan Gp., the 845 Ma Little Dal Gp. and the 1040 Ma Arctic Bay Fm. (all Canada) will be presented. The deeper waters sampled by the Rapitan BIF show neither a negative Ce anomaly nor a positive Eu anomaly and are therefore consistent with a ventilated deep ocean. The carbonate facies of the Little Dal Gp. and the ca. 1040 Ma Arctic Bay Fm. sampled surface waters that were sufficiently oxygenated to generate a negative Ce anomaly. Corresponding black shales and deep water laminites, respectively, were deposited below a chemocline where Ce was re-released from particles. However, none of the deep water samples shows have a significant positive Eu anomaly. This observation is confimed by reactive Fe speciation in the Little Dal black shale, which rarely record sulphidic conditions. While supportive of a reduced deep ocean, these data cannot be explained if all hydrothermal Fe was sequestered as sulphide.

In summary, the redox evolution during the Neoproterozoic was likley very complex and may have involved a ventilated stage as well as ferruginous and sulphidic episodes. The lack of a strong positive Eu anomaly in Mesosproterozoic and early Neoproterozoic deep waters requires a more complex deep ocean redox in general, likley to have been influenced by the relative supply of Fe, S and C.

Emission of trace gases from the marine diatom *Thalassiosira pseudonana* (CCMP1335) was continuously monitored with a proton transfer reaction-mass spectrometry (PTR-MS) in an axenic batch culture system under a 13:11-h light:dark cycle. Substantial increases in the signals at *m*/*z* 49, 63, and 69, attributable to methanethiol, dimethyl sulfide (DMS), and isoprene, respectively, were observed in response to increases in cell density. Signals at *m*/*z* 69 showed diurnal variations throughout the experiment whereas those at *m*/*z* 49 were more pronounced at the beginning of the incubation. Interestingly, the signals at *m*/*z* 49 and 69 changed immediately following the light-dark and dark-light transitions, suggesting that light plays a crucial role in the production of methanethiol and isoprene. However, in the latter half of the experiment, methanethiol showed negligible diurnal variations regardless of light conditions, suggesting the production of methanethiol from enzymatic cleavage of DMS. The trend in signals at *m*/*z* 63 was similar to that of the abundance of senescent cells plus cell debris rather than vegetative cells. The results suggest that aging or death of phytoplankton cells could also substantially control DMS production in natural waters along with the other microbial processes related to bacteria and zooplankton.

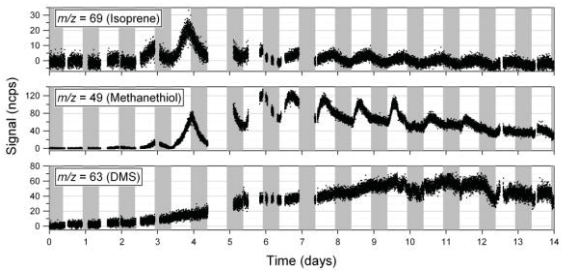

Figure: Time series of PTR-MS signals at *m*/*z* 69, 49, and 63

Sulfur isotope systematics of sulfide oxidation intermediates: implications for organic geochemistry

A. KAMYSHNY, JR.[1]

[1]Geological and Environmental Sciences, Ben-Gurion University of the Negev, Beer Sheva, Israel, alexey93@gmail.com

Bacterial sulfate reduction in natural anoxic aqautic systems produces hydrogen sulfide. Chemical and biological oxidation of sulfide results in formation of sulfate as well as variety of intermediate species, such as polysulfides (S_n^{2-}), elemental sulfur (S_8), thiosulfate ($S_2O_3^{2-}$), sulfite (SO_3^{2-}) and polythionates ($S_nO_6^{2-}$). Many of sulfide oxidation intremediates are highly reactive toward other inorganic and organic species. Such reactions result in formation of secondary products including dimethylpolysulfanes, carbonyl sulfide, and sulfur cross-linked oganic macromolecules [1-3]. Sulfurization of organic matter during early diagenesis occurs due to reactions of organic molecules with polysulfides and possibly with other sulfide oxidation intremediates (e.g. thiosulfate, sulfite) [4,5].

Bacterial sulfate reduction and bacterial sulfur disproportionation are known to result in relatively high sulfur isotope fractionation. On the other hand, processes involved in reoxidative part of sulfur cycle produce only small sulfur isotope fractionations. For example, $\delta^{34}S$ values of fractionation between H_2S and HS^- were reported to be up to 2.7‰ [6], between sulfur and hydrogen sulfide (by anaerobic bicterial sulfide oxidation) – 2‰ [7], between HS^- and inorganic polyuslfides (S_n^{2-}) – up to 4‰ [8], and between thiosulfate and sulfide during bacterial reduction of thiosulafte – 10‰ [9].

A new powerful tool, sumultaneous mesurement of abundances of all four stable isotopes of sulfur, was recently applied for studying reoxidative part of biogeochemical sulfur cycle [10-12]. First miultiple sulfur isotope fractionation fingerprints look promising for future decoupling of various pathways of sulfide reoxidation in natural aquatic systems.

Future application of multiple sulfur isotope approach to formation of sulfide oxidation intermediates as well as to reacions between sulfide oxidation intermedates and organic molecules have a potential to shed a light on mechanisms of diagenetic sulfurization of organic matter as well as on oil formation scenarios.

Biomineralization of Mg-rich calcite by aerobic microorganism enriched from rhodoliths

SERKU KANG[1, *], SUNGJUN YOON[2], AND YUL ROH[3]

Chonnam National University, Gwangju, Korea, rohy@jnu.ac.kr

Introduction

The formation of carbonate minerals by biological processes may play an important role in carbon and metal geochemistry in natural environments. The objectives of this study were to investigate biomineralization of the carbonate minerals using microorganisms enriched from rhodoliths and to identify environmental factors that control the formation of calcite by the microorganisms.

Materials and Methods

Carbonate forming microorganisms were enriched from rhodoliths, which were sampled at Seogwang-ri coast in the western part of Wu Island, Jeju-do, Korea. Microorganisms enriched from rhodoliths were aerobically cultured at 25℃ in D-1 media containing various concentrations (0, 30, 100 mM) of Ca and Mg-acetate, and the microorganisms were analyzed by 16S rRNA gene DGGE analysis to confirm microbial diversity. Mineralogical characteristics of the rhodoliths and carbonate minerals preciptated by the enriched microrganisms were determined by XRF, XRD, and SEM-EDS analyses.

Results and Conclusion

XRF and XRD analyses showed the rhodoliths mainly consisted of CaO (46%) and and MgO (5%) and major mineral is Mg-rich calcite. A 16S rRNA sequence analysis showed the enriched microorganisms contained carbonate forming microorganisms such as *proteus micrailis* and *marinobacterium coralli* [1, 2]. The enriched microorganisms precipitated carbonate minerals using D-1 media containing Ca and Mg-acetate (30, 100 mM) and mineralogy of the precipitated carbonate mineral was Mg-rich calcite. Whereas, the microorganisms did not form carbonate minerals without Ca and Mg-acetate in D-1 media. SEM-EDS analyses showed that the Mg-rich calcite formed by the microorganisms had a rhombohedron shape and consisted of Ca, Si and Mg with extracelluar polymeric subtance (EPS). These results indicate that the microorganisms induce precipitation of Mg-rich calcite on the cell walls and EPS via the accumulation of Ca and/or Mg ions on the cells. Therefore, microbial precipitation of carbonate minerals may play one of important roles in metal and carbon biogeochemistry as well as carbon sequestration in natural environments.

Effect of Oxalic Acid on Geological Storage of CO_2 Using Serpentinite

SEUNG-HEE KANG[1*], NATALIE C. JOHNSON[2], BURT THOMAS[3], KATE MAHER[1], DENNIS K. BIRD[1], ROBERT J. ROSENBAUER[3], AND GORDON E. BROWN, JR.[1]

[1]Stanford University, Geological & Environmental Sciences, envlover@stanford.edu (*presenting author)
[2]Stanford University, Chemical Engineering, nataliej@stanford.edu
[3]United States Geological Survey, burt.thomas@gmail.com

Mineral carbonation of Mg-silicates ensures stable CO_2 storage over geologic time periods. This reaction takes place in natural systems but is kinetically slow [1]. In order to make mineral carbonation an efficient means of sequestering CO_2, we have investigated the effect of oxalic acid in enhancing the kinetics of the serpentinite-CO_2-H_2O reaction.

Serpentinite used in this study was obtained from the New Idria, California serpentinite massif and consists primarily of antigorite. For faster reaction, the rock was ground and sieved, and the 60 to150 μm size range was separated. After washing with methanol five times, the serpentinite was characterized by XRD, XPS, SEM-EDX, and XRF.

Our experiments were conducted under 100 bars CO_2 at 60˚C in 0.5M NaCl solution for one month with a water-to-rock mass ratio of 20:1. A Dickson-type rocker bomb reactor used for these experiments is able to maintain constant pressure and temperature while samples are withdrawn at regular intervals. Thorough mixing was achieved by rocking the reactor.

Magnesite and siderite were generated within 25 days, as revealed by XRD and SEM/EDX analyses. SEM and EDX analysis showed widely dispersed magnesite on the edges of serpentinite grains. Siderite, although less abundant than magnesite, showed more euhedral shapes. The overall carbonation reaction was enhanced in the presence of oxalic acid.

Solution pH was calculated from alkalinity and was found to increase from 3.0 to 5.3 within two days as H^+ was consumed during Mg^{2+} dissolution from serpentine. The serpentinite surface was positively charged under all experimental pH conditions as revealed by zeta potential measurements, suggesting that oxalate anions are likely to be electrostatically attracted to the particle surfaces. Therefore oxalate is predicted to form Mg- and Fe-complexes, which should enhance dissolution. The amounts of Mg, Ca, Fe, and Si released during dissolution were quantified using ICP-OES and indicate initial incongruent dissolution (excess concentrations of Mg, Ca, and Fe, relative to Si). The Mg and Fe concentrations along with pH changes in this experiment indicated favorable conditions for magnesite and siderite formation.Although Krevor and Lackner discussed enhanced serpentine dissolution in the presence of oxalate for CO_2-H_2O-serpentine reaction [2], the present study presents new data on both Mg dissolution and magnesite formation, which will be presented.

The Volcanic Rocks of Bima Formation, Sangri Group in Gangdese Belt: Products of Intra-Oceanic Subduction

ZHI-QIANG KANG[1]*, JI-FENG XU[2], DI-CHENG ZHU[3], JIN-LIN CHEN[3], ZUO-HAI FENG[1], XI-JUN LIU[1], BING-KUI MIAO[1], BAO-CHENG PANG[1], WEI FU[1], QING-WEI ZHANG[1]

[1]College of Earth Sciences/Guangxi Key Laboratory of Hidden Metallic Ore Deposits Exploration,Guilin University of Technology,Guilin 541004, China, zk99201@163.com (* presenting author)
[2] State Key Laboratory of Isotope Geochemistry, GIG, CAS, China
[3] School of Earth Sciences and Resources, CUGB, Beijing, China

The Sangri group volcanic rocks lie in Middle-Eastern part of south edge of Gangdese belt, thought to be the production of Neo-Tethys' northward subduction. However, its geochronology, feature and tectonic setting remains a debate. The previous researches mainly focus on the underlying Mamuxia formation, which originated from the melting of subducted oceanic crust[1,2]. But so far, there is not any study about the overlying Bima formation, so in this study, we focus on the Bima formation and acid intrusions in Sangri group, in order to understand its petrogenesis, tectonic setting and constrain the age and evolution of the whole Sangri arc. The two conclusions as following:

1.We selected zircons from the acid intrusion to do LA-ICPMS U-Pb dating, obtaining an age of 93.4±1.1Ma, which can constrain the upper limit of Sangri group's age. Combining our new data with previously zircon SHRIMP U-Pb age of andesite from the underlying Mamuxia formation by Zhu[2], we firstly obtain the activity time of Sangri group, from 136.5Ma to 93.4Ma.

2. Bima formation mainly consists of basalt, basalt-andesite and andesite. We chose the most mafic rocks to discuss magmatic origin and tectonic setting.These rocks are tholeiite basalt, with high Al_2O_3 (average 17.72wt%), MgO (average 7.82wt%), $Mg^{\#}$ (average 65.52), Cr (215ppm) and Ni (140ppm), hinting that the magma did not undergo significant differentiation. In the spider diagram its geochemical characteristics are similar with those of island arc volcanic rocks, e.g., the enrichment of LILE and depletion of HFSE. However, the basalts have very low K_2O（average: 0.13wt%）、Th（average: 0.8ppm）and flat REE pattern（La_N/Sm_N=1.37; La_N/Yb_N=2.12), the initial Sr^{87}/Sr^{86} ratios vary in range of 0.703965~0.704316, while Nd^{143}/Nd^{144} ratios are from 0.512895 to 0.512944 with high εNd (5.78~6.30), all these characteristics indicate that the basalts were likely generated from partial melting of the depleted mantle wedge without remarkable crustal and sediment influence. So we suggest that Bima formation volcanic rocks are not from the northward subduction of Neo-Tethy along the southern margin of Gangdese belt but products of an intra-oceanic subduction system.

The Phanerozoic minimum in seawater $^{87}Sr/^{86}Sr$: Middle Permian mid-Panthalassan seamount record

TOMOMI KANI[1*], CHIHIRO HISANABE[1], AND YUKIO ISOZAKI[2]

[1]Kumamoto University, Kumamoto, Japan
kani@sci.kumamoto-u.ac.jp (* presenting author)
[2]The Univerisity of Tokyo, Meguro, Japan
isozaki@ea.c.u-tokyo.ac.jp

We report a detail secular change of the Late Guadalupian (Permian) seawater $^{87}Sr/^{86}Sr$ ratio with the unique "Permian minimum" interval detected in mid-Panthalassa (superocean) paleo-atoll carbonates. The analyzed two sections at Akasaka and Kamura (Japan) occur as exotic blocks within the Jurassic accretionary complex. The two sections are separated from each other for 500 km at present, thus were likely derived from different paleo-seamounts formed in mid-Panthalassa. The detected intervals of the minimum and the following increase in $^{87}Sr/^{86}Sr$ are common between the two sections. The new data of the lowest ratio (0.706808) in the Capitanian *Yabeina* (fusuline) Zone at Akasaka give the minimum $^{87}Sr/^{86}Sr$ ratio not only of the Paleozoic but also of the entire Phanerozoic. The extremely low values lower than 0.70690 were detected from 18 samples in the *Yabeina* Zone and the barren interval. In particular, the extremely low values continued up to the topmost barren interval immediately below the Guadalupian-Lopingian (G-L) boundary.

The newly detected Sr record likely represents the general trend of the Guadalupian seawater in mid-Panthalassa. The rapid increase during the Late Permian-Early Triassic interval suggests that a large amount of radiogenic terrigenous clastics have been shed into Panthalassa through rift-related new drainage systems in Pangea [1]. The initial breakup of Pangea may have started around the G-L boundary, clearly before the final opening of the Atlantic in the Jurassic [2].

Effect of fluid flow rate on Fe^{3+}/Fe^{2+} ratios of Paleoproterozoic paleosols and its implication for atmospheric oxygen levels

YOSHIKI KANZAKI* AND TAKASHI MURAKAMI

Department of Earth and Planetary Science, the University of Tokyo, Tokyo 113-0033, Japan
(*Correspondence: kanzaki@eps.s.u-tokyo.ac.jp)

The Great Oxidation Event (2.5 – 2.0 Ga) is one of the most important events in the Earth's history because of its coevolution with organisms and redox surface-environments. Compiled geological records constrain the timing of the oxygen rise and the threshold levels of oxygen concentration, but few investigations have not shown quantitative estimation of oxygen variation as a function of age during the Paleoproterozoic. As demonstrated by Murakami et al. (2011) [1], paleosols allow us to challange such estimation. The recorded behavior of Fe(II) and Fe(III) in paleosols can lead us to understand redox conditions of the Earth's surface at the time of ancient weathering. To properly interpret the behavior of Fe, one must consider: (1) dissolution from primary minerals, (2) oxidation of Fe(II) into Fe(III) (which immediately precipitates as (oxyhydr)oxides), and (3) transport of dissolved Fe(II) outside the weathering profile by fluid (groundwater). The weathering model that considers these factors can calculate Fe(III)/Fe(II) ratios for a given oxygen level, and therefore, predict inversely the P_{O_2} levels from the recorded Fe(III)/Fe(II) ratios in paleosols [2].

The sensitivity analysis of the weathering model revealed that the relationships between Fe(III)/Fe(II) ratios and oxygen levels vary with fluid flow rate. This causes large uncertainty in the predicted levels of P_{O_2}. To properly predict the P_{O_2} levels, the fluid flow rates must be constrained.

The estimation of fluid flow rates for five Paleoproterozoic paleosols has been made based on Si behavior during weathering; loss of Si in each paleosol (mol km^{-2}) against Si in corresponding parent rock was used for the estimation. Using the calculated amounts of Si loss from the paleosols and assuming 50 kyr – 5 myr of weathering duration, the relationships between silica flux (mol km^{-2} yr^{-1}) and runoff (cm yr^{-1}) for basalt and granite [3] gave estimated values of fluid flow rate ranging from 8×10^{-3} to 46 m yr^{-1}. These estimates match well with those calculated based on the mass balance principal of Si between water and rock assuming steady state concentrations of dissolved silica as 10^{-4} – 10^{-3} mol L^{-1}, average porosity of a whole weathering profile as 0.2 and weathering duration as 50 kyr – 5 myr.

The weathering model adopting an average value of the estimated fluid flow rates, that is ~ 0.1 m yr^{-1}, have calculated P_{O_2} levels from the Fe(III)/Fe(II) ratios of the five Paleoproterozoic paleosols. Although there remains an uncertainty about the fluid flow rate, the most likely results suggest a gradual rise of atmospheric oxygen, from < ~ 10^{-6} to > ~ 10^{-3} atm between 2.5 and 2.0 Ga.

Microbial Fe, Mn & As redox transformations and their contributions to As removal from drinking water in household sand filters in Vietnam

ANDREAS KAPPLER[1]*, KATJA NITZSCHE[1], ANKITA BHANSALI[1], MICHAEL BERG[2], PHAM THI KIM TRANG[3], PHAM HUNG VIET[3], SEBASTIAN BEHRENS[1]

[1]Geomicrobiology Group, University of Tuebingen, Germany, andreas.kappler@uni-tuebingen.de (*presenting author)

[3]Center for Environmental Technology and Sustainable Development (CETASD), Hanoi University of Science

Worldwide more than 100 million people ingest detrimental concentrations of arsenic by consuming groundwater contaminated from natural geogenic sources. Many Asian countries, in particular Vietnam, Bangladesh, India, and Cambodia are known to be affected by high groundwater arsenic concentrations as a result of reducing aquifer conditions [1]. Household sand filters are simple to operate and remove most of the arsenic from the groundwater containing arsenic and ferrous iron with an iron/arsenic ratio of at least 50 leading to As values of <50 or even <10 µg/L [2]. The installation and operation costs of household sand filters are low and the construction materials are locally available. The filters can treat a reasonable amount of groundwater within a short time and they are easily installed by the affected communities. Oxidation of dissolved iron present in the groundwater leads to the formation of sparsely soluble iron (oxyhydr)oxide particles in the sand filters, which bind negatively charged and neutral arsenic species and reduce arsenic concentrations in the water [2, 3].

Although household sand filters are an effective technical solution for mitigating arsenic exposure, not much is known about microbial iron, manganese, and arsenic redox transformations occurring in the filters and their effect on filter efficiency. Therefore, one of the goals of this study was to isolate, identify, and quantify Fe, Mn, and As-oxidizing and -reducing microorganisms from a arsenic removal sand filter and to study their specific Fe, Mn, and As redox activities. Water samples and filter solids were collected from a local sand filter close to the city of Hanoi, Vietnam. The samples were geochemically and mineralogically characterized. Total iron, arsenic, manganese, and phosphate concentrations, pH, TOC, TIC measurements, as well as total cell counts were performed on samples from various depths of the sand filter. Most probable number counts confirmed the presence and activity of various iron, manganese, arsenic redox-processes and their distribution within the water filter. This research aims to better understand the microbial redox transformation processes that drive arsenic/manganese/iron mineral interactions in household sand filters and to give recommendations for improved filter use and filter material disposal.

First principles study of the structure and compressibility of $MgSiO_3$ glass

DIPTA GHOSH[1], BIJAYA KARKI[1*] AND LARS STIXRUDE [2]

[1]Louisiana State University, Baton Rouge, USA, dghosh2@lsu.edu, karki@csc.lsu.edu (* presenting author)

[2]University College London, London, UK, l.stixrude@ucl.ac.uk

Silicate glasses have been widely studied because they are considered as analog of geologically relevant silicate melts. Experimental studies have suggested that silicate glasses undergo significant structural changes including irreversibility under compression. Here, we report first-principles molecular dynamics study of the equation of state and structure of $MgSiO_3$ glass at 300 K as a function of pressure. Our simulations show that the glass at ambient condition is composed of primarily Si-O tetrahedra (with ~95% abundance, the mean coordination number being ≥ 4), which are partially linked with each other via bridging oxygens (present in 35%, the remaining being non-bridging oxygens). As pressure increases, the mean Si-O coordination gradually increases to 6 occurring through the increased appearance of five-fold (pentahedral) states at low pressure and then six-fold (octahedral) states at high pressure. On the other hand, Mg-O coordination, which is a mixture of four-, five- and six-fold species at zero pressure, picks up more high-coordination (seven- to nine-fold) species on compression and its mean value increases from 4.5 to 8 over the pressure range studied. Consistently, the anion-cation coordination increases under pressure with the appearance of oxygen triclusters (O atoms coordinated with 3 Si or 3 Mg atoms) and the mean O-Si (O-Mg) coordination eventually reaching (exceeding) 2. We find that glass densification is rather rapid initially and becomes more gradual at pressures above 20 GPa. This behavior can be associated with the way the glass structure changes in terms of bond distances, bond angles and coordination environments as pressure increases. On decompression, the system fails to revert back to its initial structural state, consistent with the experimental observations, and this irreversibility can be attributed to the memory effects, i.e., to continuing existence of high coordination species (pentahedra and octahedra) to larger volumes.

Mechanisms of isotopic fractionation of Mo on ferromanganese oxides based on the systematics of its surface complex structures

TERUHIKO KASHIWABARA[1]* AND YOSHIO TAKAHASHI[2]

[1]Japan Agency for Marine-Earth Science and Technology (JAMSTEC), teruhiko-kashiwa@jamstec.go.jp*

[2]Hiroshima University, ytakaha@hiroshima-u.ac.jp

Molybdenum (Mo) shows a large mass-dependent isotopic fractionation during adsorption on ferromanganese oxides, which is responsible for isotopic composition of Mo in modern oxic seawater [1]. This fractionation process is the basis of the utility of Mo isotope system as a paleocean redox proxy. The aim of this study is to reveal the fractionation mechanisms of Mo isotopes during adsorption on natural ferromanganese oxides. We investigated surface complex structures of Mo on various Fe/Mn (oxyhydr)oxides, key factors for the isotopic fractionation, and discussed the relationship among the degree of isotopic fractionation, surface complex structures, and characteristics of various oxides.

Our XAFS analyses revealed that Mo forms a *Td* outer-sphere complex on ferrihydrite and distorted *Oh* inner-sphere complexes on δ-MnO_2 [2]. In addition, Mo forms inner-sphere complexes as *Td* edge-sharing (46%) and *Oh* double corner-sharing (54%) for goethite, and as *Td* double corner-sharing (14%) and *Oh* edge-sharing (86%) for hematite [3]. This structural information showed the excellent correlation with the degree of isotopic fractionation of Mo reported in previous studies: the proportion of *Oh* species in surface Mo species becomes larger in the order of ferrihydrite < goethite < hematite < δ-MnO_2, a trend identical to the degree of isotopic fractionation [4]. Based on the comparison with previous reports for surface Mo species on various oxides such as MgO, Al_2O_3, and TiO_2, the symmetry change from *Td* to *Oh* is suggested to be driven by the formation of inner-sphere complexes on specific sites of the oxide surfaces. In addition, the mode of attachment (inner- or outer-sphere) of surface Mo species is well correlated with the hydrolysis constant of the cation (e.g. Mg^{2+}, Al^{3+}, Fe^{3+}, Ti^{4+}, and Mn^{4+}) in oxides. These facts imply that large isotopic fractionation as the case of Mo between seawter and marine ferromanganese oxides could occur as a general phenomena for other unknown elements and/or adsorbents[5], which would considerably influence their isotope systems in the environment.

Sr and Nd isotopes from Diorites and Granites (Damara Orogen, Namibia): Partial melting of juvenile mafic crust?

NICO KASTEK[1], STEFAN JUNG[1], JASPER BERNDT[2] AND ANDREAS STRACKE[2]

[1]Mineralogisch-Petrographisches Institut, Universität Hamburg Germany, nico_kk@web.de

[2]Institut für Mineralogie, Westfälische Wilhems-Universität, Münster, Germany

The high-grade central zone of the Pan-African Damara Orogen in Namibia hosts abundant granitoidswith ages from c. 540 to c. 480 Ma. New LA-ICP-MS zircon ages of 541±3 Ma obtained on qtz diorites show that these rocks intruded close to the first peak of regional metamorphism, whereas granodiorites and granites intruded close to the main peak of metamorphism (506±6 Ma). Qtz diorites are meta-aluminous with A.S.I (A.S.I.: Al/(Ca+Na+K)(molar)) up to 0.8. The granites are slightly peraluminous high-K calc-alkaline I-type granites. All rocks are enriched in light rare earth elements relative to heavy rare earth elements with La_N/Yb_N ranging from 13 to 18 in the qtz diorites and from 9 to 26 in the granodiorites and granites. The qtz diorites have Eu/Eu* (Eu/Eu*: Eu/√(Sm*Gd)) from 0.8 to 0.9 whereas the granites have Eu/Eu* = 0.1-0.4. The qtz diorites have the most radiogenic Nd isotope composition among the qtz diorites of the Damara orogen (εNd_i: -1.50 to -1.78) together with unradiogenic Sr isotope compositions ($^{87}Sr/^{86}Sr_i$: 0.7049-0.7058). The granodiorites and granites have less radiogenic Nd isotopic compositions (εNd_i: -2.74 to -5.31) and more radiogenic initial Sr isotope ratios ($^{87}Sr/^{86}Sr_i$: 0.7071-0.7082). Although fractional crystallization processes were operative, the lack of correlation between isotope ratios and elemental concentrations indicate that both rock types represent partial melts of juvenile crustal sources. Compared to experimental studies, a medium-K/high-Al-metabasaltic rock is the most plausible source for the qtz-diorites. For the granites, high-K andesitic to tonalitic rocks are plausible sources. Although both rock types were formed during the main phases of regional metamorphism, internal crustal heat production rates are probably not sufficient to generate qtz diorites and I-type granites from pre-existing crustal sources. One plausible model involves underplating of mantle derived magmas followed by sill-like intrusions in the lower crust close to the peak of high-grade metamorphism producing excess temperatures that promote partial melting of fertile crustal sources.

Don't Neglect Serpentinization

JAMES F. KASTING

Department of Geosciences, Penn State University, University Park, PA, USA, jfk4@psu.edu

Why did atmospheric O_2 only increase at 2.45 Ga when various indirect indicators suggest that oxygenic photosynthesis had already evolved by 2.7 Ga or earlier? This question has perplexed geologists for the past decade or more. Suggested hypotheses include: 1) Oxygenic photosynthesis was not actually invented until 2.45 Ga; 2) O_2 could not rise until the dissolved ferrous iron in the ocean was titrated out; 3) The mantle became more oxidized with time so that volcanic gases also became more oxidized; 4) The continents became more oxidized with time so that metamorphic gases became more oxidized; 5) The ratio of C and S relative to H in volcanic gases increased with time because of more active recycling of carbon and sulfur; and 6) A gradual switch from submarine to subaerial volcanic outgassing caused volcanic gases to become more oxidized with time. This last hypothesis has at least two variants, presented, respectively, by Kump and coauthors [1,2] and Gaillard et al. [3]. These variants differ with respect to the temperature at which submarine volcanic gases last equilibrate with basalts before being vented into the ocean. Here, I suggest that hypothesis (6) is indeed correct, but that the interaction of hydrothermal fluids with seafloor rocks is not well accounted for by any of the existing models [1-3]. Warm (~350°C) water can react with ultramafic rocks, generating hydrogen, by the process of serpentinization. This process happens only in restricted environments today, e.g., in deep fracture zones around the Mid-Atlantic ridge. However, on the early Earth, a hotter mantle may have generated thicker, more ultramafic oceanic crust, along with widespread hydrothermal activity. Gradual cooling of the mantle led to a change in tectonic styles, reflected by the Archean-Proterozoic geologic boundary, and also to a reduction in production of hydrogen from serpentinization. Thus, this hypothesis is closely related to the Kump and Gaillard models, but it includes additional types of water-rock interactions.

Experimental and field studies of Li cycling in subduction zones

Miriam Kastner[1]*, Evan A. Solomon[2]

[1]Scripps Institution of Oceanography, La Jolla, CA 92093, USA, mkastner@ucsd.edu
[2] School of Oceanography, University of Washington, Seattle, WA 98195, USA, esolomn@u.washington.edu

Li is one of the most prominent tracers that provides insights on fluid-rock diagenetic or metamorphic reactions, hence, on the subsurface hydrology in subduction zones. Like the other alkali elements it strongly partitions into the fluid-phase, in particular at moderate to elevated temperatures; the magnitude of the partition is strongly temperature dependent. Li and its isotopes have been used for tracing fluid reactions and cycling at plate boundaries. In subduction zones the nature of the subducted material has a strong influence on the observed variations in Li isotopes. Data from two subduction zones, Costa Rica, and Nankai Trough, will be presented.

Recent hydrothermal experiments by Wei Wei on MORB-seawater and smectite-seawater, 35-350 °C at 25 °C steps, and 600 bars, greatly expanded the data-base and insights on the behavior of Li. The results indicate that Li is released into the fluid-phase throughout the temperature range of the experiments, with a strong threshold of significant release at ~250 °C; indeed, Li concentrations increase in fluids with depth in subdution zones. Accordingly, because clay-rich sediments and altered oceanic crust are enriched in Li and the Li isotope values are lower than seawater value; the fluids that migrate up-dip from a deeper source into the ocean should have a lower isotope signature, eventually approaching the source material, as observed in the pore fluids of the décollement zones at the Costa Rica and Nankai Trough subduction zones. The experiments show a linear trend starting at seawater and decreasing with temperature (δ^7Li versus T), and can facilitate estimation of the fluid source temperature if the mineralogy of the subducting material is known.

The formation fluids recently recovered at two sites at the Costa Rica subduction zone provide, for the first time, two-year records on temporal variations (1) on the chemistry of the incoming plate upper basement formation fluid, (2) on the décollement fluid at 0.6 km arcward of the deformation front, and (3) on the relations of chemistry, tectonic events, and flow rates. The formation fluid Li concentrations and isotope data at the ODP reference Site 1253 support mixing between seawater and a deep-sourced fluid in the forearc of the Costa Rica subduction zone, implying that the uppermost permeable basement serves as pathway of fluid expulsion from the forearc. At the Nankai Trough décollement the Li concentrations are significantly higher and the δ^7Li value is lower than at Costa Rica, reflecting the different sediment inputs and geothermal gradients at these two subduction zones.

Redox oscillations in a freshwater analogue of marine pelagic sediments: Lake Superior

S. KATSEV[1*], J. LI[1], S.A. CROWE[2], D. MIKLESH[1], M. KISTNER[1] AND D.E. CANFIELD[2]

[1]Large Lakes Observatory, University of Minnesota Duluth, Duluth, MN, USA, skatsev@d.umn.edu (* presenting author)
[2]NordCEE, University of Southern Denmark, Odense, Denmark

Much attention has been given recently to the dynamics of redox boundaries in environments ranging from coastal sediments to flood planes to abyssal Arctic sediments [1]. We report on a multi-year investigation of transient diagenetic phenomena in a freshwater system. Deep (160-318 m) sediments in Lake Superior have sedimentation rates (0.01-0.04 cm y^{-1}) similar to those in marine hemipelagic and pelagic sediments and are similar to such sediments in terms of oxygen uptake, carbon degradation rates, carbon mineralization efficiency, and surface bioturbation rates. The reactivity of deposited organic carbon decreases with age according to a power law similar to the one established for marine environments. In Lake Superior, oxygen penetration into sediments ranges from 3.5 to >12 cm. Seasonal variations of only ~20% in bottom water oxygen concentrations cause it to vary by several cm, more than previously acknowledged. Using measurements and diagenetic modeling, we analyze the causes of these variations and their effects on sediment diagenesis and fluxes. On decadal time scales, our results show that multiple Mn- and Fe-rich (up to 10 wt %) layers in Lake Superior sediments are diagenetically mobile even where organic carbon is only weakly reactive (k≈0.005 y^{-1}). We draw parallels with the metal-rich layers that are found in deep Arctic sediments where they are often used as indicators of paleo-redox conditions [2] and discuss the diagenetic mobility of such layers on time scales up to 100 ky.

Impact of Ternary Surface Complexes on Metal Ion Adsorption

LYNN E. KATZ[1]*

[1]University of Texas, Austin, USA,
lynnkatz@mail.utexas.edu (* presenting author)

Introduction

The fate and transport of metal ions released into the environment rely heavily upon their interactions with the mineral–water interface. Surface complexation models (SCMs) such as the Charge Distribution Multi-Site Complexation (CD-MUSIC) model are capable of describing and predicting adsorption processes over a range of environmental conditions in well-controlled systems with few competing or co-adsorbing species. In recent years, research objectives have focused on applying these models to more complex systems containing multiple adsorbing species and mixed mineral assemblages.

Results

In this research, surface charge, isotherm, and pH adsorption edge data taken from several published studies were modeled using CD-MUSIC to examine how different adsorbents (goethite and gibbsite) and complexing ligands (e.g. carbonate, chloride, selenite, and sulfate) influence metal ion adsorption and surface speciation (e.g. Figure 1). Mineral's surface site density was estimated, when possible, using a new approach that incorporates the proton reactive site density [1], along with maximum oxyanion adsorption data and pertinent crystallographic information regarding the adsorbent of interest. The impact of ternary complexes was ligand and adsorbent dependent.

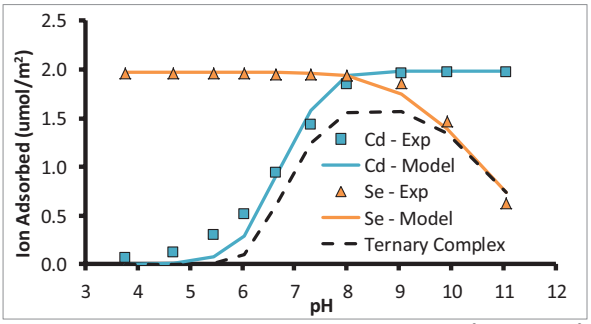

Figure 1: Adsorption and CD-MUSIC model for Cd^{2+} and SeO_3^{2-} bi-solute adsorption to goethtite. Model predictions of the $CdSeO_3$ ternary complex are represented by the dashed line.

Conclusion

This investigation reveals the pivotal role that ternary surface complexes can play in adsorption processes, and further illustrates the necessity of accurately depicting surface and aqueous complexes in SCM predictions.

Solubilization of trace elements from coal fly ash in relation to chemical speciation

NAVDEEP KAUR[1], DEAN L. HESTERBERG[1]*, OWEN W. DUCKWORTH[1], DAVID B. BUCHWALTER[1] & COLIN R. WARD[2]

[1]NC State University, Raleigh, United States, dean_hesterberg@ncsu.edu (* presenting author)
[2] University of New South Wales, Sydney, NSW, Australia, C.Ward@unsw.edu.au

Abstract

In December 2008, approximately 4.2 million cubic meters of coal fly ash were discharged into the Emory and Clinch Rivers from a holding pond in Kingston, TN. A fundamental understanding of the chemistry of the ash is required to develop long-term management strategies for the site. The objective of this study was to relate the pH-dependent kinetics of trace-element dissolution to chemical speciation in the ash. A fly ash sample from TVA's Kingston power plant contained 60% aluminosilicate glass in addition to mullite, quartz, and other minerals. Synchrotron x-ray absorption spectroscopy (XAS) indicated that trace elements (As, Cr, Cu, Se, Sr, and Zn) were associated with both the glass and mineral phases.

Initial experiments on dissolution kinetics were conducted on suspensions of ash in 0.05 M KCl (10 g kg^{-1}) in a continuously stirred batch reactor at 25 °C under oxic conditions, both at pH 5 and at ambient pH (buffered at pH 10) over a period of 10 days. Similar trends in increasing dissolved Sr and Ca concentrations with time at both pH levels were observed, and both elements were found predominantly in the glassy phase. General trends of increasing dissolution with time of As, Cr, Se, and S at pH 10, and of Zn, Mn, and Fe at pH 5 were observed. Speciation analyses of unweathered ash samples indicated the presence of mainly As(V), Se(IV) and Cr(III), along with ferrihydrite-like Fe and discrete Zn phases. A decline in dissolved concentrations of some elements with time was attributable to precipitation of secondary solids. Results from a stirred-flow reactor system will also be presented.

Conclusions

Over time, alkaline fly ash residues in circumneutral or acidic river sediments are expected to become acidified. Elemental speciation in fly ash provides insights on solubilization of potentially toxic trace elements under varying pH conditions. However, transformations of initial solid-phase species into other, possibly more insoluble species, must also be considered. Continuing experiments across a range of geochemical conditions to which fly ash residues might be exposed will assess potential, long-term environmental impacts of ash-contaminated sediments.

This research was funded by Tennessee Valley Authority (TVA) through a grant administered by Oak Ridge Associated University (ORAU). We appreciate Dr. Neil Carriker's assistance in obtaining fly-ash samples for this research. Synchrotron XAS analyses were done at Beamline X11A at the DOE's National Synchrotron Light Source, Brookhaven National Laboratory and at Beamline 4-3 at the Stanford Synchrotron Radiation Lightsource.

Modeling the impact of soil aggregate size on selenium immobilization

MATTEO KAUSCH[1]* AND CÉLINE PALLUD[1]

[1]ESPM, University of California, Berkeley, USA, mkausch@berkeley.edu (* presenting author)

Soil mineral and organic particles are commonly bound together into mm to cm sized microporous structures (aggregates) separated by macropores. While fast advective transport prevails in macropores, the transport inside aggregates is mostly diffusive (slow) which leads to the formation of aggregate-scale concentration gradients impacting biogeochemical reactions. Selenium (Se) is an essential micronutrient that has recently emerged as an environmental contaminant. The bioavailable oxyanions selenate, Se(VI), and selenite, Se(IV), can be microbially reduced to solid, elemental Se, Se(0), and anoxic microzones within aggregates are thought to promote this process in soils. A mechanistic understanding of Se reduction and retention in soil aggregates can lead to better predictions of Se transport and attenuation in seleniferous soils which may help improve the management of such ecosystems.

Using a dynamic 3D reactive transport model of a single idealized aggregate, we model the coupling between physical transport and biogeochemical reactions controlling Se reduction at the aggregate scale. The model was developed and validated based on a series of flow-through reactor experiments involving artificial soil aggregates. Each experiment/model scenario consisted of a spherical aggregate (experimental diameter: 2.5 cm) surrounded by a constant flow providing Se(VI) (0.4 or 0.8 mM) and pyruvate (0.3 or 1.2 mM) for 8 days under oxic or anoxic conditions. Aggregates contained a Se-reducing bacterial strain (*Enterobacter cloacae* SLD1a-1) that oxidizes pyruvate while reducing Se(VI) to Se(IV) and Se(IV) to Se(0). These two reactions were implemented in the model as double-Monod rate equations with literature based kinetic parameters. Reactions were coupled to transport of pyruvate, O_2, and Se species modelled *via* advection-diffusion equations with static flow fields calculated using Navier-Stokes/Brinkman equations (macropore/aggregate). Concentrations of Se(VI) and reduced Se (Se(IV)+Se(0)) were measured in the outflow solution (temporally resolved) and in concentric solid phase sections of aggregates (spatially resolved). This data was used to validate the dynamics of the reactive transport model and all subsequent simulations where performed within experimentally validated dimensions ($\leq$ 2.5 cm, 8 days).

Simulations predict that larger aggregate size leads to increased Se retention. For example aggregates, surrounded by oxic conditions and a flow of 0.3 mM pyruvate/0.4 mM Se(VI) solution, are predicted to retain 0.4 and 0.1 nmol/g/day of Se(IV) and Se(0) respectively if they are 2.5 cm in diameter, but this decreases continuously over the simulated size spectrum to 0.07 and 0.01 nmol/g/day for 1 cm diameter aggregates. While the absolute amount of reduction depends on aeration, as well as Se(VI) and carbon concentrations, this trend persists across all chemical conditions investigated. Promoting soil aggregation on seleniferous agricultural soils, through addition of organic matter and decreased use of tillage may thus be an effective management practice to decrease impacts of Se contaminated drainage water on downstream ecosystems.

Rainfall induced isotope effects in rice (*Oryza sativa* L.) grain organics: A palaeo perspective

RITIKA KAUSHAL[1*], PROSENJIT GHOSH[1], WILLI A. BRAND[2], AND HEIKE GEILMANN[2]

[1] Centre for Earth Sciences, Indian Institute of Science, Bangalore, India, rithikakaushal@ceas.iisc.ernet.in (* presenting author), pghosh@ceas.iisc.ernet.in

[2] Max Planck Institute for Biogeochemistry, Jena, Germany wbrand@bgc-jena.mpg.de , geilmann@bgc-jena.mpg.de

The relationship between $\delta^{18}O$ of environmental water and organic-starch present in rice (*Oryza sativa* L.) and its usefulness to reconstruct precipitation patterns from archaeological samples is being explored in this paper. Rice grows in an environment saturated with water which is derived primarily from rainfall. Being a crop which grows across latitude from tropical to temperate regions, it offers the possibility to explore the relationship that it exhibits with the oxygen isotopic composition of rainfall. Rainfed water is the primary source of water in agricultural fields and is responsible for controlling the growth and productivity of the rice crop. A strong and significant relationship was found to exist between the all-India rice production and Indian summer monsoon rainfall [1]. Here we used $\delta^{18}O$ signature of rice grain samples originating from different latitudes, and compared it with the zonal temperature and respective precipitation isotopic ratios. Oxygen isotope ratios in rice grains were obtained from the literature [2, 3] and were also generated upon analysis of samples originating from different locations over India. The isotopic composition of precipitation and temperature were retrieved from International Atomic Energy Agency–Global Network of Isotopes in Precipitation (IAEA – GNIP) dataset [4]. A careful inspection of precipitation isotope ratios and rice isotopic composition, allowed the determination of $\delta^{18}O$ fractionation factor between rice organics and precipitation water. The fractionation factor observed in here varies between ~23‰ to ~35‰ and is mainly controlled by temperature. The latitudinal effect on rice isotopic composition and rainfall is observed in majority of the locations. However, the regions affected by dual monsoon show tendency of large scatter owing to contribution of moisture from different ocean basins [5]. The oxygen isotope ratios in rice samples will provide an opportunity to understand the rainfall pattern from isotopic composition of rice samples belonging to archaeological sites of older civilizations.

Stable-isotope insights into mineral-fluid redox reactions

ABBY KAVNER[1,*], JAY R. BLACK[1,2]

[1]University of California. Los Angeles, Earth and Space Sciences Department akavner@ucla.edu (* presenting author)
[2]Geoscience Australia, Canberra ACT 2601 jay.black@ga.gov.au

We present a synthesis of a series of experiments which use metal stable isotope behavior as a probe of the kinetics of redox reactions at an aqueous/solid interface. Measurements of isotope fractionation during potentiostat-controlled electroplating has led to observations of large isotope fractionation factors in a large variety of metal systems including Fe [1-3], Zn [2-5], Li [6], and Cu[7]. Our observed isotope fractionations vary strongly as a function of electrochemical driving force and temperature. We interpret our observations in terms of a competition between two rate-limiting steps at a redox-sensitive interface: mass transport to the interface, which results in small isotope signatures, and the steps associated with the electron transfer reaction, which results in much larger isotope signatures. Our experimental data which measures both overall reaction rates and rate-dependent isotope separation cannot be explained simultaneously using rate laws involving simple single-step activated processes governing mass transport and redox reaction steps. Instead, to explain all of our observations, we require rate-dependent isotope fractionation factors. Our results are consistent with a theory predicting isotope-dependent electrochemical reaction rates that is based on theory for electron transfer reactions[1,4]. The results imply that stable isotope behavior at a redox-active interface provides an exquisitely sensitive probe of the details of the activated processes governing the reactions, eslucidating small variations in rate that cannot be observed by measuring reaction rates alone. This is especially true in regimes where redox processes are not rate-limited by mass transport of material to the reaction zone.

High-precision temperature change at the western Japan during the past 10,000 years and its effect on the human activity

HODAKA KAWAHATA [1]*, MEGUMI MATSUOKA[1], AMI TOGAMI[1], AND NAOMI HARADA[2]

[1] Atmosphere and Ocean Research Insttitute, The University of Tokyo, Kashiwanoha 5-1-5, Kashiwa, Chiba 277-8564, Japan, kawahata@aori.u-tokyo.ac.jp (* presenting author),
[2] JAMSTEC, Natsushima 2-15, Yokosuka, 237-0061, Japan

A continuous record of terrestrial environments is difficult to reconstruct because terrestrial sediments are often eroded and transported away by wind or water. In contrast, marine sediments often provide a continuous record of both marine and terrestrial environments in their sedimentary sequence. Therefore, we collected a shallow-marine sediment cores near Hiroshima-city, located near Inland Sea of Japan in the western Japanese Islands, and conducted the reconstruction of Holocene environmental change with ultra-high resolution of environmental change during 700-1700 AD. SST (sea surface temperature) declined (26.2-23.7oC) from 10,300 to 3,900 cal. Yr. BP), which is quite different from those recorded in surrounding areas including Yellow Sea, Japan Sea, and the western Pacific, which show increase in SST or a maximum around mid-Holocene. We attributed the decrease in SST to the large heat capacity of Inland Sea of Japan and general decrease in insolation. SST fluctuated between 22.3 and 24.3 during 1900BC-1800AD). With respect to historical record, Asuka (592-610AD) and Nara (710-794AD) eras showed reduced and enhanced SSTs, respectively. The former half of Heian era (794-1000AD) showed very mild and optimal climate, which enabled aristocracy by noblemen. In contrast, SST drastically declined from the latter half of Heian era to majority of Kamakura eras (1000-1230AD), which could promote the change to Samurai government by power politics. After that a relative mild climate prevailed about 200 years (1230-1500AD) and then cold weather was observed during 1500-1800AD, corresponding to Little Ice Age.

Melt inclusions in zircon from the migmatite zone, Ryoke belt, Japan

TETSUO KAWAKAMI[1*], ISAO YAMAGUCHI[1,2], AKIRA MIYAKE[1], KENSHI MAKI[1], TOMOYUKI SHIBATA[1], TAKAOMI D. YOKOYAMA[1], AND TAKAFUMI HIRATA[1]

[1]Department of Geology and Mineralogy, Kyoto University, Japan. t-kawakami@kueps.kyoto-u.ac.jp (* presenting author).
[2]DOWA Holdings Co. Ltd., Tokyo, Japan

Melt inclusions in Zrn is a clear evidence of the presence of melt during Zrn formation and therefore, places an important constraint on the timing of Zrn growth. In the Ryoke belt at the Aoyama area, Japan, pelitic and psammitic schists dominate in the north, and migmatites dominate in the south [1]. Zrn in pelitic and psammitic schists from the low-*T* part of the Grt-Crd zone is coarse-grained and shows almost no syn-metamorphic overgrowth. On the other hand, Zrn in migmatites from the mid-*T* and high-*T* parts of the Grt-Crd zone has thin, bright annulus under BSE image along which tiny inclusions of several microns are aligned [cf. 2]. TEM observation of the inclusions gave halo patterns, revealing that they are glass rich in Si, Al and K. This inclusion alignment divides the Zrn into the core with various detrital ages and the rim with 92.6±2.0Ma $^{206}Pb/^{238}U$ concordant age. Presence of the melt inclusions at the core/rim boundary shows that the melt was present when the Zrn rim grew. Low Th/U ratio (<0.02) of the Zrn rim implies that Mnz also coexisted then. A reaction Bt+Sil+Qtz = Grt+Crd±Kfs±Ilm+melt is considered responsible for partial melting in this area [1]. However, Bt is not an important sink of Zr [3], and Bt breakdown cannot supply sufficient Zr to form Zrn rim. Therefore, dissolution of pre-existing Zrn is required to grow new Zrn rim. It would be difficult to saturate melt in Zrn component by dissolving Zrn when the amount of melt is increasing. Therefore, 92.6±2.0Ma Zrn rim probably crystallized during the solidification of the melt in migmatites, possibly near the wet-solidus. Thin, similar-aged rim is developed in Zrn from the mid-*T* part as well. These data suggest that presence of the melt controls dissolution and recrystallization of Zrn [e.g. 4].

Although the whole-rock Zr content is not especially high in the pelitic-psammitic schists from the low-*T* part, modal amount of Zrn (>20μm) is higher in them. Zrn (<20μm) is confirmed to become common in mid-*T* and high-*T* parts, and young, ca. 30μm Zrn without detrital core are rarely found in the high-*T* part. These Zrn are probably newly nucleated grains during the Ryoke metamorphism.

On the other hand, Mnz grows at amphibolite facies grade and the presence of the melt does not largely affect its recrystallization [4]. In the Aoyama area, Mnz from the migmatites records the prograde growth age of 96.5±1.9Ma during the regional metamorphism [5]. Using the difference of growth timing of Mnz (prograde) and Zrn (retrograde), the duration of metamorphism higher than the amphibolite facies grade can be constrained to be ca. 4Ma for the Ryoke metamorphism at the Aoyama area.

Crustal Destruction: Delamination Processes and Rates

ROBERT W. KAY[1*] AND SUZANNE M. KAY[1]

[1]Cornell University, Earth and Atmospheric Science and INSTOC, Ithaca, NY, USA rwk6@cornell.edu

Narratives of Earth's continental crust formation need to devote time to both crustal creation and destruction. For creation, mantle melting yields magmas that add new mass; destruction involves sediment subduction, subduction erosion, and lower crustal delamination (foundering, dripping) and slab breakoff. Processes like relamination only involve recycling. Issues include rate and relative importance of basaltic versus andesitic magmas, criteria for identification of destruction processes and rates. Here, we examine criteria for identifying delamination and focus particularly on the role of delamination in ultimately producing an andesitic crust. In general, delamination occurs in contractional regimes, is episodic, and recycles mafic/ultramafic lower crust. On-going delamination is being observed in seismic images of the mantle and crust under areas like the high Central Andean plateau and the Sierras and Colorado Plateau of the western US. Abrupt changes in magma composition and xenolith populations along with structural changes and uplift complement and provide a temporal context to geophysical observations. Adakitic rocks that form in equilibrium with dense eclogitic residues are distinctive, as is the presence of magmatic "flare-ups". In older contractional orogens, similar thermal-compositional-structural observations, constrained by high precision chronology permit identification of delamination episodes as in the Tertiary Tibetan Plateau and in the Proterozoic Grenville. In accretionary orogens like the Palaeozoic Altaids (central Asia) identification of delamination is aided by present-day analogues. In collages of sutured arc terranes, mafic lower crust and forearcs often appear under-represented and were presumably destroyed. In contrast, regions like the Ural arc-continent collision zone appear to have remained largely intact. Integrated over a long time scale, the rate of lower crustal destruction by delamination at subduction zones and during continental collision is on the order of 2 AU (Armstrong units at km^3/year globally).

EM-like sources in Patagonian plateau basalts: Auca Mahuida case

SUZANNE M. KAY[1]* AND HELEN JONES[1]

[1]Cornell University, Earth and Atmospheric Science and INSTOC, Ithaca, NY, USA smk16@cornell.edu

Plateau basalts in the northern Patagonian ~1.8 to 0.8 Ma Auca Mahuida volcanic field, which is centered at 37.8°S and 68.7°W and is ~225 km from the Andean Southern Volcanic Zone arc front, have trace element and Sr, Nd and Pb isotopic similarities to nearby early Miocene basalt flows as well as oceanic OIB basalts that are primarily mixtures of EM1 and depleted mantle. The isotopic ratios and the presence of positive Sr, K, Ba and Rb spikes on primitive mantle normalized plots of both the Auca Mahuida basalts and the early Miocene basalts indicate a mantle source containing old slab modified continental lithosphere. As similar positive spikes are absent on trace element patterns of north-central Patagonian ~48-32 Ma backarc basalts with more depleted isotopic signatures, major additions of slab-modified lithosphere and crust into the mantle source are conjectured to have occurred in the late Oligocene to early Miocene as the Andean margin adjusted to major changes in plate convergence parameters. Relatively higher Ba, Rb, Th, U and K concentrations and subtly lower La/Ta ratios in the Auca Mahuida basalts than in the early Miocene basalts are attributed to interaction of the local mantle source with slab-derived fluids or melts during the episode of late Miocene shallow subduction of the Nazca plate recorded in the near-by arc-like Chachahuén volcanic complex.

On the scale of the Auca Mahuida volcanic field, the relatively homogeneous trace element and isotopic chemistry of the basaltic lavas are consistent with their formation as melt batches of a similar mantle source. Calculated temperatures and pressures for the most primitive basalts are 1350° to 1380°C at 1.8 to 2.0 GPA, which correspond to depths of 65-74 km. These depths are consistent with independent estimates for the depth to the base of the lithosphere from xenolith and seismic studies in the same region by others. Calculated melting percentages from a moderately enriched mantle source for the most mafic basalts range from about 6% to 3%. The associated mugearitic, trachyandesitic and trachytic volcanic rocks can be modelled as being derived from fractionation of the basaltic magmas along with some mixing with evolved magmas, and possibly with partial melts of recently underplated magmas. The small range of Sr, Nd and Pb isotopic variation in the Auca Mahuida volcanic suite fits with little old crustal contamination of the magmas in the refractory crust left over from the major melting event that produced the Permo-Triassic Choiyoi granite-rhyolite province.

Examining the root exudate-induced cycling of reactive manganese species in the rhizosphere

MARCO KEILUWEIT[1,2]*, PETER NICO[3], JEREMY BOUGOURE[2], JENNIFER PETT-RIDGE[2], AND MARKUS KLEBER[1]

[1] Department of Crop and Soil Science, Oregon State Universtity, Corvallis, USA, marco.keiluweit@oregonstate.edu (* presenting author)

[3] Lawrence Berkeley National Laboratory, Earth Sciences Division, Berkeley, USA

Dynamics of reactive metals and soil organic matter (SOM) operating in the rhizosphere can be dramatically different from those occurring in the surrounding bulk soil due to the many interactions between roots, microorganisms, soil particles, and SOM. One of the main driving forces in changing the chemical, biological, and physical properties of the rhizosphere is the exudation of low molecular weight (LMW) organic compounds by the root. LMW exudates represent a significant C flux into soil ecosystems; compounds such as simple sugars, organic acids, and phenols have also been shown to facilitate cycling of redox active metals (e.g., Fe and Mn). This phenomenon is not only observed in aquic and poorly drained soils, but seems to be common in any upland soil with moisture regimes other than aridic or xeric.

In the research presented here we assumed that LMW exudates and microbial activity in the rhizosphere act together to create redox active microsites in soil. We further hypothesize that redox active microsites are short-lived and continuously recreated, thereby generating a steady supply of reactive manganese (Mn) species. This rhizosphere redox cycling may control the availability of reactive forms of Mn that have been mechanistically linked to the oxidative breakdown of complex organic substrates such as lignin.

We tested our hypothesis by examining the effect of different LMW exudates (oxalate, glucose, acetate, and vanillin) on the Mn dynamics of two different soil types in rhizosphere microcosms. Artificial roots allowed for the release of LMW exudates into structurally intact soil at realistic rates. Results from O_2 microsensor measurements as well as bulk and spectroscopic analyses show how root exudates vary in their ability to (i) induce reducing conditions, (ii) influence the activity of lignolytic enzymes, and (iii) affect the abundance and speciation of reactive Mn species in the rhizosphere.

Our results indicate that Mn redox cycling in the rhizosphere may be plant-driven. If confirmed for natural soil environments, the exudates-induced formation of reactive Mn species may have important implications for the turnover of complex biopolymers such as lignin in the rhizosphere.

Ongoing Formation of Continental Crust: Batholiths Are Forever

PETER B. KELEMEN[1*], BRADLEY R. HACKER[2], MARK D. BEHN[3] AND OLIVER E. JAGOUTZ[4]

[1]LDEO, Palisades NY, USA, peterk@LDEO.columbia.edu (*presenting author)

[4]MIT, Cambridge MA, USA, jagoutz@mit.edu

We propose that formation of continental crust is a uniformitarian process dominated by arc magmatism and gravitational instabilities that remove dense lithologies and/or add buoyant ones. Rates have varied, lithologies other than arc rocks are present in continental crust (CC), and weathering has modified the composition, but all of these factors are relatively unimportant.

Some arc lavas are geochemically identical to bulk CC. These include andesites and dacites with molar Mg# > 0.5 in the western Aleutian arc, that are the most isotopically depleted arc magmas worldwide. They contain little or no material recycled from older CC. Throughout the Aleutians, sparse data show that intermediate to felsic plutons also have compositions similar to CC. Thus, modern arc processes form voluminous juvenile igneous rocks identical to CC.

The Talkeetna and Kohistan arc crustal sections may have andesitic rather than basaltic bulk compositions. For Talkeetna, there is a gap in exposure from ~ 7 to 20 km paleodepth, so the bulk crustal composition is uncertain. When the missing section is assigned the composition of upper crustal, felsic plutonic rocks, bulk crust is andesitic and calculated seismic sections are similar to the modern IBM arc (Behn & Kelemen JGR 2006; Hacker et al. JGR 2008). For Kohistan, combined barometry and geochemistry yield a more certain, andesitic bulk crust (Jagoutz et al. EPSL 2011, Jagoutz & Schmidt Science 2012). Foundering of dense ultramafic rocks and garnet granulites may help convert basaltic to andesitic arc crust.

Talkeetna and Kohistan (and the central Aleutians, based on geologic and seismic data) have chemically stratified sections, with felsic rocks in the upper crust, mafic rocks in the lower crust, and ultramafic plutonic rocks directly overlying residual mantle peridotite. When such sections undergo subduction, during arc-arc or arc-continent collision, felsic upper crustal rocks with layer thickness more than ~ 100 m will rise as buoyant diapirs, either back up a subduction channel or through the mantle wedge, returning substantial masses of felsic material to overlying arc or continental crust (Behn et al., Nature Geoscience 2011; Hacker et al. EPSL 2011). Similar instabilities likely return andesitic trench sediments (greywacke) to the base of arc crust following subduction erosion.

Based on isotope data, felsic arc batholiths > 50% juvenile material (< 50% older, recycled CC). If such batholiths have been forming at the same average rate since the early Archean, and most of these remain in the crust via buoyancy instabilities as described above, the mass of juvenile felsic material formed in this way could be greater than or equal to the present mass of CC. So far, we have only calculated this approximately for North America. By the 2012 Goldschmidt, we will formalize and evaluate this hypothesis using data on batholiths from all of the continents.

Secular geochemical evolution linked to atmospheric oxidation

C. BRENHIN KELLER* AND BLAIR SCHOENE

Department of Geosciences, Princeton University, Princeton NJ, USA (*cbkeller@princeton.edu, bschoene@princeton.edu)

Secular geochemical evolution of the Earth's crust has typically been obscured by the geochemical heterogeneity of the rock record along with imperfect sampling[1]. In order to ameliorate this problem, we have taken a new approach: weighted bootstrap resampling Monte Carlo analysis of a ~70,000 sample igneous rock database. In addition to gradual trends in compatible and incompatible elements expected from secular cooling, the results reveal a period of dramatic geochemical change near the Archean/Proterozoic boundary. Temporal correlation of this event with stepwise atmospheric oxidation circa 2.4 Ga[2] may suggest a link between deep earth geochemical processes and the rise of atmospheric oxygen on Earth.

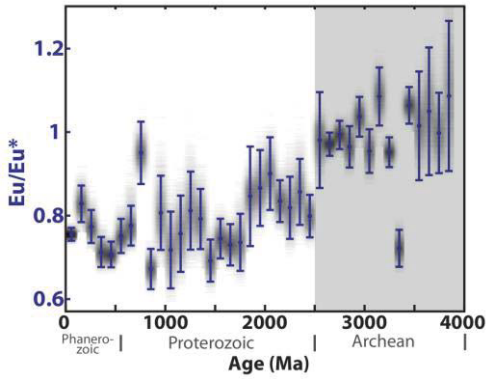

Figure 1: Monte Carlo analysis of mean europium anomaly in felsic (62-73% SiO_2) samples through time. Error bars: 2σ standard error.

Notable changes across the boundary include decreases in deep meltitng/fractionation indicators such as La/Yb and Eu/Eu* of felsic rocks (Figure 1), as well as decreases in mantle melt fraction in basalts. In the context of observed increases in preserved crustal thickness across the Archean-Proterozoic boundary[3,4], these data suggest a model where high degree Archean mantle melting produced a thick, mafic lower crust, leading to deep crustal delamination; delamination and associated lower crustal anatexis in turn resulted in abundant tonalite-tronhjemite-granodiorite (TTG) magmatism and a thin preserved Archean crust.

Since higher pressure restitic assemblages may contain substantial Fe^{3+}, we speculate that deep melting or deep fractionation in the Archean may have resulted in magmas with lower Fe^{3+}/Fe^{2+}, and consequently larger budgets of reduced volcanic volatiles. Cessation of abundant deep crustal melting at the end of the Archean may therefore have resulted in decreased reducing flux to the atmosphere, contributing to the atmospheric Great Oxidation event.

The role of pre-nucleation clusters in the crystallization of $CaCO_3$

MATTHIAS KELLERMEIER* & DENIS GEBAUER

Physical Chemistry, University of Konstanz, D-78457 Konstanz, Germany, matthias.kellermeier@uni-konstanz.de (* presenting author), denis.gebauer@uni-konstanz.de

Introduction

Recent studies have revealed that stable pre-nucleation clusters exist in both super- and undersaturated solutions of calcium carbonate prior to the formation of a solid phase [1]. Computer simulation data indicate that the thermodynamic stability of these species is based on strong hydration in combination with a distinct entropic contribution, resulting from the high degree of disorder inherent to their dynamic chain-like structure [2]. Nucleation of solid particles from this solute form appears to occur through aggregation of the clusters, rather than by the stochastic assembly of ions into metastable nuclei envisaged in classical theories [3,4]. However, direct insight into these processes has not yet been gained.

The phase initially precipitated from these pre-nucleation clusters was found to be amorphous calcium carbonate (ACC) exhibiting distinct short-range structural features, which resemble the long-range order in calcite or vaterite [5] and moreover seem to be already encoded in the clusters [1]. Transformation of ACC into more stable crystalline polymorphs usually takes place within minutes unless kinetic stabilization is provided, as for instance achieved by coating the nanoparticles with silica [6].

Results and Conclusions

In the present contribution, we outline the concept of non-classical nucleation via stable ion clusters and highlight experimental evidence supporting this scenario for the case of calcium carbonate as well as other important minerals. It is furthermore demonstrated that silica can be used as an additive slowing down or impeding the nucleation process due to colloidal shielding of the clusters [7]. In this manner, details of the transformation of ion clusters into ACC nanoparticles could be resolved experimentally. Results corroborate that nucleation of ACC relies on aggregation and coalescence of the clusters, yielding primary particles that exceed a certain critical size. In addition, our methodology facilitates preparation of solutions rich in pre-nucleation clusters, which – despite high supersaturation – do not nucleate even after periods of more than a year, as the classical ion-by-ion pathway is obviously not accessible under the given conditions. Colloidal stabilization with silica even allows for a direct isolation of these elusive species, which may be a key step for the analysis of their structure. Our findings are likely to be relevant for crystallization phenomena in various geological settings.

Modeling mantle mixing and the persistence of geochemical reservoirs

LOUISE H. KELLOGG[1*]

[1]Department of Geology, University of California, Davis, CA USA kellogg@ucdavis.edu (* presenting author)

Understanding the dynamics of mixing in the mantle is fundamental to understanding the origins of the isotopic heterogeneity observed in oceanic islands and at mid-ocean ridges. Heterogeneity is introduced into the mantle thoughout geologic time by processes associated with melting, alteration, and subduction. Heterogeneity is continously destroyed by convection, as the stretching and folding common to all kinematic mixing processes stirs the mantle. Thus it has long been a goal of computational geodynamics to understand the factors controlling the rate and efficacy of mantle mixing. The time and spatial scales of mixing are influenced by the kinematics of flow, plate motion, viscosity variations, compositional heterogeneity, and phase transitions. Chaotic mixing is observed in time-varying 2-D flows; by contrast, the factors controlling mixing in 3-D remain somewhat poorly understood. We investigate a series of methods for computing and evaluating mixing in 3-D, and compare their utility for assessing mantle mixing and the interpretation of mantle heterogeneity. We explore a suite of models of convection in a layer and in a spherical shell. Passive tracer particles are introduced into time-varying and steady-state models of mantle flow; the particles are tracked over time as they disperse and deform, allowing the use of quantitative measures of mixing. Mixing can be assessed by calculating a Lyapunov exponent (which characterizes the separation of tracers that are initially close to each other), or by treating the tracers as ellipsoidal strain markers and computing their deformation, or by determining the configurational entropy of the sytem of tracers. Stirring may be rapid on a regional scale, while heterogeneities at the global scale are retained because of isolation across long-wavelength cells. Essentially, the regions that exhibit high rates of stretching and thinning have the most important influence on mixing, and packets of material that are stirred rapidly in regions of high strain rate are carried wholesale into regions of more sluggish convection.

Geochemical perspectives on local versus global ocean redox at 1.64 Ga

AMY E. KELLY[1,2,3*], TIMOTHY W. LYONS[2], ERIC B. ALSOP[3], GORDON D. LOVE[2], NOAH J. PLANAVSKY[2], BRIAN KENDALL[3], AND ARIEL D. ANBAR[3]

The chemistry and redox structure of the ancient ocean played a key role in influencing the evolution of life throughout Earth's history. Surface waters in the mid-Proterozoic ocean (~1.8-1.0 billion years old [Ga]) were oxygenated, but a number of lines of evidence point toward anoxic, iron-rich (ferruginous) and sulfide-rich (euxinic) deeper waters. Geochemical data indicate that euxinia was confined to ocean margins and restricted basins. Nevertheless, these euxinic waters may have impeded diversification of eukaryotic life.

We studied a suite of thermally well-preserved black shales from drill core of the 1.64 Ga Barney Creek Formation using detailed biomarker, sulfur isotope, iron speciation, and trace metal redox proxies. High abundances of Type 1 microaerophilic methanotrophic bacteria, as evidenced by elevated 3β-methylhopane indices suggest low marine sulfate concentrations, an inference corroborated by highly variable, heavy pyrite sulfur isotopic values, and likely reflects globally low values exacerbated by local restriction of the Glyde Sub-basin. Iron speciation and organic biomarker data provide evidence for extensive and persistent euxinic waters within the sub-basin.

Despite the presence of oxic surface waters and euxinic deep waters in the sub-basin, the predicted light iron isotope signature of an iron shuttle, like that in the Black Sea, is not observed. Typically, with the shuttle, isotopically light iron from oxic sediments on the shelf is transported to and trapped in sediments of the deep euxinic basin via pyrite formation in the water column. In contrast, our iron isotope values are positive, so the source had to have been isotopically heavy. There are several possible interpretations for this observation. We are intrigued by the possibility that the source of heavy iron was precipitated iron oxide from the redoxcline in a ferruginous ocean, which converted to Fe^{2+} and then to pyrite in a sulfidic local environment, which suggests a relatively high iron ocean with strong redox stratification. It is also possible that the positive values are linked to both removal of isotopically light sulfides in a moderately Fe-rich system and transport of heavy dissolved iron, since sulfide formation may have a positive kinetic isotope fractionation. Both hypotheses necessitate a fundamentally different iron cycle compared to that found in Phanerozoic/modern restricted basins.

Our integrated results point to a sub-basin with oxic surface waters and euxinic deep-waters. This restricted basin was likely connected to an ocean with oxic surface waters, ferruginous deep-waters, and limited expanses of euxinic conditions along productive margins, as well as within other restricted basins. Nevertheless, euxinia in the mid-Proterozoic ocean was likely orders of magnitude more widespread than it is today, and the deleterious impacts on nutrient availability could have been enough to throttle the early evolution and expansion of eukaryotic organisms.

Detrital zircon: a foggy window into early Earth evolution

JEFFREY VERVOORT[1], ANTHONY KEMP[2*] AND MARTIN WHITEHOUSE[3]

[1]Washington State University, Pullman, USA, vervoort@wsu.edu
[2]The University of Western Australia, Perth, Australia, tony.kemp@uwa.edu.au (* presenting author)
[3]Swedish Museum of Natural History, Stockholm, Sweden, martin.whitehouse@nrm.se

A basic tenet of terrestrial geochemistry is that the continental crust has been extracted from the mantle leaving the latter depleted in incompatible elements. Nd and Hf isotopes have long shown that this process has been an essential feature of the Earth throughout its history, yet the details of the isotopic record—and the implications for the timing and rates of mantle depletion and continental crust extraction—remain debated. Recently, much attention has been given to detrital zircons in both modern and ancient sediments. Integration of the crystallization history of the zircon from the U-Pb chronometer with its Hf isotopic composition can reveal whether the zircon derived from juvenile or reworked crust. This approach critically requires that the crystallization age of the zircons can be unambiguously determined. We suggest that this represents an important—but generally overlooked—limitation in the Hf isotope record from detrital zircons.

The quality filter most often used to assess the integrity of zircon U-Pb systematics is concordance; if a zircon is concordant, it is assumed that the U-Pb age is accurate. A concordance filter is less effective in old zircons because ancient Pb loss, viewed today, parallels concordia. Ancient Pb loss in zircons produces an apparent age less than the true magmatic age, and so the initial Hf isotopic composition will be anomalously low (by ~2.2 epsilon Hf units per 0.1 Ga). Hf model ages, calculated from these parameters, will be artificially old and spurious. The combination of unradiogenic Hf and Hf model ages > U-Pb ages in the zircon record are often given as prima facie evidence of crustal reworking and recycling during Earth's early history, and underpin models for large volumes of ancient continental crust. For many old zircons these features may simply reflect unrecognized ancient Pb loss.

A more robust picture of the isotopic evolution of the Earth can be gained from an integrated approach of Hf and Nd isotopes in well age-constrained magmatic samples: careful U-Pb zircon geochronology; Hf isotopic composition of the zircons; and Hf and Nd isotopic measurements of the whole-rocks. We also highlight strategies for minimising complexities from ancient Pb loss, with respect to Hadean detrital zircons from the Jack Hills and zircons from multiply metamorphosed Archean TTG gneisses of Greenland and Scotland. In these cases, oxygen isotopes, time-resolved Pb/U isotope profiles, trace elements and microstructures provide additional quality filters. An important part of this approach is the realization that not all rock samples (or zircons!) yield useful, unambiguous results. Inclusion of all Hf isotope data from large zircon databases, unscrutinized for quality and lacking in context, will do more to obscure the isotopic evolution of the first billion years of Earth history than to clarify it.

The Hf-Nd isotope barcode of crust formation in the Archean Earth

ANTHONY KEMP[1*], JEFFREY VERVOORT[2], MARTIN WHITEHOUSE[3], ARTHUR HICKMAN[4], MARTIN VAN KRANENDONK[5] AND TOMAS NAERAA[6]

Information from long-lived radiogenic isotope tracers has long been used to argue for the extraction of at least 50% of the Earth's continental crust before the end of the Archean [1]. This implies high, but largely cryptic rates of ancient silicate Earth differentiation not matched by preserved crustal materials of these ages. The geodynamic environment for the generation of these putative early continents remains enigmatic, and this affects models for mantle and atmospheric evolution. Plume-driven crustal growth accords with a hotter early Earth and with inferred episodicity in crust formation, but is difficult to test in the absence of diagnostic chemical signatures. Other studies invoke convergent plate margin processes by 3.8 Ga or earlier – yet, given evidence that crust generation and crust destruction rates are balanced at modern subduction zones, rapid crustal growth at ancient arcs would require a fundamentally different subduction regime to that of the present day. Impediments to understanding early Earth geodynamics include the fragmentary Archean geological record, preservation and sampling bias and overprinting by younger thermal events. It is also increasingly recognised that the isotope testimony of a key mineralogical witness to early Earth processes, zircon, is not always robust.

We examine the constraints on the timing and composition of crust formation from the Hadean to the end of the Archean Eon, focussing on the Hf-Nd isotope record. This information is compared to isotope-time patterns produced by igneous rocks of subduction-related Phanerozoic orogens. The simple Hf isotope-time array defined by the Hadean Jack Hills zircons is not consistent with arc magmatism in its modern guise, but suggests repeated remelting of a basaltic protocrust extracted from primitive mantle at ~4.5 Ga, perhaps during magma ocean solidification [2]. Felsic rocks of the oldest continental nuclei in Greenland (3.85-3.82 Ga) and the Pilbara Craton (3.65-3.42 Ga) appear to have tapped an undifferentiated, near-chondritic mantle source, possibly of deep-seated origin. Both cratons record distinct switches in Hf-Nd isotope signatures after 3.1 Ga that reflect changes in magma sources and enhanced recycling of crust into the mantle. The resulting temporal Hf-Nd isotope trends resemble those produced by plate tectonic processes involving arc accretion and ocean closure, and suggest a transition from a deep to a shallow mantle source of new continental crust after 3.1 Ga.

A new view of Proterozoic ocean chemistry is emerging from sedimentary Fe speciation and Mo abundance and isotope data from black shales. Fe speciation has revealed examples of anoxic/sulfidic (euxinic) mid-depth waters that were underlain by anoxic/ferruginous (Fe^{2+}-rich) deep waters. Mo data indicate a moderate-sized oceanic Mo inventory, consistent with pervasive oxidative weathering but a pronounced Mo sink into euxinic sediments. However, Fe speciation is strictly a local redox proxy. Furthermore, the high efficiency of Mo burial in sulfidic environments relative to oxygenated and ferruginous settings renders the oceanic Mo inventory sensitive to small changes in the extent of water column euxinia.

To test the hypothesis of ferruginous Proterozoic deep oceans we turned to Re abundances in black shales. Like Mo, Re is oxidatively mobilized from the upper crust and accumulates in oxygenated seawater. Re and Mo have long oceanic residence times (~10^5 years today) that enable their use as global redox proxies. Both metals are removed in sulfidic marine settings. In contrast, Re burial rates in O_2-deficient sediments beneath low-O_2/ferruginous and mildly oxygenated bottom waters are high and low, respectively, whereas Mo burial rates in these settings are low and negligible, respectively.

We found that Re abundances in most Paleoproterozoic and Mesoproterozoic shales are similar to those in Late Archean shales. Re (up to 50 ppb) is enriched relative to upper crust (~1 ppb), indicating that dissolved Re was supplied to the oceans via oxidative weathering. However, the low Re abundances in Proterozoic shales point to widespread low-O_2/ferruginous conditions that maintained a low oceanic Re inventory. Higher Mo (but not Re) abundances in Proterozoic relative to Late Archean shales is consistent with increased oxidative weathering, limited extent of sulfidic conditions, and low Mo burial rates beneath ferruginous deep waters. Re is a global redox proxy, so our data confirm the widespread ferruginous Proterozoic deep oceans inferred from local Fe speciation data.

Exceptions to the Late Archean-to-Mesoproterozoic baseline are found in black shales deposited during the Paleoproterozoic Lomagundi positive carbon isotope excursion (the later stage of the Great Oxidation Event) and the late Mesoproterozoic. Re abundances in these shales reach 200 ppb, similar to the lower end of the range observed in Ediacaran and Phanerozoic shales, and hence suggests a greater extent of ocean oxygenation at these times.

Microbial hydrogen sulfide generation within Syncrude composite tailings

KATHRYN KENDRA[1*], KATE STEPHENSON[1], TARA COLENBRANDER NELSON[1], RODERICK AMORES[1], STEVEN HOLLAND[1], TARA PENNER[2] AND LESLEY WARREN[1]

[1]School of Geography and Earth Sciences, McMaster University, Hamilton, Canada, kendrake@mcmaster.ca (*corresponding author)
[2]Syncrude Environmental Research, Edmonton, Canada, penner.tara@syncrude.com

Surface mining of Alberta's Oil Sands has led to significant land disturbance, making reclamation one of the largest challenges facing the industry today. With increased production from Alberta's Oil Sands, sustainable development of this resource has emerged as a substantial environmental issue facing Canadians. Syncrude Canada Ltd. has developed an innovative technique to reclaim composite tailings (CT) through constructed wetland landscapes and is currently investigating the viability of a pilot-scale freshwater fen built over sandcapped CT. Episodes of hydrogen sulfide (H_2S) gas release have been encountered during the initial stages of fen construction; these occurrences were not predicted by abiotic geochemical models, thus highlighting the likely importance of microbial metabolic activity in controlling H_2S generation. Previous research in our group has demonstrated the occurrence of H_2S within CT and sandcap porewaters. The interfacial surficial sandcap between the CT and fen has revealed a widespread presence of diverse microbial communities capable of Fe and S metabolisms, suggesting that microbial Fe and S activity within the deeper CT itself is likely. However, to date, no systematic study of CT Fe and S biogeochemistry has occurred. The objectives of this study are to: (1) characterize the mineralogy, microbial Fe and S metabolisms and biologically accessible Fe and S pools with depth in the CT (over 40m) and; (2) constrain microbial and geochemical variables affecting H_2S generation throughout laboratory experimentation. Microcosm experiments are being conducted in an effort to monitor H_2S generation in CT collected from 2 different depths under varying microbial Fe and S metabolic influence. Preliminary results of these experiments will be presented in conjunction with the field based mineralogical, geochemical and microbial CT characterization to identify the constraining variables of the system.

Introduction

Seismogenic faulting and rapid slip (>0.1 m/s) of rock may result in non-equilibrium frictional melting [1] at temperatures >1000 °C after few centimetres of slip [2]. Upon cooling (and recrystallization) this melt forms a pseudotachylyte [3].

In active volcanoes, the transition from endogenous to exogenous growth is generally attributed to a shift in magma rheology into the brittle regime. The ascent of this high-viscosity magma can form discrete shear zones via strain localisation along conduit margins [4]. Although comparable to tectonic faults, little information regarding the slip processes and generation of fault products in such shear zones are known. Pseudotachylytes have, until now, rarely been noted in volcanic materials [5, 6], and seldom in active volcanic environments [4, 7] despite laboratory experiments which support magma's propensity for frictional melting [8].

Here, we combine field evidence and experimental data to demonstrate that pseudotachylyte ought to be a common product of volcanic activity due to simultaneously high ambient temperatures and differential stresses, and propose a hypothesis for this conspicuous absence of pseudotachylytes in the volcanic record.

Results and Conclusion

Experimental results demonstrate that higher slip rate and/or axial load increases the rate of heat production by friction. At volcanoes, repeated slip events at a high ambient temperature during the ascent of a magma may thus promote melting (as well as subsequent cooling) in (near-)equilibrium, hence eradicating some of the key pseudotachylyte characteristics, including heterogeneous melt filaments formed by selective melting of crystals [9]. Our studies suggest that the indentification of volcanic pseudotachylytes relies upon combined investigations of structural characteristics, magnetic properties (Curie temperature, remanence, susceptibility and domain state) and calorimetric glass transition, which can identify different P-T equilibrium conditions between the wallrock and pseudotachylyte.

Extremely high iodine and noble gas abundances in forearc serpentinites

MARK A KENDRICK[1*], MASAHIKO HONDA[2], THOMAS PETTKE[3], DAVID PHILLIPS[1]

[1]School of Earth Sciences, University of Melbourne, Victoria, Australia. (*mark.kendrick@unimelb.edu.au)
[2]Research School Earth Sciences, Australian National University, Canberra, Australia.
[3]Institute of Geological Sciences, University of Bern, CH-3012 Bern, Switzerland.

Combined Cl, Br, I and noble gas analyses have been undertaken on 16 'seafloor serpentites' obtianed from IODP drill cores (Atlantic and Hess Deep MOR; Marianas and Guatemala forearcs; Iberian and Newfoundland passive margins; see [1]). The serpentinite halogen data overlap those of sedimentary marine pore fluids, with forearc serpentinites being most enriched in iodine (Fig 1). The maximum iodine concentration of ~50 ppm, is similar to the iodine content of organic-rich marine sediment.

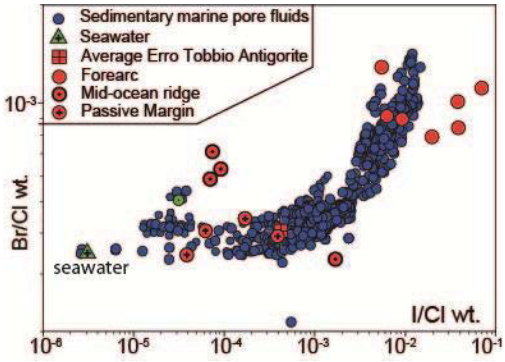

Figure 1: Br/Cl versus I/Cl three element plot showing the compositional range of sedimentary marine pore fluids (refs in ref [3]) and seafloor serpentinites.

The chrysotile-lizardite serpentinites all have atmospheric He, Ne, Ar, Kr and Xe isotope signatures. The maximum noble gas abundances of ~2×10^{-11} mol ^{36}Ar g^{-1} exceed those of antigorite serpentinites, by an order of magnitude[2]. Noble gas abundances are not simply correlated with serpentinites halogen signatures. However, the serpentinites preserving Br/Cl and I/Cl closest to the pore fluid trend have the highest ^{36}Ar concentrations. The data suggest that serpentinisation takes place at variable water-rock ratios. Serpentinites formed at low W/R, with pore fluids 'consumed' during serpentinisation, preserve halogen signatures close to the marine pore fluid trend, and the highest noble gas abundances. Serpentinites formed at higher W/R, do not preserve the halogen signature of the marine pore fluid, and trap an order of magnitude less noble gas.

The combined halogen and noble gas data show that the conditions of serpentinisation, as well as the involvement of sedimentary marine pore fluids in near subduction zone settings, exert critical controls on subduction zone volatile budgets.

Soil CO_2 as a proxy for heat and mass flow

A significant challenge to geothermal exploration is accurate quantification of the heat and mass flow between deep reservoir(s) and the surface. Here, we use high resolution measurement (10's of m's) of carbon dioxide (CO_2) flux and heat flow at the land surface to characterise the mass (CO_2 and steam) and heat released from the geothermal reservoir. Statistical and isotopic characterisation of atmospheric, biogenic and hydrothermally sourced CO_2 reduces the level of uncertainty when deriving mass (emissions) and heat flow estimates from high temperature reservoirs. Our results include soil CO_2 flux, soil $\delta^{13}C$, and soil temperature (0.1m depth) measurements at the surface of Rotokawa geothermal field (2.5km^2), in the Taupo Volcanic Zone, New Zealand. Data is modelled and interpolated to predict total CO_2 emissions which are used in conjunction with historic fumarolic discharges to calculate reservoir mass and heat flow. Soil temperature measurements are converted to heat flow units and summed to produce a surface heat flow value.

Initial results indicate a total CO_2 emission rate of 633 ± 16td^{-1} which includes 22td^{-1} from biogenic and atmospheric sources. The $\delta^{13}C$ range (-16 and -8‰) is plotted as an isoscape (i.e. isotope value contours) and illustrates spatial variance in magmatic, biogenic and atmospheric CO_2 contribution. The reservoir's steam mass flow of 10,150td^{-1} is calculated from the total hydrothermal CO_2 emission (611 ± 16td^{-1}) multiplied by the H_2O:CO_2 molar weight ratio (16.6) characterised for major fumaroles. The equivalent thermal energy of the mass flow of the reservoir is 317 ± 8MW, while the observed surface heat flow through soil is equivalent to 73 ± 5MW. The discrepancy in these two heat flow values is attributed to water vapour condensing (scrubbed) within cool (<160ºC) meteoric groundwaters that overly the high temperature reservoir prior to reaching the surface. In contrast, CO_2 is more conservative and therefore less susceptible to scrubbing by meteoric groundwaters making it a better proxy for heat and mass release from the deep reservoir.

By spatially mapping and comparing the soil flux, temperatures, and $\delta^{13}C$, there is more control over the soil permeability/soil gas flux (magnitude) relationship. The connectivity from the deep source through to the shallow subsurface through structural (fault/fracture) control of fluid flow pathways can be constrained with more certainty by identifying the CO_2 source.

This study concludes that the combination of CO_2 flux and $\delta^{13}C$ can successfully quantify heat flow and predict connectivity to deeper heat sources as well as illustrate shallow spatial variation in permeability.

The effect of extracellular polysaccharides on the mobility of phosphates bound to iron oxides

JANICE P.L. KENNEY [1*] AND PER PERSSON[1]

[1]Department of Chemistry, Umeå University, Umeå, Sweden,
(* presenting author: janice.kenney@chem.umu.se)

Introduction

The biogeochemical cycle of P is unique due to its strong tendency to adsorb to environmental particles, such as iron oxides, resulting in the formation of sparingly soluble solid phases. Furthermore, phosphorus does not form volatile compounds in the environment; hence the biogeochemical cycle of phosphorus occurs exclusively in the biosphere. Thus, due to the high stability of phosphates, key processes for biomass production are the transfer of phosphorus from adsorbed, solid, or organically bonded states into bioavailable forms, and these processes occur primarily at primarily at solution interfaces with minerals, microbes, or organic ligands.

The types of environmental perturbations that may result in the release of phosphates from iron oxide surfaces are not well understood. For example, many microorganisms and plants can release extracellular polysaccharides (EPS) into their local environments. EPS is known to adsorb to environmental particles, including iron oxides, and therefore the adsorption of EPS may out-compete the adsorbed phosphate, or even preferentially bind the oxyanion. It was previously thought that organics that form inner sphere complexes with the iron oxides would be able to out-compete the phosphates and remobilize them into solution. However, Lindegren et al. [1] found that strong, multiple H-bond donors and acceptors, in lieu of inner sphere species, out-compete phosphate. Therefore, EPS may be expected to have an effect on phosphate mobility in the subsurface. Currently, there is little information available regarding the ability of EPS to remobilize essential nutrients, such as phosphate, into the environment.

Experimental

In this study we investigated the remobilization of both inorganic and organophosphate following their adsorption to iron oxides. The inorganic phosphate used was orthophosphate and the organophosphate was the phosphate monoester, glucose phosphate. We examined qualitatively and quantitatively the effect of alginate, which was used as a model for EPS, on the remobilization mechanisms and competition reactions of pre-adsorbed phosphates. This was accomplished by a combination of in-situ infrared spectroscopy and wet-chemical experiments. Data were collected as a function of phosphate and alginate concentrations, pH, and time, and the collective results from these experiments will be presented and the co-adsorption and competitive mechanisms will be discussed. These results are important as they provide constraints on the mobility and, thereby, bioavailability of phosphate in the environment.

Modeling the impact of variable pH and dissolved salt concentrations on metal ion transport observed in field experiments

DOUGLAS B. KENT[1*], MATTHIAS KOHLER[2], GARY P. CURTIS[3], GILLIAN M. FAIRCHILD[4], AND DENIS R. LEBLANC[5]

[1]U. S. Geological Survey, Menlo Park CA, USA, dkbent@usgs.gov (*presenting author)
[2] U. S. Geological Survey, Menlo Park CA, mkohler@usgs.gov
[3] U. S. Geological Survey, Menlo Park CA, gpcurtis@usgs.gov
[4] U. S. Geological Survey, Northborough MA, gfairchi@usgs.gov
[5] U. S. Geological Survey, Northborough MA, dleblanc@usgs.gov

Field experiments show that the mobility of the divalent metal ions Ni, Zn, and Pb in a mildly acidic aquifer varies with both pH and dissolved salt concentrations. Field experiments were conducted by injecting groundwater with added Ni, Zn, and Pb at 2 or 20 μM into a shallow aquifer on Cape Cod, Massachusetts, USA. The mineralogy of the sediments is dominated by quartz but the sorption properties are controlled by well-ordered, nanometer-size Al-substituted goethite and micrometer-size clay minerals like chlorite and illite in mineral-grain coatings [1]. Uncontaminated groundwater had approximately 90 μM Na, 8 μM K, 20 μM Mg, and 9 μM Ca. Concentrations in a wastewater-contaminated zone of the aquifer were 10-20 times higher. Much more extensive retardation of Ni and Zn were observed in the uncontaminated zone at pH 6 over a one-meter transport distance than in the wastewater-contaminated zone. Much less extensive retardation of Zn and minimal retardation of Ni was observed in the uncontaminated zone at pH 5 than at pH 6. Concentrations of Pb remained above background in the injection ports for several months under all sets of conditions. Lead still had not been detected one meter downgradient one year after the injection but was readily mobilized by EDTA.

Models for metal ion sorption were calibrated by using laboratory experiments conducted with site-specific aquifer sediments over the relevant range of chemical conditions. Sorption of all three metal ions increased with increasing pH (4.8-6.3). Sorption decreased with increasing dissolved salt concentrations, but the impact on Pb sorption was much less extensive than for Ni and Zn. Sorption of Na, K, Mg, and Ca also increased with increasing pH. Sorption could be described quantitatively by using a set of cation exchange and surface complexation reactions: M^{n+} + $nHY = MY_n + nH^+$ and $Me^{2+} + >SOH = >SOMe^+ + H^+$, where M = Na, K, Mg, Ca, Ni, Zn, or Pb; Me = Ni, Zn, or Pb; and HY and >SOH represent generic surface sites.

Reactive transport simulations incorporating the laboratory-calibrated sorption models capture the principal trends in the field experimental data. Mobility of Ni is controlled by ion-exchange-type reactions, mobility of Pb by surface-complexation-type reactions, and mobility of Zn by both types of reactions. Results show that simple model structures like this can account for the impact of pH and dissolved salt concentrations on metal ion mobility.

Changes in North Atlantic deepwater circulation during the past 4 Myr

NABIL KHÉLIFI[1*], MARTIN FRANK[1], AND DIRK NÜRNBERG[1]

[1]Helmholtz Centre for Ocean Research (GEOMAR), Kiel, Germany, nkhelifi@geomar.de (* presenting author)

Abstract

Changes in northern North Atlantic deep water circulation during the past 4 million years (Ma) were studied at a suite of five IODP/ODP sites at water depths from 2400 to about 5000 m. Benthic $\delta^{13}C$ records at these sites oscillate in parallel around values lower than today by ~0.2 ‰ during interglacials and by ~0.7 ‰ during pronounced glacials of the late Pliocene warm period. However, Pliocene Mg/Ca-based deep-water temperatures were 2 to 3 °C higher than today during interglacials and near modern levels during glacial periods. The coeval changes in ventilation at a lower level than today may indicate a weaker difference between these warm water masses than today, which is probably caused by water mixing in the northern North Atlantic. This is corroborated by ε_{Nd} bottom seawater values near -9 to -10 at all sites, which differs markedly from the modern situation characterized by clear differences in ε_{Nd} signatures between the water masses at these sites. Accordingly, the lesser ventilated, warm, and mixed water masses are most likely the result of the weaker overturning in the northern North Atlantic during that time of global warmth [1].

After 1.6 Ma, benthic $\delta^{13}C$ records show a gradually improving ventilation, with pronounced glacial/interglacial oscillations, which came close to the modern-to-late-Pleistocene levels. This ventilation change in deep water masses was coeval with a clear divergence in ε_{Nd} of bottom water masses between the different sites towards modern signatures. This is apparently linked to a significant change in the sources of circulating deep waters in northern North Atlantic. Accordingly, the first reorganization of the deep circulation in northern North Atlantic towards the modern situation appears to have started only after ~1.6 Ma, most likely as a response to increases in the amplitude of the Earth's obliquity cycle during that time [2].

$U_K^{37'}$ in eastern tropical Pacific surface sediments: Implications for alkenone paleothermometry at the 'warm end'

M. KIENAST[1*], G. MACINTYRE[1], N. DUBOIS[1,2], S. HIGGINSON[1], S.S. KIENAST[1], AND T.D. HERBERT[3]

[3]Brown University, Dept. of Geological Sciences, Providence, Rhode Island, USA

Introduction

The eastern equatorial Pacific (EEP) is arguably the oceanic region where reconstructions of past sea surface temperature (SST) variability based on different proxies disagree most significantly. For instance, foraminiferal Mg/Ca and alkenone paleothermometry-based SST estimates disagree on the timing and pattern of the glacial-interglacial warming, and the inferred amplitude of the glacial cooling, in particular in the cold tongue off Peru, ranges from 2 to 8 °C depending on the proxy used.

Results and Conclusion

Here we present the first regional calibration of alkenone unsaturation in surface sediments versus World Ocean Atlas (WOA) 09 mean annual sea surface temperatures (maSST). Based on 81 new and 48 previously published data points, it is shown that open ocean samples conform to established global regressions of $U_K^{37'}$ versus maSST and that there is no systematic bias from seasonality in the production or export of alkenones, or from surface ocean nutrient concentrations or salinity. The flattening of the regression at the highest maSSTs is found to be statistically insignificant. For the near-coastal Peru upwelling zone between 11-15 °S and 76-79 °W, however, we corroborate earlier observations that $U_K^{37'}$ SST estimates significantly over-estimate maSSTs at many sites. We posit that this is caused either by uncertainties in the determination of maSSTs in this highly dynamic environment, i.e. by substantial small-scale SST variability not captured by WOA, or by biasing of the alkenone paleothermometer toward El Niño events as postulated by Rein et al. [1].

Introduction

Saline groundwaters with distinct water stable isotope composition above the Global Meteoric Water Line (GMWL) are common in continental shields all over the world [1]. Microbial life thrives in these extreme environments. The 2516 m deep Outokumpu Deep Drill Hole, located in eastern Finland, is an uncased hole hosted by Palaeoproterozoic turbiditic metasediments, ophiolite-derived altered ultramafic rocks and pegmatitic granitoids, and provides a direct access to gas rich formation waters, where diverse microbial communities have been found [2]. Isotopic composition of water and dissolved strontium as well as geochemistry has been used to characterise the drill hole water profile in order to trace water origin and evolutionary time scales [3]. Along with microbiological studies this helps to reveal the extent of isolation of sub-surface ecosystems.

Results and conclusions

Water stable isotope composition of the Outokumpu Deep Drill Hole water is typical for shield brines, and clearly different from shallow fresh groundwater in the area. High salinity up to 70 g l^{-1} of total dissolved solids and high $^{87}Sr/^{86}Sr$ ratio also indicate strong water-rock interaction. Five isotopically and geochemically distinct water types occur along the 2.5 km drill hole section. Two-component mixing between the ^{18}O and ^{2}H enriched saline water and lighter meteoric water can not explain the isotopic composition and trends observed. Instead, ancient meteoric waters recharged at different, warmer than present climatic conditions and subsequent evolution of groundwater by hydration of silicates is the most likely cause for the observed variation. In the plate tectonic and palaeoclimatic framework, residence times in the order of tens of millions of years are suggested. However, the time which these waters have been isolated from surficial waters and from each other may differ substantially between the water types. Changes in bacterial communities with depth correlate with the different water types indicating the occurrence of separate ecosystems at different depths.

Reassessment of the dispersion of uranium originating from nuclear test explosions across East Asia through the atmosphere

YOSHIKAZU KIKAWADA[1*], YUSUKE MATSUMOTO[1], TAKAO OI[1], MASAO NOMURA[2] AND KATSUMI HIROSE[1]

[1]Sophia University, Materials and Life Sciences, Tokyo, Japan, y-kikawa@sophia.ac.jp (* presenting author), t-ooi@sophia.ac.jp, hirose45037@mail2.accsnet.ne.jp

[2]Tokyo Institute of Technology, Research Laboratory for Nuclear Reactors, Tokyo, Japan, mnomura@nr.titech.ac.jp

Background and Methodology

We have already reported that some Japanese atmospheric deposits have been contaminated with the uranium whose isotope ratio ($^{235}U/^{238}U$) had been fractionated from the natural ratio [1, 2]. For example, the uranium with a high $^{235}U/^{238}U$ ratio relative to the natural ratio (enriched uranium) has continuously been transported to the western side of the Japanese Islands since the 1960s until today. This suggests that the debris of nuclear test explosions conducted in Asia before the 1980s have continuously drifted east through the atmosphere. These debris must have been transported to the east end of Asia not only directly but also through several resuspension processes from their hypocenter region. However, the actual source region and transportation processes of such nuclear debris have never been identified clearly. In this context, we preliminarily measured the uranium isotope ratios of the dry deposits from Asian mineral dust events at Nagasaki, Japan and of surface soils across East Asia to clarify the mechanisms for the transportation of nuclear debris. The dry deposits from dust events had been collected at Nagasaki, which is located at western Japan near the Korean Peninsula, in March 2001, just at the time of a huge Asian mineral dust (Kosa, yellow-sand) event.

Results and Remarks

The $^{235}U/^{238}U$ ratios in the dry deposits samples from Nagasaki are obviously higher than the natural ratio (maximally *ca.* +20‰). Contrastively, no obvious fractionation in the uranium isotope ratio is found for the surface soils in the East Asian region served to this study, although they tend to have slightly higher $^{235}U/^{238}U$ ratio than the natural one. Our results undoubtedly reveal that Asian mineral dust has been transported with nuclear debris which contains enriched uranium. The contribution of secondary processes like repeated resuspension of contaminated surface soils, which had been overlaid with nuclear debris through fallout processes, to the anomalous uranium isotope ratios found in Japanese atmospheric deposits may not be so substantial.

Decrease of Arsenate Adsorption onto Bacteriogenic Iron Oxies by the Presence of Organic Materials

S. KIKUCHI [1*] AND Y. TAKAHASHI[1]

[1]Graduate School of Science, Hiroshima University, Hiroshima 739-8526
([*]correspondence: m103384@hiroshima-u.ac.jp)

The adsorption behaviour of trace elements onto iron (Fe) oxides has been well demonstrated for their importance in water chemistry. Especially, bacterial-induced iron oxides (Bacteriogenic iron oxides: BIOS) are of common interest because of their ubiquity and characteristics of adsorption of various ions. In this study, arsenate adsorption behaviour onto (A) synthetic ferrihydrite, (B) natural BIOS collected from Okinawa hydrothermal vent, (C) synthetic BIOS obtained by incubation of iron-oxidizing bacterium (*Mariprofundus ferroxydans*) were compared. BIOS synthesis was performed using a set of diffusion cells by which can obtain pure BIOS free from other inorganic and organic materials which are abundant in natural BIOS (e.g., silica, clay mineral, and other ions adsorbed onto BIOS). Adsorption experiments were performed under sea water condition (I: 0.7 M; initial arsenate concentration: 70 mg/L; adsorbent: approx. 0.5 mg) as a function of pH 4-10. Iron mineral species of iron oxides were specified by Fe K-edge X-ray adsorption fine structure (XAFS) [1] and adsorption structure of arsenate was examined by As K-edge XAFS analysis.

Iron K-edge XAFS analysis revealed that both natural and synthetic BIOS consisted mainly of ferrihydrite with 45-55 % of highly amorphous Fe hydroxides that is characterized by the primitive Fe hydrothesis stages. The crystal size was nano-scale which was smaller than the synthetic ferrihydrite. Thus, It was expected that BIOS sholud have more arsenate adsorption capacity than synthetic ferrihydrite. However, the amount of arsenate adsorbed onto each iron oxides decreased in the order of synthetic ferrihydrite > natural BIOS = synthetic BIOS with a same adsorption trend as a function of pH. XAFS and μ-XRF analysis indicated that arsenate was mainly adsorbed onto Fe phase within natural and synthetic BIOS forming inner-sphere complexatation to the Fe oxides. These results were consistent with previous results on arsenate adsorbed onto synthetic ferrihydrite. Contrary to their reduced crystal particle size, specific surface areas of synthetic BIOS was decreased by 25% from synthetic ferrihydrite, which is possibly caused by the coprecipitation of Fe oxides with organic materials [2]. Thus, it is suggested that strong aggregation of Fe particles by the presence of orgainic material reduces (i) the surface area and/or (ii) the active adsorption site within BIOS, which ultimately result in the decrease of the arsenate adsotion onto BIOS. These results also suggests that direct and indirect effects of organic material sholuld be taken into account to evaluate the anion adsorption onto BIOS.

Magmatic processes at Mt. Ruapehu, New Zealand: melt-mush interactions determined from melt inclusions

GEOFF KILGOUR[1,2*], JON BLUNDY[2], KATHY CASHMAN[2,3], HEIDY MADER[2]

[1]Wairakei Research Centre, GNS Science, Taupo, New Zealand g.kilgour@bristol.ac.uk (* presenting author)
[2]School of Earth Sciences, University of Bristol, Bristol, UK
[3]Dept. of Geological Sciences, University of Oregon, USA

Mt. Ruapehu is an andesitic cone volcano situated at the southern end of the Taupo Volcanic Zone. Historical activity has consisted of frequent small phreatic and phreatomagmatic eruptions through Crater Lake - a warm, acidic lake. Eruptions are difficult to predict due to the very short seismic precursors and typically provide only minutes of warning. Three popular ski fields are located on the mountain and therefore it is important that the processes responsible for the generation of eruptions are better constrained.

Ruapehu scoria exhibit phenocrysts of plagioclase, clinopyroxene, and orthopyroxene with rare microphenocrysts of ilmenite and magnetite. We present geochemical data and volatile contents of phenocryst-hosted melt inclusions and groundmass glass from scoria erupted in 1969, 1971, 1977, 1995, and 1996. The groundmass glass composition spans a similar range to the melt inclusions (58-74 wt % SiO_2). The volatile content of melt inclusions is very low in H_2O (~ 1.5 wt %), high in F (up to ~ 2000 ppm), and high in CO_2 (up to ~ 1000 ppm). These magmas record some of the lowest H_2O contents of an andesite in an arc setting.

Many phenocryst-hosted melt inclusions plot on a separate mixing line from the groundmass glass, which suggests that the phenocrysts are exotic to the melt. We show that the small volume magmas that are erupted at Ruapehu leave a remnant crystal mush that is re-entrained by the following eruption. This is seen in eruptions where the time interval between eruptions is short (e.g. 1969/1971 and 1995/1996). Consequently, most Ruapehu magmas interact with a resident crystal mush prior to eruption. The interation of magmas with a crystal mush is probably a common process at other volcanoes, and the small volume of magmas at Ruapehu allows for more common preservation of these magmatic interactions at depth.

Mineral Dissolution Kinetics Under Conditions Relevant to Geological Storage

ANDREW D. KILPATRICK*, JÖRGEN ROSENQVIST AND BRUCE W. D. YARDLEY

School of Earth and Environment, University of Leeds, Leeds, LS2 9JT, United Kingdom
ee07adk@leeds.ac.uk (* presenting author)
j.rosenqvist@leeds.ac.uk, b.w.d.yardley@leeds.ac.uk

In the field of geological storage of carbon dioxide, a detailed understanding of the geochemical behaviour of the host reservoir is important in terms of both storage potential and security. Currently, most predicitions of geochemical behaviour rely on sparse data from single mineral experiments conducted under a wide variety of pressures, temperatures and salinities not all of which will be relevant to specific storage sites.

Our experiments aim to bridge some of these knowledge gaps: CO_2 solubility and the kinetics of mineral dissolution in CO_2-mineral-brine systems have been examined in a number of batch experiments at sub-critical (3 bar – 30 bar, 20°C – 70°C) conditions. Common reservoir mineral and rock samples have been utilised in these experiments, including dolomite, quartz, feldspar and UK sandstone. Figure 1 shows the results from an experiment following cation release from c.150µm sized dolomite in a CO_2 saturated brine at 21°C and 3 bar CO_2 pressure. Concentrations plateau at between 400 and 500 hours, a fairly long time relative to dissolution rates expected for calcite. The dissolution is highly incongruent, with calcium concentrations five to six times higher than those of magnesium. The exact reaction mechanism is still under investigation. These rates appear to be closer to those expected for silicate minerals and suggest that reaction rate imbalance between carbonate rocks and silicate rocks must be evaluated for specific lithologies and mineralogies.

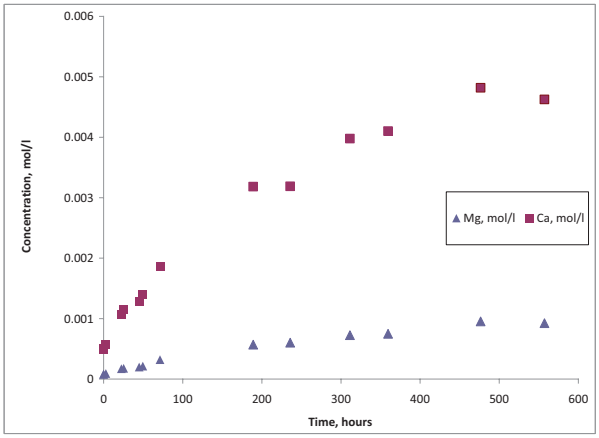

Figure 1: Ca and Mg release during a CO_2-brine-dolomite batch experiment. Temperature: 21°C, Pressure: 3 Bar, Brine: 1.36M NaCl.

Fluvial and windborne transport of arsenic-bearing mine tailings in semi-arid environments

CHRISTOPHER S. KIM[1*], DAVID H. STACK[1], JAMES J. RYTUBA[3]

[1]Chapman University, School of Earth and Environmental Sciences, Orange, USA, [*]cskim@chapman.edu

[3]U.S. Geological Survey, Menlo Park, USA, jrytuba@usgs.gov

Gold and silver mining throughout the state of California has left an environmental legacy of exposed mine wastes (tailings) containing elevated levels of arsenic (As) and other potentially toxic trace elements. The uncontrolled movement of mine tailings by erosion and natural transport processes poses challenges to the long-term containment and remediation of these contaminated materials.

The typically fine-grained size distribution of mine tailings combined with decades of exposure and weathering of large tailings piles has resulted in the mobilization of As-bearing mine wastes by both fluvial means (rainwater runoff and streams) and by transport of windblown mine waste particles. While airborne mobilization of mine tailings is diffuse and covers large areas, in semi-arid mining areas with relatively low rainfall rates fluvial transport is both sporadic and much more localized down narrow semi-linear streambeds (washes), facilitating the movement of tailings across significant distances and into ephemeral lakes/playas.

We have conducted extensive geochemical, mineralogic, and spatial characterization of tailings throughout the Mojave Desert, CA to assess the degree of surface arsenic enrichment in soils surrounding tailings piles, identify arsenic concentration trends with distance in sediments located within different washes, and measure arsenic in surface water runoff from a tailings pile during a rare storm event. EXAFS spectroscopy was also applied to selected samples to determine arsenic speciation at various locations.

Intense precipitation events were determined to mobilize mine wastes as a series of discrete pulses down a wash, which could be effectively modeled as a series of overlapping pulses with power-law exponential decay characters. Similar exponential decay behavior was observed by windblown tailings and maximized in the direction of prevailing winds. In the majority of samples, arsenic was found to exist as As(V), either in the form of secondarily-mineralized iron arsenate phases or in a sorbed phase onto iron (hydr)oxide phases.

By examining fluvial and windborne transport of As-enriched tailings at various mines throughout the western Mojave Desert, we have developed a conceptual model for the transport of mine wastes within alluvial systems that provides a sound basis for formulating strategies for the effective remediation and monitoring of historic mine areas in semi-arid environments.

Introduction

The spent mushroom compost(SMC) has been generally used as substrate for passive treatment systems, especially for SAPS in Korea. More effective substitutes to replace the SMC have always been a key concern. In this study, rice wine waste(RWW) was tested as substrates for use in acid mine drainage treatment.

Materials and methods

Batch tests were conducted to evaluate the material's efficacy in reducing sulfates and removing heavy metals within the artificial AMD. AMD was made from the standard solution for some heavy metals, mixed with distilled water and strong acid. During the test, limestone aggregates were added for increasing the pH of AMD. Batch test was continued for 27 days, and samples were taken every 3 days. The ORP, pH, and the sulfate concentration of each sample were recorded, and the concentration of heavy metals was measured with ICP.

Results and Conclusion

Test results showed that both SMC(#1) and RWW(#2) have similar efficiency in total sulfate reduction capacity(Fig. 1). However, the RWW has a little higher reducing rate, and the mixture of SMC and RWW(#3) showed the highest reducing rate. In terms of the heavy metal removal, including Fe, Al, and Cu, both materials showed similar results. Overall, the batch test results indicated that RWW has a good potential as a substrate for SAPS.

[3]University of Calgary, Mathmatics and Statistics

Nitrate contamination of groundwater is a serious environmental problem in South Korea and elsewhere. Better understanding of the source(s) and spatial land use control of groundwater nitrate pollution is required to manage nitrate contamination. In this context, we used a GIS technique integrated with a Bayesian statistical approach to interpret hydrochemistry data of groundwater, in order to produce a spatial map reliably showing groundwater vulnerability to nitrate contamination. For this purpose, we used the hydrochemistry data of 45 groundwater samples from the Pyosun Watershed located on Jeju volcanic island, Korea. The studied groundwater system is considered to be highly susceptible to non-point contamination sources such as agricultural pollutants because of the short residence time in the permeable basaltic aquifer.

The vulnerability (i.e., pollution probability) was initially predicted using a logistic model on the relationship between observed nitrate concentrations and the distribution of agricultural fields within a land use map. However, the initial results on vulnerability prediction were not satisfactory yielding a few unreliable results. This is likely due to inherent uncertainties of the adopted statistical model (i.e., model error) and the land use classification obtained from the GIS technique (i.e., data error). To assess such uncertainties, we re-evaluated the spatial information with the membership probability in relation to the extent of agricultural lands, using a fuzzy algorithm on a remote sensed image. In the next step, the results estimating data error were compared with the improved spatial map showing the probability of the nitrate concentrations to exceed a natural background (2.5 mg/L in the studied area). Finally, we compared the results of two probability maps for each GIS grid cell using the Bayesian regression, in order to assess the model uncertainty. As a result of these steps, the obtained results on groundwater vulnerability were significantly improved to yield a significant correlation between predicted nitrate concentrations and observed nitrate concentrations. Therefore, our technique developed in this study can be successfully used for evaluating groundwater vulnerability to nitrate contamination based on the hydrochemistry and land use data in agricultural areas.

Interaction of supercritical CO_2 with bentonite

JIN-SEOK KIM[1]*, HO-YOUNG JO[1], AND SEONG-TAEK YUN[1]

[1]Korea university, Earth and Environmental science, Seoul, Republic of Korea, darkach@korea.ac.kr (*presenting author)

Physical properties (e.g., porosity and permeability) of caprocks may be altered by interaction between Supercritical (SC) CO_2 and caprock. Caprocks in potential geological carbon sequestration sites can have clay minerals, which is mainly affected by SC CO_2. In this study, interaction between SC CO_2 and clay minerals was evaluated at various conditions. Bentonite was used in this study because bentonite mainly consists of montmorillonite, which is the expandable clay mineral.

SC CO_2/bentonite/water interaction kinetic tests were conducted in a stainless steel autoclave reactor at various conditions for a week to investigate how bentonite is altered in saline water when contacted with SC CO_2. The tests were conducted at 50℃ and 12 MPa. Two reaction systems (SC CO_2/bentonite and SC CO_2/water/bentonite) were used to mimic the geologic CO_2 sequestration environment. The water/bentonite system without addition of SC CO_2 was also used as a reference system. 1N NaCl, $MgCl_2$, and $CaCl_2$ solutions and sea water were used to investigate the effect of salts on the bentonite alteration in the presence of SC CO_2.

In the SC CO_2/bentonite system without water, the mass and volume of bentonite sample decreased probably due to pore water in bentonite gradually dissolved in SC CO_2. In the SC CO_2/water/bentonite system, blue and greenish mineral precipitation was observed on surface of bentonite samples. In addition, the bentonite samples swelled during the interaction. The bentonite samples swelled in the presence of salts, even though the degree of swelling was less than that without salts. These results implies that salinity and water content can affect the extent of bentonite alteration in the presence of SC CO_2. Further evaluation of the effect of precipitation and dissolution of minerals on the physical properties of bentonite when contacted SC CO_2 is needed.

Effect of Dissolved Ions on $\delta^{18}O$ Measurement of Saline Aqueous Solutions: Experimental Results

SANG-TAE KIM[1*], SEONG-SOOK PARK[2], AND SEONG-TAEK YUN[3]

[1]McMaster University, School of Geography and Earth Sciences, Hamilton, Canada, sangtae@mcmaster.ca (* presenting author)
[2]Hanyang University, Department of Natural Resources and Environmental Engineering, Seoul, Republic of Korea, pss2907@hanyang.ac.kr
[3]Korea University, Department of Earth & Environmental Sciences, Seoul, Republic of Korea, styun@korea.ac.kr

The oxygen isotope ratios of aqueous solutions have been typically determined by either "the classic CO_2–H_2O equilibration method" or a quantitative conversion of H_2O to a gas (e.g., CO, CO_2, or O_2), followed by an isotopic analysis of the gas on an isotope ratio mass spectrometer (IRMS). However, many stable isotope laboratories use the classic CO_2–H_2O equilibration technique for their routine $\delta^{18}O$ analysis of aqueous solution samples due to its analytical simplicity. In recent years, the classic CO_2–H_2O equilibration method has gained more popularity because of the introduction of an automated on-line CO_2–H_2O equilibration system coupled to a continuous-flow isotope-ratio mass spectrometer (CF-IRMS). This relatively new but innovative CF-IRMS technique requires a considerably smaller amount of aqueous solutions, compared to the conventional off-line or on-line CO_2–H_2O equilibration technique for a dual-inlet isotope ratio mass spectrometer (DI-IRMS).

Whatever the type of preparation technique or the stable isotope ratio mass spectrometry, the kinetics of oxygen isotope exchange for a given CO_2–H_2O system have to be carefully evaluated in order to accurately determine the oxygen isotope ratio of the corresponding aqueous solution when the classic CO_2–H_2O equilibration method is employed. This is because oxygen isotope exchange kinetics in the CO_2–H_2O system for a high ionic strength solution (e.g., hydrothermal brines) are not the same as that for a low ionic strength solution (e.g., freshwater) [1, 2]. Guidelines for the $\delta^{18}O$ analysis of high ionic strength solutions of geological importance will be presented at the meeting based on the experimentally determined results of oxygen isotope exchange kinetics and equilibrium isotope effects in various CO_2–high ionic strength solution systems, such as CO_2–a 1.0 molal solution of Na_2SO_4.

[3]Atmosphere and Ocean Research Institute, The University of Tokyo, Kashiwa, Japan
[4]Geological Survey of Japan, National institute of Advanced Industrial Science and Technology, Tsukuba, Japan
[5]Kochi Institute for Core Sample Research, JAMSTEC, Kochi, Japan

Oman ophiolites are regarded as a fossil oceanic crust which was hydrothermally altered by seawater-derived fluid [1]. Li isotopes can be utilized for tracing hydrothermal alteration because of their large isotopic fractionation at low-to-medium temperature between rock and fluid phase [2]. Here, we determined the Li abundances and isotopic compositions of the ophiolites from the Wadi Fizh section in Oman with multi-collector ICP-MS, IsoProbe in the University of Tokyo and Neptune in JAMSTEC. The precisions of δ^7Li measured by IsoProbe and Neptune are ± 0.7 and 0.3 ‰ (2σ), respectively.

The Li abundances vary from 0.1 to 8.0 ppm, and decrease with depth. The δ^7Li values of the Wadi Fizh section represent a variation ranging from +2.9 to +23.5‰, which is heavier than those of normal MORB. The samples deeper than 2 km also show heavy Li-isotopic signatures, different from drill hole samples of the ODP sites 504B and 896A in the present oceanic crust [3]. There is no distinct correlation between the δ^7Li values and depth. The sheeted dike and dolerite dike samples near the boundary between the sheeted dike and gabbro layer have heavy δ^7Li values up to ca. +23‰. These large variations in the δ^7Li values are likely to result not only from temperature variation, but from changes in the Li composition of hydrothermal fluid and water/rock ratios.

The Li compositions of initial hydrothermal fluid which altered the samples of ophiolites were calculated with changing water/rock ratios, and show deviation from the reaction array between seawater and fresh MORB. This suggests that the initial fluid of the Wadi Fizh section has evolved via other pathway than the simple interaction array between seawater and fresh MORB. The range of inferred initial fluid is similar in the Li compositions with pore fluids in high-temperature diagentic environment and marine brines [4, 5]. It is suggestive that the Li composition of initial hydrothermal fluid in the Wadi Fizh section is modified by another process by the interaction between original seawater-derived fluid and sediment or secondary mineral at the surface level of the oceanic crust.

Mercury Sorption on Apatite: Effects of pH and Ionic Strength

YOUNG JAE KIM[1], SOO-OH PARK[1], YOUNG JAE LEE[1*]

[1]Department of Earth and Environmental Sciences, Korea University, Seoul 136-701, Korea (*Correspondence: youngjlee@korea.ac.kr, jjbsnlove@korea.ac.kr, orange261@korea.ac.kr)

Mercury (Hg) has been the subject of interest due to its substantial toxicity on humans and living organisms. Apatite such as hydroxylapatite (HAP, $[Ca_5(PO_4)_3OH]$) is one of abundant minerals in nature but also the essential constituent for bone of vertebrates. In spite of such importance, Hg sorption on hydroxylapatite (HAP) has been barely adressed yet. In this study, sorption of mercury on HAP is investigated through batch experiments over a wide range of physicochemical conditions such as different pHs and concentrations of background electrolyte in solution.

Upon [Hg] < 20 μM, Hg sorption on HAP shows that mercury uptake by HAP increases with increasing the mecury concentration in solution over a wide range of pH between 5.0 and 9.0. Total amount of mercury sorbed on HAP decreases with increasing pH; the total amount of Hg sorption on HAP at pH 5.0 is twice greater than that of pH 8.5, suggesting that the sorption of Hg could be critically controlled by pH at the HAP-water interface. Compared to that of pH 8.5, we found that an ionic strength dramatically influences Hg uptake by HAP at pH 5.0, showing that Hg sorption increases with increasing the concentration of background electrolyte at pH 5.0. Although this study is an on-going research, it is likely that these observations would be relevant to Hg species as a function of pH. With PHREEQC modeling for Hg speciation, our results show that $Hg(OH)_2^0$ is dominant at pH 8.5, whereas at pH 5.0 $HgCl_2^0$ plays as a major species under the experiment conditions in this study, indicating that changes in Hg species as a function of pH play an important role in the sorption of Hg on HAP. In kinetic experiments at pH 8.5, the initial uptake of Hg by HAP is rapid and ~85% of Hg is rapidly sorbed on the HAP within 1 hr, suggesting that adsorption plays a key role in the initial uptake of mercury at the HAP-water interface. With our results, it is found that the mercury uptake by HAP is greatly influenced by different physicochemical conditions such as pH and ionic strength of the solution.

Silver reduction and synthesis of elemental silver nanoparticles by metal-reducing bacteria

YUMI KIM* AND YUL ROH

Chonnam National University, Gwangju, Korea, rohy@jnu.ac.kr

Introduction

In the recent years, a new dimension of the microbe-metal interactions has been explored for synthesis of metal nanoparticles such as gold and silver[1]. Although Ag(0) is known to be an antibacterial agent, metal-reducing bacteria such as *Geobacter* sp. and *Shewanella* sp. have shown the surprising ability of actively growing and precipitating Ag(0) nanoparticles within and around the cell surface via reduction of Ag(I) [2-3]. The objectives of this study were to synthesize Ag(0) nanoparticles via microbial Ag(I) reduction as well as to determine the effects of various experimental conditions such as silver nitrate concentrations, pHs, temperatures, and reaction time controlling for the optimal biosynthesis of Ag(0) nanoparticles.

Materials and Methods

The Ag(0) nanoparticles were synthesized by metal-reducing bacteria (Suncheon-1) enriched from inter-tidal flat sediments from southwestern part of South Korea. The 16S rRNA gene DGGE analysis showed the metal-reducing bacteria consisted of *Shewanella* sp., *Clostridium* sp., and *Vibrio* sp. Microbial synthesis of Ag(0) nanoparticles was examined under different concentrations of silver nitrate (1 − 10 mM), medium pHs (6.5 − 8.5), incubation temperatures (5 − 35℃) and reaction time (for 7 days) for crystal growth. The precipitates resulted from silver reduction by the bacteria were analyzed with XRD and TEM-EDS for mineralogical characterization.

Results and Conclusion

The metal-reducing bacteria (Suncheon-1) enzymatically transformed silver nitrate to Ag(0) nanoparticles with their metabolism. The Ag(0) nanoparticles were rapidly synthesized when silver nitrate ($AgNO_3$) was injected into the medium enriched the bacteria compared with initial injection at once. Microbial reactions with silver ion led formation of homogeneous sized Ag(0) nanoparticles (5 − 15 nm) by reduction of silver nitrate (0.5 − 1 mM) under the conditions around 15 − 25℃ and medium pH 8.5 within 3 days of incubation time. These results show that metal-reducing bacteria enzymatically reduced Ag(I) to Ag(0) and formed homogeneous size and shape of Ag(0) nanoparticles. Moreover, the capability of silver precipitation by microbial Ag(I) reduction suggests expanded application of recovering silver nanoparticles from silver-containing water and/or silver enriched natural environments.

Copper speciation in variably toxic sediments: Ely Copper Mine Superfund Site, Vermont

BRYN E. KIMBALL[1*], ANDREA L. FOSTER[2], ROBERT R. SEAL II[1], NADINE M. PIATAK[1] AND JANE M. HAMMARSTROM[1]

[1]US Geological Survey, Reston, VA, USA, bekimball@usgs.gov (* presenting author), rseal@usgs.gov, npiatak@usgs.gov, jhammars@usgs.gov

[2]US Geological Survey, Menlo Park, CA, USA, afoster@usgs.gov

Near the Ely Copper Mine, a Superfund site in Vermont, both surface water and sediment quality are impacted by acid rock drainage and elevated metal concentrations, with Cu being the dominant metal and contaminant of concern [1]. Chronic water-quality criteria for Cu are exceeded in the section of Ely Brook that drains mine waste. In this same section, however, stream bed sediment toxicity, as measured by detritus-feeding invertebrates called amphipods, varies. At an upstream sample location where surface and *in situ* pore water pHs are near 7, stream bed sediments display high toxicity (6% survival), but at a downstream sample location where surface and *in situ* pore water pHs are near 3, stream bed sediments have lower toxicity (91% survival) [1]. Because Cu concentrations in Ely Brook stream bed sediments are high throughout the study area (0.33 – 0.93 wt.%), the toxicity results suggest that Cu in upstream sediments is more bioavailable than Cu in downstream sediments. In sediment samples examined using bulk X-ray diffraction, no Cu minerals were detected above detection limits, so we hypothesize that the variable Cu toxicity is due to differences in the identity, relative abundance, and/or distribution of solid-phase Cu species, where Cu is a trace to minor component.

In an effort to characterize Cu speciation in these distinct toxicity environments, we collected six stream bed sediment samples along the toxicity gradient and conducted meso-scale (50-100 µm beam size) X-ray fluorescence microscopy (XRF) on sediment thin sections, and X-ray absorbance spectroscopy (XAS) on bulk dried sediment powders and representative model compounds. Both datasets were collected under ambient conditions.

Preliminary XRF results indicate that Cu in the relatively toxic upstream sample correlates with Mn, and generally coats mineral grain surfaces. In less toxic downstream samples, Cu correlates strongly with S and Zn, and weakly with Fe. Preliminary analysis of calibrated and normalized X-ray absorption near edge spectra (XANES) shows clear evidence of the presence of a Cu-sulfide phase in downstream, low-toxicity sediments. The upstream, high-toxicity sample displays an overall XANES spectrum similar to spectra for Cu-sorbed Fe- and Mn-(hydr)oxides. The relative abundance of dominant Cu species is being determined by linear-combination, least-squares fitting. Preliminary results indicate that downstream sediment spectra are fit 80-90% by chalcopyrite and 10-20% by Cu-jarosite. The upstream sediment spectrum is fit nearly 100% by Cu-sorbed MnO_2. The spectroscopic findings are consistent with the toxicity results given the lower solubility of Cu sulfides relative to Cu sorbed phases under relevant environmental conditions.

Sulphate inhibition of magnesite dissolution: An in-situ AFM study

HELEN E. KING[1*] AND CHRISTINE V. PUTNIS[1]

[1]Institut für Mineralogie, University of Münster, Münster, Germany, hking_01@uni-muenster.de (* presenting author), putnisc@uni-muenster.de

Magnesite is the expected product phase of CO_2 sequestration in strategies involving Mg-silicates. Its formation and stability in these environments will be controlled by the ions present in rock pore fluids, e.g. NaCl and sulphates, as well as temperature and pH. The effect of different ligands on magnesite stability has been studied at aquifer conditions, i.e. low concentrations, in *ex-situ* flow-through experiments where sulphate was shown to enhance the dissolution [1]. To test whether this effect is also prominent at higher sulphate concentrations we have conducted *in-situ* dissolution experiments of the $\{10\bar{1}4\}$ magnesite surface using atomic force microscopy (AFM) at room temperature with Na_2SO_4 concentrations between 0.01 and 0.1 M. Solutions were acidified to pH 2 because magnesite dissolution under ambient conditions is slow. However, rather than observing an increase in dissolution under our experimental conditions, sulphate dramatically reduced the magnesite dissolution rate. To determine whether this effect was a consequence of the mixed electrolytes used in the experiments of Pokrovsky et al. [1] magnesite dissolution in solutions of 0.1 M NaCl and 0, 0.01, 0.03 or 0.1 M Na_2SO_4 was tested. Experiments at approximately 40 °C were also conducted to study the role of temperature on the sulphate effect.

Increased dissolution was observed with 0.1 M NaCl without sulphate in comparison to dissolution in 0.1 M Na_2SO_4. The effect of sulphate was not diminished by the concomitant presence of chloride even when the concentration of the different anions was equal. Increasing the solution temperature also did not change the effect of sulphate on magnesite dissolution. Formation of Mg-sulphate interactions are expected to be facilitated by the presence of NaCl in solution due to its effect on ion hydration [2]. Similarly, higher temperatures have been shown to increase the number of contact ion pairs between Mg and sulphate in solution [3]. Both of these effects are possibly a consequence of changes in the ion hydration. Therefore, it would be expected that the presence of sulphate in higher ionic strength solutions or higher temperatures would also retard magnesite dissolution. A precipitate was observed on the surface during the experiments despite the undersaturation of the input solution with respect to Mg-carbonate phases and the inhibition of magnesite dissolution in the presence of sulphate. This indicates that in our experiments the fluid boundary layer present at the mineral surface plays a crucial role in the reaction. Thus, sulphate in this boundary layer, which could be present in nature but was minimized in previous *ex-situ* flow-through experiments, plays a critical role in magnesite reactivity.

Petrogenesis of CAMP dolerites from Suriname and West Africa

NICOLE KIOE-A-SEN[1*] AND MANFRED VAN BERGEN[2]

[1]Anton de Kom University of Suriname, Paramaribo, Suriname, nicole.kioe-a-sen@uvs.edu (* presenting author)
[2] Department of Earth Sciences, Utrecht University, The Netherlands, m.j.vanbergen@uu.nl

We performed a petrological and geochemical investigation on dolerites from Suriname and West Africa to explore the extent to which CAMP products from areas on opposite sides of the present-day Atlantic have a common petrogenetic heritage. Dykes in Suriname and the Ivory Coast (IC) are mainly tholeiitic basalts, while sills in Burkina Faso (BF) are mostly basaltic-andesites with tholeiitic as well as calc-alkaline affinities. The Surinamese rocks are slightly more evolved (Mg#=34-46) than the IC dolerites (Mg#=43-51), whereas the BF dolerites include the least evolved compositions (Mg#=45-66).

A geographic subdivision into high-Ti (1.9-3.7 wt.% TiO_2) and low-Ti (0.9-1.2 wt.%) dolerites is consistent with findings in other CAMP regions. Nevertheless, overall geochemical characteristics of the studied rocks tend to be distinct. The Surinamese and IC dolerites fall in a narrow zone of high-Ti magmatism along the margins of the present-day Atlantic Ocean, where preferential upwelling shortly before initial rifting has been proposed. Trace-element signatures and inferences from partial melting models suggest that mantle sources of the Surinamese and IC dolerites were different from those of the BF rocks. Modestly contrasting geochemical signatures point to source inhomogeneity and variations in melting conditions on regional as well as local scales. Relatively deep melting of a garnet-rich source with primitive-mantle like composition may have produced the Suriname and IC magmas, whereas the BF magmas possibly originated by shallower melting of a more spinel-rich source that might have been affected by subduction-type enrichment. Our findings indicate that chemostratigraphic criteria, used in correlations of northern CAMP basalts, are not directly applicable to southern counterparts on both sides of the Atlantic.

Plutonium redox chemistry under anoxic conditions in the presence of iron(II) bearing minerals

REGINA KIRSCH[1,2*], DAVID FELLHAUER[3,4], MARCUS ALTMAIER[4], LAURENT CHARLET[2], THOMAS FANGHÄNEL[3], ANDREAS C. SCHEINOST[1]

[1]Institute of Resource Ecology, HZDR, Dresden, Germany, kirsch@esrf.fr (*presenting author), scheinost@esrf.fr
[2]ISTerre, UdG/CNRS, Grenoble, France, charlet38@gmail.com
[3]EC-JRC-ITU, Karlsruhe, Germany, thomas.fanghaenel@ec.europa.eu
[4]Institute for nuclear waste disposal, KIT, Karlsruhe, Germany, marcus.altmaier@kit.edu, david.fellhauer@kit.edu

The environmental fate of plutonium, the major transuranium actinide in nuclear waste, is largely impacted by its sorption onto and redox reactions with iron oxide, carbonate or sulfide minerals that form as corrosion products of steel in the "near field" and occur widely in sediments. To obtain information on oxidation state and local structure of Pu in the presence of Fe(II) bearing minerals, electrolytically prepared Pu(V) or Pu(III) (^{242}Pu, 1-3·10^{-5} M) were, under anoxic conditions, reacted with magnetite ($Fe^{II}Fe^{III}_2O_4$) (pH 6-8.5), chukanovite ($Fe_2(CO_3)(OH)_2$) (pH 8.5) and mackinawite (FeS) (pH 6-8.5). Pu-L_{III}-edge X-ray absorption spectra (XAS) were collected after 40 d and 8 months of reaction.

In all 14 samples, more than 98 % of Pu was associated with the solid phase and its redox speciation thus accessible by XAS. With magnetite, only the sample prepared at the highest pH and highest Pu loading contained $Pu(IV)O_2$ while in all others Pu was solely present as a tridentate Pu(III) surface complex [1]. The three chukanovite samples all contained both Pu(III) (15 to 40 %) and PuO_2. With mackinawite at pH 6 only Pu(III) was present, while all samples prepared at pH 7 and higher contained mostly PuO_2 and up to approx. 10 % Pu(III).

Through comparison of the different types of minerals (oxide, carbonate, sulfide), reaction pH and Pu/mineral ratios, it becomes apparent that the type of surface complexation (e.g. inner-sphere on magnetite vs. outer-sphere on mackinawite) and total mineral surface area are key parameters in controlling concentrations of dissolved Pu and in determining whether a PuO_2 solid phase precipitates. While PuO_2 provides an upper limit for concentrations of dissolved Pu, the available mineral surface area and sorption complex stability control what percentage of Pu is present in surface complexes. Under reducing conditions as established through the Fe(II) bearing minerals used here, this mineral surface associated Pu was found to be trivalent. Surface complexed Pu(III) and PuO_2 can be thought of being in equilibrium with each other via two processes: a sorption reaction between dissolved and surface complexed Pu(III) and a heterogeneous redox reaction between dissolved Pu(III) and solid phase $Pu(IV)O_2$. It remains to be investigated if and through what mechanisms the Pu solid phase speciation (sorbed Pu(III) vs. solid phase PuO_2) might impact the migration behavior of Pu and how, for risk assessment purposes, Pu(III) surface complexes with iron minerals can be implemented into geochemical models.

Archean "whiffs of oxygen" go Poof!

JOSEPH L. KIRSCHVINK[1,*], TIMOTHY D. RAUB[2], & WOODWARD FISCHER[1]

[1] Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, California, USA.

[2] Department of Earth Sciences, University of St. Andrews, St. Andrews, United Kingdom.

NASA's scientific drillcore ABDP-9 penetrated ~90 m of strata from the Archean-Paleoproterozoic boundary interval in the mid-Hamersley Basin of the Pilbara craton, Western Australia beneath ~100 m of regolith. A series of geochemical studies of the core in the past 5 years starting with [1, 2] have reported Mo and Re concentration enrichments, mass-independent sulfur isotope fractionations, ^{15}N-enrichments, and iron speciation that were argued to represent "whiffs" of atmospheric oxygen. These datasets have lent support to controversial traces of biomarkers in both this unit and strata elsewhere in the Hamersley Basin that have been interpreted to contain evidence for cyanobacteria and eukaryotes inhabiting widespread late Archean niches. Similar, though less conspicuous Mo, Re, S, N, Fe, and lipid biomarker anomalies in ~2.7-2.5 Ga marine strata of South Africa's Kaapvaal cratonic margin have been interpreted in context of ABDP-9 "whiffs" of oxygen to suggest even "pervasive" Late Archean oxygenation. These interpretations are surprising because they appear to conflict with other longstanding geological proxies (e.g. red beds, redox-sensitive detrital grains, mass independent S fractionation) that suggest the rise of oxygen occurred several hundred million years later. If correct, these data solicit a complete reevaluation of our knowledge of how solid Earth and surface Earth processes operate to keep oxygen in balance over geological time. It is reasonable to ask whether the inferences made from elemental and isotopic relationships captured in these rocks are sufficiently strong to warrant such reevaluation.

We present new observations from ABDP-9 that reveal significant open-system, post-depositional alteration of the sedimentary rocks in this region of the Hammersley Basin: these include observations of widespread highly-crystalline, high-temperature, late-stage chlorite veins, preferentially developed within shale lithologies and concentrated in the "whiff" interval, locally associated with iron and sulfur metasomatism; and regionally set in ~300-450 °C burial metamorphic, multiply-deformed terrane. Preliminary micro-scale work to measure isotopic and elemental abundances show clear texture-specific differences that may allow untangling of several episodes of diagenesis and metasomatism to provide a framework for better interpreting the bulk data.

These post-depositional features in ABDP-9 argue that the 'whiffs' are metasomatic artifacts. We suspect similar problems in other Archean cores, which are sulfide-remagnetized during orogenic episodes associated with Pb-Zn-mineralizing crustal fluids in the foreland. We note that a late origin of oxygenic photosynthesis can explain the Lomagundi-Jutali event, the Makganyene snowball, the Kalahari Mn field, the Sishen iron deposit, and Shungite deposition [3]. The timing is consistent with recent molecular clock estimates for the radiation of the Eukaryotes, which post-date 2 Ga. [4].

Nitrate transformation and immobilization: effects of biotic-abiotic and oxic-anoxic conditions

FIONA KIZEWSKI[1*], JASON KAYE[1], AND CARMEN ENID MARTÍNEZ[1]

Biogeochemistry under redox-dynamic conditions: processes, speciation, and fluxes

It has been hypothesized that incorporation of dissolved inorganic nitrogen into organic matter (OM) via abiotic (chemical) prossesses is one of the mechanisms that account for the high N retention observed in temperate forest soils [1]. Soil incubations under sterile conditions have shown that N from nitrate (N-NO_3^-) is rapidly transformed to organic nitrogen [2, 3]. Transformation of N-NO_3^- to organic nitrogen involves a decrease in N oxidation state. Hence, NO_3^- reduction to nitrite (NO_2^-) or other more reduced species may be a required step prior to N immobilization. In this study, solid OM was spiked with $^{15}NO_3^-$ and incubated in suspensions in four combinations of biotic-abiotic and oxic-anoxic conditions at pH 6.5 for five days. Our objectives are to elucidate how biotic-abiotic and redox conditions affect NO_3^- transformations and to determine whether N-NO_3^- will be incorporated into solid OM under abiotic conditions.

Within the first hour, the experimental (NO_3^- spiked) system incubated under biotic and oxic (Bio-Ox) conditions showed a drastic decrese (22%) in NO_3^- concentration, which increased again towards the end of incubation. Increases in the concentrations of NH_4^+ and dissolved organic nitrogen (DON) in the experimental system were of the same magnitude as in the blank (no NO_3^- spiked) systems. However, significant increases did not occur until after ~3 days in the blank. These results suggest that NO_3^- addition accelerates microbial activity, which facilitates N mineralization to NH_4^+. Incubations of experimental and blank systems under abiotic oxic (Abio-Ox) conditions showed no significant change in NH_4^+ with time; but a steady increase, of the same magnitude, was observed for DON. The experimental system showed a steady decrease in NO_3^- of 8% with time under Abio-Ox conditions. Comparison of Bio-Ox and Abio-Ox systems thus suggests that microbial activity is not required for the production of DON, but seem to be needed for DON mineralization to NH_4^+.

We also performed incubations under anoxic conditions to test whether the same mechanisms are operative in reduced environments, e.g., in the interior of soil aggregates or wetlands. Under anoxic conditions, the spiked NO_3^- disappeared within the first 24 h in both the biotic and abiotic experimental systems. In these systems, NO_2^- was detected; its concentration first increased then droped to zero. Biotic anoxic (Bio-Anox) systems showed an increase in the concentration of NH_4^+ with time. However, the increase of NH_4^+ in the experimental system was twice that of the blank. Another striking result is that DON in the blank increased with time whereas it remained constant in the experimental system. Under abiotic anoxic (Abio-Anox) conditions, the experimental and blank systems showed the same trend and magnitude in DON decrease and NH_4^- increase.

Disappearance of NO_3^- and NO_2^- detection under anoxic conditions suggest that NO_3^- is reduced to NO_2^- which is either volatized or incorporated into the solid OM. Under biotic conditions, immobilization (microbial and chemical) seems to be the primary pathway for NO_3^- disappearance. Our interpreation of the fate of NO_3^- under various conditions will be further verified by ^{15}N measurements.

Abstract

A comparative till and bedrock study in the Thompson Nickel Belt (TNB), Manitoba, Canada, was carried out by the Geological Survey of Canada (GSC) and Manitoba Geological Survey in collaboration with a Canadian Mining Industry Research Organization (CAMIRO) project with the aim of identifying potential resistate indicator minerals for Ni-Cu-mineralization. The TNB is a 10 to 35 km wide belt consisting of variably reworked Archean gneisses and Early Proterozoic cover rocks along the northwestern margin of the Superior Craton in central Canada. It hosts several world-class magmatic Ni-Cu deposits that have been strongly metamorphosed under upper amphibolite to granulite conditions. Nickel sulphide mineralization is associated with komatiitic ultra-mafic bodies (meta-pyroxenite, meta-peridotite) within the lower part of the Proterozoic Ospwagan Group. Of all the potential resistate minerals picked from till and representative bedrock samples of the main lithological units within the TNB, chromite is the most useful indicator mineral because it is more resistate than the sulphides, occurs both in ore and barren ultramafic rocks and has distinctly different compositions in mineralized samples compared to un-mineralized. Chromite in barren TNB peridotite contains moderate MgO (1.5 - 5 wt.%) and 40 to 52 wt.% Cr_2O_3 while chromite in massive sulphide ore varies from chromian magnetite to extremely Mg-poor, Zn-rich chromite in contact with pyrrhotite. The chromite analyzed in the massive Ni-ore contained > 2 wt.% to 8 wt.% ZnO. Chromite in till samples immediately down ice of the Thompson and Pipe deposits, are MgO-poor chromite - gahnite solid solutions spanning the entire range from 2 to 18% ZnO. In contrast, chromite in barren ultramafics and in till samples from non-mineralized areas of the TNB consistently contain <2 wt.% ZnO.

While Zn-rich chromite has been observed in other areas of the world hosting magmatic NiCu-deposits (e.g. Vammala belt, Finland and Kambalda, Australia), the compositions found in the TNB are extreme and are attributed to the high metamorphic grades reached during peak metamorphism.

Magma chamber heterogeneities recorded by melt inclusions from Mt. Somma-Vesuvius, Italy

RITA KLÉBESZ[1,2*], ROBERT J. BODNAR[1], BENEDETTO DE VIVO[2], ROSARIO ESPOSITO[1], ANNAMARIA LIMA[2], PAOLA PETROSINO[2], KALMAN TÖRÖK[3]

[1]Virginia Tech, Blacksburg, VA, USA, krita@vt.edu (* presenting author), rjb@vt.edu, rosario@vt.edu
[2]University of Naples "Federico II", Naples Italy, bdevivo@unina.it, anlima@unina.it, petrosin@unina.it
[3]Eötvös Loránd Geophysical Institute of Hungary, Hungary, torokklm@elgi.hu

Nodules (coarse-grain "plutonic" rocks) from the ~20 ka Pomici di Base (PB)-Sarno eruption of Mt. Somma-Vesuvius, Italy show petrographic features, such as porphyrogranular texture, slight zonation and irregular edges of phenocrysts, and crystallized melt pockets, which are all consistent with the interpretation that these nodules represent the crystal-rich part of the mush-zone of the active plumbing system beneath Mt. Somma-Vesuvius.

Melt inclusions (MI) are abundant in clinopyroxenes in the nodules. All MI observed in this study are partially to completely crystallized, suggesting they cooled relatively slowly after trapping. Two types of MI can be distinguished based on petrography. Type I consists of mica, Fe-Ti-oxide minerals and/or dark green spinel, clinopyroxene, feldspar and a vapor bubble. No volatiles (CO_2, H_2O) were detected in the bubbles during Raman analysis. Type II inclusions are generally lighter in color and they contain subhedral feldspar and/or glass and oxides. Both types of MI are randomly distributed in the crystals or they occur along a growth zone and are interpreted to be primary. MI were homogenized and analyzed to determine their major and trace element, and volatile compositions. MI homogenized between 1227°C and 1267°C, with most homogenizing at 1230-1235°C. In addition to petrographic differences, the two types of MI can also be distinguished based on their chemical compositions. Type I MI can be classified as phono-tephrite – tephri-phonolite – basaltic trachy-andesite, while Type II MI have a mainly basaltic composition. The two different types of MI also show different trace element patterns. Type I MI are more enriched in incompatible elements compared to Type II MI. SIMS analysis of homogenized MI show variations in the volatile composition of the melt, both within and between MI types.

The presence of spatially associated MI with different compositions in individual phenocrysts is interpreted to represent small scale heterogeneities within the magma chamber due to reaction of crystals and/or wall rock in the mush zone at the margin of the magma chamber with the newly intruded magma [1].

Compositional controls on hydrogen generation during serpentinization

FRIEDER KLEIN*[1], WOLFGANG BACH[2], THOMAS M. MCCOLLOM[3]

[1] Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA, fklein@whoi.edu

[2] Geoscience Department, University of Bremen, Klagenfurter Str., 28359 Bremen, Germany, wbach@uni-bremen.de

[3] CU Center for Astrobiology and Laboratory for Atmospheric and Space Physics, University of Colorado, Boulder, CO 80309-0392, USA, mccollom@lasp.colorado.edu

At the Earth's surface peridotites and pyroxenites are inevitably unstable in the presence water causing the formation of serpentine, brucite or talc, magnetite and, most notably hydrogen. We compute equilibrium mineral assemblages, mineral compositions and the fluid/gas chemistry during serpentinization of an array of olivine- and/or pyroxene-rich rocks under near surface conditions from 25-400 °C and 50 MPa at a water-to-rock mass ratio of one. Our results indicate that the optimal temperature for hydrogen generation during serpentinization of olivine (Ol, Fo90)-rich peridotite and dunite is at about 300-330°C. At this temperature we predict that rocks having an Ol -orthopyroxene (Opx) mass ratio > 1 generate more hydrogen during serpentinization than rocks having an Ol – Opx mass ratio < 1. There is a direct link between the fayalite content of olivine, its stability relative to water, temperature, and redox conditions. Fayalite-rich olivine is stable to significantly lower temperatures in the presence of water than fayalite-poor olivine. Accordingly, the most reducing conditions during serpentinization of fayalite-rich olivine develop at temperatures lower than 330 °C. Notwithstanding the lower temperatures, rocks having abundant fayalite-rich olivine are predicted to generate significantly more H_2,aq during serpentinization than typical forsterite-rich (Fo90) mantle rocks.

Our modeling results indicate that serpentinization of Fe-rich ultramafic rocks might represent one of the most reducing environments at or close to the Earth's surface. The results also suggest that serpentinization on Mars, where Fe contents of olivine in peridotites are higher than in terrestrial counterparts, will generate higher levels of H_2.

Partitioning of F between nominally fluorine-free minerals and basaltic melts: Implications for the global cycle of halogens

S. KLEMME [1*], C. BEYER[1], C. VOLLMER[1], M. WIEDENBECK[2] AND A. STRACKE [1]

[1]Institut für Mineralogie, University of Münster, Germany stephan.klemme@uni-muenster.de (*presenting author) christian.vollmer@uni-muenster.de, stracke.andreas@uni-muenster.de, christopher.beyer@uni-bayreuth.de

[2]GFZ, Potsdam, Germany, michawi@gfz-potsdam.de

We present preliminary experimentally determined partition coefficients for fluorine (F) between nominally fluorine-free minerals and corresponding basaltic melts in the systems CaO-MgO-Al_2O_3-SiO_2+F, Na_2O-CaO-MgO-Al_2O_3-SiO_2+F, and in natural compositions at pressures up to 2.5 GPa and temperatures between 1285°C and 1445°C. F is incompatible in olivine, whereas the F in orthopyroxene is slightly more compatible. Our preliminary partition coefficients agree well with our analyses of F in natural olivines and orthopyroxenes from spinel peridodites and oceanic basalts, both indicating that F is much more compatible in olivine and orthopyroxene than hydrogen. Based on high-resolution TEM images of one of the samples, we argue that the F incorporation into the olivine structure is mass balanced via oxygen defects.

Hence, fluorine, and to a lesser extend chlorine, may be effectively stored in nominally fluorine-free mantle minerals such as olivine and orthopyroxene. By considering their high modal proportions in the upper mantle, both phases are the major hosts for F in the Earth's mantle, and must be taken into account when calculating the Earth's budget of halogens or global cycles of halogens in the deeper Earth. It, therefore, seems that other F-bearing minerals such as amphibole or phosphates are not required in order to balance the F concentrations between crust and mantle.

Applying our new partition coefficients to primitive olivine hosted melt inclusion data from mid-ocean ridge basalt (MORB) and from primary melt inclusions from ocean island basalts (OIB), we suggest slightly higher fluorine contents in OIB than in MORB.

Recrystallization of Barite in the presence of Ra at elevated temperatures up to 90 °C

MARTINA KLINKENBERG[1*], FELIX BRANDT[1], KONSTANTIN ROZOV[1], GIUSEPPE MODOLO[1], DIRK BOSBACH[1]

[1] IEK-6 Nuclear Waste Management and Reactor Safety, Forschungszentrum Jülich, Germany m.klinkenberg@fz-juelich.de(*presenting author), f.brandt@fz-juelich.de, k.rozov@fz-juelich.de, g.modolo@fz-juelich.de, d.bosbach@fz-juelich.de

The uptake of Radium by Barite via solid solution formation is an important process controlling the solubility of Ra in aqueous systems. Recent studies have focused on ambient conditions (Bosbach et al., 2010; Curti et al., 2010). Here, we have focused on the understanding of kinetics and uptake mechanisms at elevated temperatures.

New experimental data of batch recrystallization experiments at room temperature (RT) and 90 °C are presented. A pure barite solid was put into contact with an aqueous solution (0.1 n NaCl) with an initial Ra/Ba ratio of 0.3 ($5 \cdot 10^{-6}$ mol/L Ra) and neutral pH. The solid/liquid ratio was 5 g/L. A barite which consists of blocky crystals with a particle size of > 10 µm and a specific surface area of 0.17 m²/g was used for the recrystallization experiments at close to equilibrium conditions. The evolution of the Ra and Ba concentration in solution with time was monitored via Gamma spectrometry and ICP-MS. Furthermore, the morphological evoution of the barite crystals was investigated by SEM.

A faster decrease of the Ra concentration in solution is observed at 90 °C compared to room temperature. A steady state of the Ra concentration is reached at $3 \cdot 10^{-8}$ mol/L for experiments at 90 °C after 30 days and after 70 days at $3.5 \cdot 10^{-9}$ mol/l for experiments at room temperature.

Our results agree with the thermodynamic data of the $RaSO_4$ and $BaSO_4$ endmembers. At room temperature, $RaSO_4$ is less soluble than $BaSO_4$ whereas estimated solubilities indicate that $RaSO_4$ is more soluble than $BaSO_4$ at 90 °C. As a consequence, a lower retention capacity for Ra can be expected for 90 °C.

Electron microscopy results of the crystal morphology show a distinct influence of the presence of Ra on recrystalization at close to equilibrium conditions and 90 °C. In the presence of Ra, the crystals show plain crystal faces. In the absence of Ra rough surfaces and deep holes in the crystals are observed. These differences clearly indicate different recrystallization mechanisms.

TEM studies will be carried out to achieve a nanoscopic system understanding of micro structural evolution and Ra incorporation into the barite crystal as well as its spatial distribution in the crystal.

Prebiotic selection of D-ribose on mineral surfaces

K. KLOCHKO[1*], R.M. HAZEN[1,2], D.A. SVERJENSKY[1], AND G.D. CODY[1]

[1]Geophysical Laboratory, Carnegie Institution of Washington, Washington DC, USA, kklochko@ciw.edu (* presenting author)
[2]Department of Earth and Planetary Sciences, Johns Hopkins University, Baltimore, USA

Pentose sugars are major biochemical building blocks. Prebiotic syntheses have been proposed leading to complex mixtures including 4-, 5-, and 6-carbon sugars [1,2]. However, the pentose sugar D-ribose has the greatest biological importance because it is the sugar found within modern nucleic acids. We are investigating whether this is due to some exceptional characteristic of ribose associated with its interaction with mineral surfaces.

Some studies have shown that D-ribose can be stabilized in the presence of borate [3] or silicate [4] minerals. Recent study of the adsorption of nucleosides and nucleotides on rutile [5] indicates that adjacent OH-groups on the ribose part of these molecules play a critical role in the attachment to mineral surfaces. The four pentose sugars ribose, xylose, lyxose and arabinose differ only in the arrangement of the OH-groups and their stereochemistry in solution. This suggests that the different structures of these sugars might lead to selective adsorption on mineral surfaces.

The present study is focused on interactions of pentose sugars on rutile (α-TiO_2, pH_{PPZC} = 5.4, BET = 18.1 m^2/g) in the presence of light: in pure water; and in the dark: in pure water, 10 and 100 mM NaCl solutions over a wide range of pH conditions (5-11).

In the presence of light, the results of our batch adsoption experiments indicate an occurance of a photocatalytic reaction between rutile surface and four pentoses. Xylose and lyxose form threose via loss of an aldehyde group. The reaction product of ribose or arabinose and rutile has not yet been identified.

In dark conditions, batch adsorption experiments of the four sugars individually and in mixtures indicate that adsorption increases with increasing pH and salt concentration of the solution. The salt effect and pH dependancy of adsorption is more pronounced for ribose. Ribose adsorption is the strongest among the pentose sugars, suggesting that ribose's cis diol OH-groups play a critical role in the attachment to mineral surfaces. Overall, our results are consistent with the hypothesis that mineral surfaces could potentially have played a role in selecting ribose relative to the other pentose sugars.

Man made water cycles: Isotope tracing of desalinated seawater through water supply, sewage and groundwater

WOLFRAM KLOPPMANN[1*], IDO NEGEV[2], JOSEPH GUTTMAN[2], CATHERINE GUERROT[1], CHRISTINE FLEHOC[1], MARIE PETTENATI[1], ORLY GOREN[3], AVIHU BURG[3].

[1]BRGM, Orléans, France, w.kloppmann@brgm.fr (* presenting author)
[2]Mekorot National Water Company, Tel Aviv, Israel
[3]Geological Survey of Israel, Jerusalem, Israel

Non-conventional water resources like desalinated water and treated sewage play today a key role in the water balance of many developed countries in arid and semi-arid regions. The worldwide capacity of desalination is expected to double within ten years to reach 62 Mm^3/d in 2015 [1]. This massive arrival of "man-made" fresh water in the water cycle is expected to change geochemical and isotope characteristics of surface and groundwater. A pilot study in 2008 [2] has shown the highly specific isotope signatures of reverse osmosis (RO) desalinated seawater. Our current study presents isotope data (B, $H+O_{H2O}$, $S+O_{SO4}$) on the largest system of soil-aquifer treatment (SAT) in the Middle East - the Shafdan site, Israel - where 130 Mm^3/Y of treated wastewater from the greater Tel Aviv region are infiltrated through ponds into the sandy Mediterranean Coastal Aquifer, recovered and then transported 70 km further to the South for unrestricted irrigation in the Negev desert. In Sept. 2010 and Feb. 2011, we analysed treated wastewater before infiltration, together with groundwaters at different distances from the infiltration ponds, as well as samples from the Tel Aviv drinking water supply and the product waters from two RO desalination plants. B isotopes of sewage show a siginficant shift from 1994 with a $\delta^{11}B$ of +9.7 ±2.8‰ *vs.* NBS951 [3] to 2010-11 with + 40.4 ±0.7‰ (n=5). This shift is explained with (1) a change in legislation lowering considerably the perborate contents in washing powders (1999-2008) and (2) the massive arrival of desalinated seawater in the drinking water supply ($\delta^{11}B$ of 53±3‰, [2]) since 2007. The breakthrough of this new boron signature has not yet been observed in the aquifer, not even for the wells closest to the infiltration ponds and no significant shift was observed between the two campaigns. This can be due to temporary sorption on clays leading to an important delay of B with respect to water [4] inducing a highly non-conservative behaviour. δ^2H and $\delta^{18}O_{H2O}$ in wastewater and groundwater can be quantitatively explained by the different components of regional water supply, including the new desalination permeate. $\delta^{34}S$ and $\delta^{18}O$ of sulphates in wastewater, observed in the vicinity of the infiltration pond, are very different from desalinated seawater, the latter very depleted in SO_4^{2-}, as sewage sulphate is dominated by other sources. This study reveals the usefulness of multi-isotope tracing for elucidating the mixing components and pathways of water and solutes in a nearly completely artificial regional water cycle.

NO_2^--induced abiotic redox processes during microbial NO_3^--dependent Fe(II) oxidation

NICOLE KLUEGLEIN*, AND ANDREAS KAPPLER

University Tuebingen, Geomicrobiology, Germany
nicole.klueglein@uni-tuebingen.de (* presenting author)
andreas.kappler@uni-tuebingen.de

Anaerobic, neutrophilic nitrate-reducing Fe(II)-oxidizing bacteria are found in many anoxic environments and were suggested to play an important role in nitrogen and iron cycling. In this study we conducted batch experiments with the mixotrophic, nitrate-reducing, iron(II)-oxidizing *Acidovorax* sp. strain BoFeN1 isolated from anoxic littoral sediments [1]. This strain produces nitrite in the low mM range as an intermediate during denitrification. Nitrite has long been identified as a strong oxidant for Fe(II) particularly under acidic pH conditions [2] but also at neutral pH in the presence of minerals and heavy metal ions that function as catalysts [3,4]. This raises the question whether the oxidation of ferrous iron is indeed enzymatically catalyzed or whether to a large extent it is just a chemical reaction as a consequence of microbial nitrite formation during acetate oxidation. A key problem occurring during investigation of these processes is the quantification of Fe(II) oxidation over time in the presence of nitrite that forms during denitrification. The acidification of the samples with HCl during dissolution of the iron mineral phases followed by the widely used spectrophotometric ferrozine assay leads to a rapid, abiotic oxidation of Fe(II) by even small amounts of nitrite. This abiotic Fe(II) oxidation in turn leads to underestimated and thus incorrect values and therefore to an overestimation of oxidation rates. To obtain correct Fe(II) data we used a revised Fe extraction protocol and added 40 mM sulfamic acid to our samples. Sulfamic acid reacts with the nitrite and prevents abiotic Fe(II) oxidation by nitrite. With this revised analytical procedure we observed a much slower Fe(II) oxidation rate with BoFeN1 (3.4 mM/day) than previously published (6 mM/day) [5]. We also quantified abiogenic oxidation of ferrous iron by mM concentrations of nitrite added to sterile culture medium at neutral pH and found rapid Fe(II) oxidation suggesting that the abiotic oxidation of Fe(II) by nitrite produced during heterotrophic denitrification contributes significantly to overall Fe(II) oxidation rates observed. Additionally, we grew strain BoFeN1 at different temperatures and found that at lower temperatures nitrite accumulated to a higher extent than in cultures growing at room temperature. This suggests that abiotic nitrite-dependent Fe(II) oxidation is even more important in low-temperature environments such as lake sediments. In summary, our experiments demonstrate the importance of nitrite formation during heterotrophic nitrate reduction in mixotrophic nitrate-reducing, Fe(II)-oxidizing cultures. The ability of nitrite to oxidize ferrous iron in the presence of biogenic Fe(III) minerals also at neutral pH raises the question if the importance of the biological process was overestimated until now. Accurate measurements of Fe(II) concentrations over time with the described revised Fe extraction method are necessary to reevaluate the Fe(II) oxidation rates of known Fe(II)-oxidizing strains. This may allow to better understand the role of abiotic Fe(II) oxidation by nitrite in these systems.

Noble gases in geothermal waters as tracers for deep fluid circulation

STEPHAN KLUMP[1*], MATTHIAS S. BRENNWALD[2], DAVID MORRISON[3] AND ROLF KIPFER[2,4]

[1]EBA, A Tetra Tech Company, Whitehorse, Canada, sklump@eba.ca (* presenting author)
[2]Eawag: Swiss Federal Institute of Aquatic Science and Technology, Duebendorf, Switzerland, matthias.brennwald@eawag.ch
[3]Yukon Energy Corp., Whitehorse, Canada, david.morrison@yec.yk.ca
[4]Swiss Federal Institute of Technology, ETH Zurich, Zurich, Switzerland, rolf.kipfer@eawag.ch

Introduction

Dissolved noble gases make excellent environmental tracers to study physical processes in groundwater and other aquatic environments. Especially helium isotopes have been widely used to trace residence time and deep circulation in groundwater systems.

Elevated $^{3}He/^{4}He$ isotope ratios were found in areas with increased geothermal resource potential in the Basin and Range Province, western United States [1]. The authors suggest that high $^{3}He/^{4}He$ anomalies, i.e., areas with admixture of mantle-derived helium in groundwater, indicate enhanced crustal permeability coupled with local zones of deep fluid production and/or hidden magmatic activity.

As part of a geothermal exploration project, samples were collected from five warm and hot springs in southern and central Yukon, Canada. All samples were analyzed for noble gas abundances of He, Ne, Ar, Kr, Xe and the isotope ratios $^{3}He/^{4}He$, $^{20}Ne/^{22}Ne$, and $^{36}Ar/^{40}Ar$, as well as stable isotopes (^{2}H, ^{18}O), tritium (^{3}H), and routine inorganic chemistry.

Results and Conclusions

All samples contained a significant component of mantle-derived helium which is characterized by a higher $^{3}He/^{4}He$ isotope ratio compared to crustal helium. The presence of a mantle-derived helium component typically suggests the existence of a deep fluid pathway, usually a steeply inclined fault or fault zone. This is in agreement with the conceptual models for the warm and hot springs which include a deep circulation system for meteoric water to reach a sub-surface heat source and a suitable, fast conduit back to surface.

However, it remains unknown whether the noble gas signatures from the warm and hot springs represent local anomalies being characteristic for areas with geothermal resource potential. If this is the case, noble gas data, especially helium isotope ratios, could be used as an exploration tool for geothermal resource assessments once background values have been established. More noble gas data from both thermal waters and cold groundwater in the wider areas of known warm and hot springs would be required to answer this question.

Molecular Dynamics study of Aqueous Solution: solubility calculation with kinetic and thermodynamic approaches

KAZUYA KOBAYASHI*, YUNFENG LIANG, AND TOSHIFUMI MATSUOKA

Kyoto university, Kyoto 615-8540, Japan
* Presenting author: k_kobayashi@earth.kumst.kyoto-u.ac.jp

Aqueous solutions are fundamental to chemistry, biology, geology and technology. Predicting the shape of growing crystals is of essential importance for industrious crystallization process. In geology, crystalization is also one of the most siginifcant phenomenon to be better understood.

The rock-salt crystal structure is the stable solid phase in contact with a saturated solution of NaCl at atomspheric pressure and at room or higher temperature, while the dihydrate is stable solid phase in contact with a saturated solution of NaCl below 0.1°C. The question is that how this different stable solid phase in contact will be reflected from the hydration structure of the solutions(namely, how the hydration structure varies with temperature), how the different hydration structure will influence the salt-solution interfacial structure and eventually affect the crystal growth. Solubility is one of the significant and measurable properties, which is directly related to these three particular aspects: 1)crystal growth; 2) salt-solution interfacial structure and 3) the ionic hydration structure.

Here, we have investigated the salt-solution interface system and the salt solution single-phase system at different temperatures by using molecular dynamics. The solubilities were calculated by using the direct calculation and the free energy calculation, which are kinetic approach and thermodynamic approach, respectively. The direct calculation employs a salt-solution combined system. When the system is equilibrated, the concentration in the solution area is the solubility. In the free energy calculation, we calculate separately the chemical potential of two systems: solid and solution. And the two chemical potential values are compared. When the chemical potential of the solution phase is equal to the chemical potential of the solid phase, the concentration of the solution system is the solubility.

Very interestingly, it was found that the crystal shapes obtained from the direct calculations are significantly different between high and low temperatures: while the clusters were observed at the crystal surface at low temperatures, the layered rock salt structure is formed at high temperatures. We found that the clustering behavior is tightly conncted with the adsorbed water.

The calculated solubilties from two different approaches have a general good agreement, where the values at low temperatures exhibit slightly lager deviation than those at high temperatures. We remarked that the solubility value from the direct calculation might be affected by the kinetic reasons: the newly formed crystal structure and the adsorbed water molecules.

Strategies of aerobic microbial Fe acquisition from montmorillonite: siderophores and Fe(III) reduction

K. KOEHN[1]*, J. DUBOIS[2], P. MAURICE[1]

[1]University of Notre Dame, 156 Fitzpatrick Hall, Notre Dame, IN 46556, USA, kkoehn@nd.edu, pmaurice@nd.edu (* presenting author)

[2]University of Notre Dame, 251 Nieuwland Hall, Notre Dame, IN 46556, USA (jdubois@nd.edu)

Abstract

Iron bioavailability in aerobic, circumneutral environments is limited by low solubilities and slow dissolution kinetics of Fe-bearing minerals. Aerobic microorganisms have developed a number of strategies to obtain Fe, including release of siderophores, which are low molecular-weight Fe(III)-specific chelators. This research investigated the role of siderophores and other Fe acquisition strategies in Fe acquisition from the Fe(III)-bearing clay mineral montmorillonite (MMT) by an aerobic *Pseudomonas mendocina* bacterium. Fe-limited batch experiments were conducted using a wild-type (WT) *P. mendocina* strain that produces siderophore and an engineered mutant with a siderophore(-) phenotype. Based on measurements of population densities coupled with a molecular biosensor assay that monitors the promoter activity of the siderophore biosynthesis gene, and measurements of cells' reducing ability, it appears that both siderophore -related and -independent Fe acquisition strategies may play a role in Fe acquisition.

WT siderophore-producing cells actively grow and metabolize when MMT is the sole Fe source, but sideorphore sorption to clay particles may limit the concentration of dissolved siderophore (and Fe-siderophore complex) accessible to cells at any given time. Cells may also obtain Fe from MMT by reducing clay-associated Fe(III), but because *P. mendocina* does not produce an exogenous reductant, such reductive Fe acquisition only occurs when direct physical contact is established between cells (or organic biofilm components) and MMT. Siderphore(-) mutant cells were able to increase intercellular Fe concentrations at earlier growth stages and to attain higher maximum population densities than the WT. This suggests that cell-associated reduction of MMT Fe(III) may potentially provide cells with a more rapid and energy-efficient Fe acquisition strategy from clays as compared with siderophore-dependent mechanism(s). Moreover, the reducing mechanism may be assisted by biofilm production that ensures direct contact with the clay and has the potential to physically limit diffusion of siderophores away from cells in batch cultures.

Changes in Southern Hemisphere atmospheric circulation over the past 2400 years inferred from the WAIS Divide ice core dust record

BESS G. KOFFMAN[1*], KARL J. KREUTZ[1], NATALIE M. MAHOWALD[2]

[1]University of Maine, Orono, USA, bess.koffman@maine.edu; karl.kreutz@maine.edu (* presenting author)

Abstract

The strength of the atmospheric circulation around Antarctica is intimately coupled to the rate of deepwater ventilation in the Southern Ocean, hypothesized to be the dominant control on atmospheric CO_2 concentrations on glacial-interglacial timescales [1, 2]. During the past ~2000 years, preindustrial atmospheric CO_2 concentrations changed significantly and, at times, rapidly [3]. There are several possible explanations for these observed changes, including changes in terrestrial biomass linked to human activities. However, the role of Southern Hemisphere westerly wind intensity on inter-annual to centennial timescales has not been evaluated fully, and may be important. High-resolution ice core microparticle records hold promise for reconstructing the strength of the atmospheric circulation because, as we have observed, the background dust particle size distribution (PSD) is primarily a function of wind strength. Moreover, PSD varies independently of total particle flux, implying different meteorological and climatic drivers. We present results from continuous analysis of mineral dust in the upper 577 m of the West Antarctic Ice Sheet (WAIS) Divide deep ice core (79.468° S, 112.086° W) and discuss the dominant controls on dust flux and PSD, as determined using reanalysis data and climate model output. In addition, we evaluate the periodicity of the dust flux and PSD records using wavelet analysis. We find that changes in the periodicity of the PSD (notably at ~1300 and 1600 C.E.) appear to be coincident with shifts in the strength of the Southern Annular Mode (SAM) climate oscillation, as inferred using the Law Dome sea salt proxy record [4]. We extend our interpretations of the dust record to the past 2400 years, offering new insights into how the atmospheric circulation around Antarctica changed, with possible impacts on ocean ventilation and atmospheric CO_2.

Dissolved organic carbon (DOC) originating from wetland and riparian soils is known to effectively bind rare earth elements, uranium, aluminum and iron and play an important role for the mobilization and transport of these elements from soils to the surface waters [1]. In this study we present long-term data from 15 nested streams and several riparian soils draining granitic till covered soils ranging over almost three pH units. We analyze for which metals dissolved organic matter can function as carrier across scales and during varying hydrochemical conditions.

Metal loading (mM Metal per mM Carbon) in the various subcatchment changes over scales in a very characteristic manner that is dominated by the relative distribution of the three prevailing landscape types: forest, wetland and sediment area. The almost constant relationship between La and U loading of organic matter throughout the whole 68km^2 large catchment is controlled by homogeneous mineralogy in the source areas, flow pathways and metal release in the riparian soils.

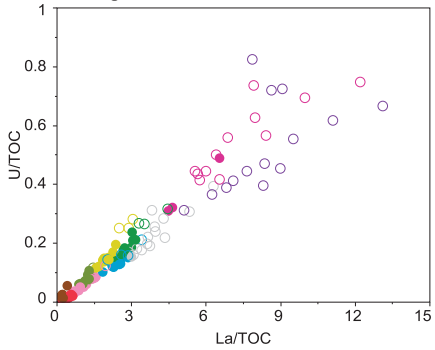

Fig. 1 Organic matter loading of U and La at all sites.

Soil solution data from one detailed soil catena along a hypothetical flowline indicate that organic matter leaches increasing amounts of trace metals during the riparian soil passage. The very similar Al and Fe loadings from 10 other riparian soils from different subcatchments are in accordance with the gradual change observed in the above transect for Al [2]. Our experimental data for metal speciation are in general accordance with those modelled using Visual Minteq [3] and confirm the importance of organic matter for metal mobility across scales from riparian soils.

Multiple growth events in diamonds from Murowa; evidence from FTIR mapping of N and H defects.

S.C.KOHN*, G.P. BULANOVA, C.B. SMITH, M.J. WALTER, A. MARKS AND A.P. MCKAY

School of Earth Sciences, University of Bristol, BS8 1RJ, UK
simon.kohn@bristol.ac.uk

The Murowa kimberlites [1] are located near the southern edge of the Zimbabwe craton. The few available measured ages suggest that the xenoliths and diamonds in the kimberlites date to 3.2 Ga and the kimberlite exhumation dates to 0.5 Ga, giving a residence time in the mantle for the diamonds of 2.7 Ga [2].

Here, we present FTIR maps of Murowa diamonds that show a range of growth histories. Whereas most diamonds show uninturrupted octahedral growth, or transitions from cubic to octahedral growth, a few show very clear evidence for at least two growth events. For example, one diamond (Mur-82) contains 130 ppm N in the core which is 82% aggregated to B centres, and a rim zone with 630 ppm N and only 16% aggregation. If both core and rim are assumed to be close in age, with a mantle residence time of 2.7 Ga, the core gives a temperature of 1205°C and the rim a temperature of 1087°C. A drop in lithospheric temperature of 120°C over a short time scale seems unlikely, so alternative scenarios with various combinations of temperature evolution through the period of growth have been modelled. Consideration of both the nitrogen aggregation zoning in individual diamonds, and the residence temperatures obtained for the collection of diamonds as a whole suggests that more than one period of diamond growth may be sampled. The implications of the results to models of the evolution of the craton (e.g. [3]) will be discussed. Detailed maps of hydrogen incorporated in diamond can also be obtained, and in some cases (e.g. Fig. 1) there is a hydrogen-rich zone or overgrowth at the rim. This implies a late stage growth event, possibly from a hydrogen-rich fluid.

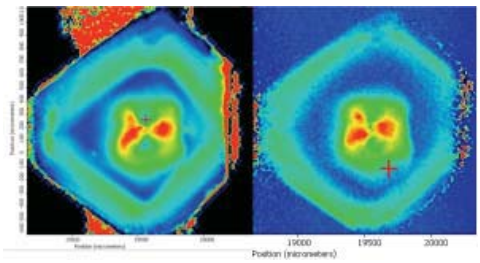

Figure 1: Contoured map of nitrogen concentration (left) and hydrogen concentration (right) in diamond Mur-79 . The diamond shows a transition from N and H rich cubic-growth core to octahedral-growth rim. Note also that the N-rich zone in the rim does not coincide with the H-rich zone at the very outer edge.

Atmospheric particulate matter in proximity to mountaintop coal mines

ALLAN KOLKER[1*], MARK A. ENGLE [1,2], WILLIAM H. OREM[1], CALIN A. TATU[1], MICHAEL HENDRYX[3], MICHAEL MCCAWLEY[3], LAURA ESCH[3], NICHOLAS J. GEBOY[1], LYNN M. CROSBY[1], AND MATTHEW S. VARONKA[1]

[1]U.S. Geological Survey, Reston, VA, USA, akolker@usgs.gov (* presenting author)
[2]University of Texas at El Paso, El Paso, TX, USA engle@usgs.gov
[3]West Virginia University, Morgantown, WV, USA mhendryx@hsc.wvu.edu

Introduction and Approach

In collaboration with West Virginia University, the U.S. Geological Survey is conducting a study of potential human health impacts associated with coal extraction by mountaintop mining (MTM). This practice, common in portions of Appalachia, exposes coal for production by explosion and removal of non-coal-bearing siliceous overburden. Past studies have primarily considered the geochemical impact of overburden disposal in valleys on aquatic life. Recent epidemiological work suggests disparities in the rates of some diseases between comparable MTM and non-MTM areas [1]. In the present study, we are evaluating potential human exposure to air- and water-sourced contaminants from MTM activity. Preliminary results reported here focus on air quality impacts. For this portion of the study, sized atmospheric particulate matter (PM) and geochemical window wipes were collected in two MTM areas and a control site over several days in June, 2011 (Table 1).

	V	As	Cd	Al	Ga	Rb	Ce
E/M fine	2.4	1.8	2.0	15.8	20.1	9.3	10.6
T/M fine	1.7	1.6	1.7	8.4	12.1	5.2	6.5
E/M	ND	ND	2.4	9.5	6.8	7.6	10.1
T/M coarse	ND	ND	3.4	7.5	5.5	5.6	5.9

Table 1: Results for selected trace elements in sized PM samples expressed as concentration ratios for MTM communities E and T vs. control area M. ND = Not detected.

Results and Conclusions

Results for PM and window wipes show anthropogenic contaminants (SO_4, V, Ni, Cu, As, and Cd) are comparable in concentration for MTM and non-MTM sites suggesting little additional local contribution in the MTM areas. However, "crustal" elements (Al, Ti, Fe, Ga, Rb, and rare earths) were much higher in concentration in the MTM areas. A preliminary analysis shows that local sources contributed 80 to 96% of these elements at sites E and T during the sampling period. Based on this analysis, residents of MTM communities are exposed to much higher levels of locally derived siliceous lithogenic material compared to the control. These results will be combined with drinking water quality data, expanded epidemiological mapping, and toxicologic studies to assess the impact of environmental factors in MTM areas on health outcomes.

Geology of the Nain Complex, Labrador, Canada: Occurrence of the Early Archean Supracrustals

T. KOMIYA[1*], M. SHIMOJO[1], S. YAMAMOTO[1], Y. SAWAKI[2], A. ISHIKAWA[1], K. KAZUMASA[1], K. D. COLLERSON[3]

[1]Dept Earth Science & Astronomy, Komaba, University of Tokyo, Tokyo, Japan, komiya@ea.c.u-tokyo.ac.jp

[3]The University of Queensland, Brisbane, Australia

The Hadean is the most mysterious period because no rocks and geologic bodies are preserved except for only the zircons in Western Australia, Canada, China and Greenland [1]. But, it is the most important period because the early evolution possibly clinched the earth's history. We try to find the earliest supracrustal rocks in the world to investigate the Hadean tectonics. As far, the oldest supracrustal rocks are found in Akilia association in West Greenland, Nuvvuagittuq in Quebec, and Nain Complex in Labrador [2,3].

We made geological survey in the Nain Complex, and reinvestigated the occurrence of the supracrustal rocks and their relationship with the ambient orthogneisses. Previous works focused on distribution of the supracrustal belts within the orthogneisses [e.g. 4], but the detailed field occurrence of the supracrustal rocks within the belts is still ambiguous. Therefore, we focus on their internal structures.

The supracrustal belts are repeatedly intruded by granitic intrusions with some ages and their original structures are obscured, but their lithostratigraphies are relatively well preserved in Nulliak, Big and Shuldham islands and St Jones Harbor. The supracrustal belts in Nulliak and Big islands comprise ultramafic rocks, mafic rocks and mafic sediments intercalated with feldspathic sediments and banded iron formations in ascending order. In the St Jones Harbor, it is composed of ultramafic rocks, mafic rocks, banded iron formation, and clastic sediments, intercalated with chert in the middle and with bedded carbonate rocks in the upper part, respectively, in ascending order. In the Shuldham Island, it consists of ultramafic rocks, layered gabbro with precursors of plagioclase and pyroxene accumulation layers, mafic rocks and terrigenous sediments in ascending order. The lithostratigraphies are very similar to oceanic plate stratigraphy. The fact that some supracrustal belts are intruded by Uivak I orthogneisses and presence of >3.86 Ga zircons in the supracrustal rocks [e.g. 3] suggest that the supracrustal belts have early Archean ages. In addition, despite of the still ambiguous relationship between Nanok Gneiss and supracrustal rocks, presence of Nanok Gneiss (3.85 to 3.91 Ga) in this area [5] implies that the supracrustal belts date back to the earliest Archean.

Banded Iron Formation as Seawater Proxies

KURT O. KONHAUSER[1*], LESLIE J. ROBBINS[1], MERLE EICKHOFF[2], ELIZABETH D. SWANNER[2] AND ANDREAS KAPPLER[2]

[1]University of Alberta, Edmonton, Canada (*kurtk@ualberta.ca)

Banded iron formations (BIF) are iron rich (~20-40% Fe) and siliceous (~40-50% SiO_2) marine sedimentary deposits that precipitated throughout much of the Precambrian. Recently, their trace element compositions have been used to determine paleo-seawater chemistry, with the ultimate goal being to better understanding nutrient availability (e.g., P, Ni, Zn) for the ancient marine biosphere [1-3]. Using BIF as ancient seawater proxies requires an understanding of the initial mineral precipitates, the adsorption/co-precipitation reactions that took place in the ocean water column, and the potential for post-depositional changes in sediment nutrient content. It has generally been accepted that ferric hydroxide, $Fe(OH)_3$, particles were the precursor sediment, and that mineral precipitation was intimately linked to the metabolism of planktonic bacteria. The nutrients that later became incorporated into BIF were either supplied as sorbates of the iron hydroxide particles or were components of the cellular biomass [4]. Subsequent deposition and burial of the mineral-cell aggregates then provided an abundant supply of electron donors and acceptors to the seafloor, which fueled sediment diagenesis and metamorphism. Preliminary work on the experimental transformations of ferric hydroxide-biomass composites at elevated temperatures and pressures has demonstrated that all of the ferrous iron minerals in BIF can be formed during late-stage diagenesis. Current experiments are being directed at understanding whether post-depositional alteration may have affected nutrient mobility, and thus, whether BIF composition can indeed be used as an ancient seawater proxy.

Mineralogical control of Se and Te signatures in peridotites: implications for the primitive mantle

STEPHAN KÖNIG[*1,2], JEAN-PIERRE-LORAND[3], FRANK WOMBACHER[2], AMBRE LUGUET[2] AND D. GRAHAM PEARSON[4]

[1] Universität Bonn, Steinmann Institut für Mineralogie, Germany, stephan.koenig@uni-bonn.de (* presenting author) [2] Universität zu Köln, Institut für Geologie und Mineralogie, Germany [3] Laboratoire de Planétologie et Géodynamique de Nantes, University of Nantes, France [4] University of Alberta, Department of Earth and Atmospheric Sciences, Edmonton, Canada

Selenium and tellurium belong to the group of highly siderophile elements (HSE) that are believed to constitute key tracers for planetary processes such as formation of the Earth's core and the Late Veneer composition. Constraints on HSE systematics on the planetary scale require, however, a previous understanding regarding the behaviour of these elements during petrogenetic processes and their abundances in the primitive upper mantle (PUM). Recent studies have shown systematic differences in Se/Te between fertile lherzolites and depleted harzburgites. In contrast to fertile lherzolites which remain at broadly chondritic values [1], depleted peridotites are highly fractionated with up to suprachondritic Se/Te (up to 35), where high Se/Te correlates with decreasing Te concentrations [2]. Fractionation is also observed at the scale of a single sample and results from the heterogeneous distribution of micrometer sized Te-bearing host phases in residual peridotites. On the whole rock scale this effect results in a more incompatible behaviour of Te compared to Se, once base metal sulfides are highly depleted and in some cases entirely consumed by partial melting. The marked differences in Se-Te systematics observed between fertile lherzolites and depleted harzburgites can be explained by the combined effect of i) different abundances and proportions of residual and metasomatic base metal sulfides and ii) discrete micrometric to nanometric platinum-group minerals. Hence, it is critical to fully understand Se-Te systematics in harzburgites if we are to provide new insights into the behaviour of Se and Te during mantle depletion. This knowledge is a prerequisite to further constrain the Se and Te abundances of the primitive upper mantle.

Complex burrow system of the mud shrimp *Laomedia astacina* and nutrient fluxes through its burrow

Bon Joo Koo [1*] and Chul-Hwan Koh[2]

[1]Korea Ocean Research and Development Institute, Ansan PO Box 29, Seoul 425-600, Korea, bjkoo@kordi.re.kr
[2]School of Earth and Environmetal Science, Seoul National University, Seoul 151-742, Korea, chkoh@snu.ac.kr

Abstract

Laomedia astacina had large and unique burrow systems (Fig. 1), and its extensive burrows increased the total area of the sediment-water interface by roughly 1,044%, the highest value among reported data on marine invertebrates. Oxygen concentrations in a *Laomedia* burrow showed large fluctuations with respect to tidal variation, and the burrow was flushed by active irrigation, which caused a more than 100 times increase in oxygen supply to the burrow when compared to passive irrigation. The range of oxygen concentrations was different depending on the location of the burrow. It seemed to be determined by the activity of the shrimp and by the burrow structure. Burrow water mainly out-flowed through the mound lumen (about 90% of total water flow) and in-flowed only through the funnel lumen. The average burrow irrigation rate during flooding of about four hours duration was 24.7ℓh^{-1} in the mound and 2.9ℓh^{-1} in the funnel. At this irrigation rate, the inhabitants would flush their burrow water a maximum of 9.4 times during a flooding event. Nutrient flux through *Laomedia* burrows ranged from 23~224% of that on tidal flats, which included the flux through both macrofaunal burrows and the sediment surface, indicating that large and actively-irrigated burrows are important in material exchange between sediments and overlying water. These results suggested that nutrient flux may not be correctly determined unless tidal variation, daily variation, and deep burrows are taken into consideration.

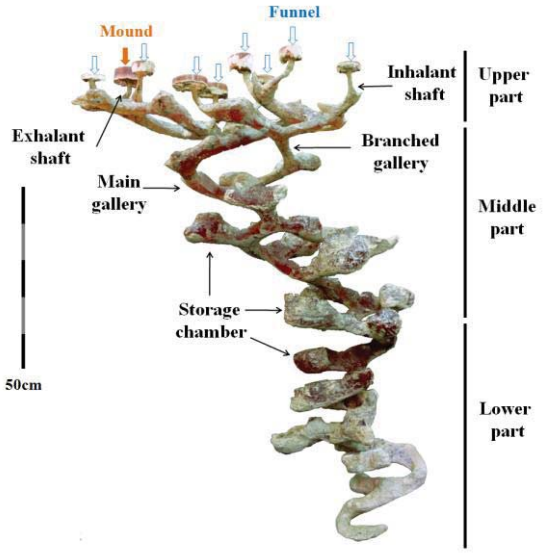

Figure 1: The complex burrow system of the mud shrimp *Laomedia astacina* recovered from Korean tidal flat.

Use of 10^{12} and 10^{13} Ohm resistors in TIMS analysis of Sr and Nd isotopes in sub-nanogram geological and environmental samples

J.M. KOORNNEEF[1*], CLAUDIA BOUMAN[2], AND G.R. DAVIES [1]

[1]Department of Petrology, Vrije Universiteit Amsterdam, the Netherlands, janne.koornneef@falw.vu.nl (* presenting author)
[2] Thermo Fisher Scientific, Bremen, Germany.

Analysis of isotope ratios in small geological and environmental samples such as inclusions in diamonds or individual human hairs is ultimately limited by the detection system of the mass spectrometer. Here we report a technique using a TRITON Thermal Ionisation Mass-Spectrometer (TIMS) equipped with nine Faraday cups to measure sample sizes up to 10 times smaller than currently feasible. Use of current amplifiers with 10^{12} Ohm and 10^{13} Ohm resistors instead of the standard 10^{11} Ohm resistors promises a 3-fold and 4-5 fold improvement in signal to noise ratios, respectively. This improvement results in higher precision on analyses of small ion beams.

The precision of measurements of 100 pg Nd and Sr standards is found to be a factor of ~2 better for the 10^{12} ohm resistors compared 10^{11} Ohm resistors (i.e., 2RSE of 64 ppm instead of 110 ppm for a Nd analysis). The reproducibility of the $^{143}Nd/^{144}Nd$ and $^{87}Sr/^{86}Sr$ ratios for 100 pg standards using 10^{12} Ohm resisitors is 235 ppm for Nd (2RSD, n=20) and 133 ppm for Sr (2RSD, n=10). Thus, variability in Nd and Sr isotope ratios in the 4th decimal place, e.g. $^{143}Nd/^{144}Nd$ 0.5110 – 0.5119 or $^{87}Sr/^{86}Sr$ 0.7100-0.7109, can be resolved in such small samples, provided that the procedural blanks and chemical separation are optimal.

Preliminary data using current amplifiers with 10^{13} Ohm resistors indicate that the precision (2SE) on Nd isotope ratios for beam sizes of 40 μV (~2500 cps) is 1%. The high gain amplifiers can thus be used instead of multi ion counting and/or in the range between ion counting and Faraday cups, equipped with the standard 10^{11} Ohm resistors. Use of the 10^{13} Ohm resistors is prefered over multiple ion counting systems as potential problems with non-linearity, instability, or the limited dynamic range of the ion counters are avoided. This new methodology thus potentially opens up new applications in a range of studies on small sample sizes.

Adsorption of Metals and Oxyanions on Mineral Assemblages

CARLA M. KORETSKY *[1]

[1]Western Michigan University, Department of Geosciences, Kalamazoo, MI, USA, carla.koretsky@wmich.edu (* presenting author)

Trace metal contamination of near surface aquatic systems has created a need for accurate predictive models of inorganic contaminant speciation and transport in the natural environment. Thermodynamically-based surface complexation models (SCMs) can successfully describe adsorption of single metals and oxyanions on a diverse suite of pure substrates, including bacteria, amorphous and crystalline solids. Application of SCMs to better understand metal fate and mobility in natural systems requires models that can correctly predict adsorption in mixed mineral assemblages and over broad ranges of pH, ionic strength, pCO_2 and metal loading.

Adsorption edges for Cd, Co, Pb, and Cu have been measured as a function of pH (~3-10), ionic strength (0.001-0.1 M $NaNO_3$) and solid loading (~2-5 g/L solid; 10^{-6} to 10^{-4} M metal) on pure kaolinite (KGa-1b), silica, and hydrous ferric oxide (HFO). Adsorption of the metals on synthetic mixtures of kaolinite, quartz and HFO are well predicted using diffuse layer models (DLMs) developed from data for the pure endmember systems under similar conditions. However, for systems of pure solids and for synthetic mineral assemblages, the DLM approach often fails to correctly capture adsorption trends over broad ranges of ionic strength and solid loading. This is a significant problem which should be recognized and explicitly addressed if SCMs developed for single solids are to be applied to natural systems.

Redox-sensitive sorbates, such as (Cr(VI), pose another challenge in developing SCMs that can correctly predict speciation in complex natural systems. Cr(VI) sorption on γ-alumina, a substrate which does not promote Cr(VI) reduction, is rapid and reversible. Single adsorption edges (pH ~4-10) measured at constant ionic strength (0.001 to 0.1 M $NaNO_3$), pCO_2 (0-2.5%) and loading (10^{-4} to 10^{-5} M Cr(VI) on 5 g/L solid) are well described using constant capacitance, double layer or triple layer models. However, none of the SCMs correctly describes Cr(VI) sorption over broad ranges in pH, ionic strength and pCO_2. Likewise, Cr(VI) sorbs quickly and reversibly on hydrous managanese oxide, and single edges are well described using the SCM approach. On clay minerals, however, development of SCMs is much more problematic due to slow and irreversible sorption, which likely reflects reduction of Cr(VI) to Cr(III) by organic matter or Fe(II) in the clay mineral lattices. On untreated kaolinite, Cr(VI) sorption at pH 3 is extremely slow, failing to reach a steady state even after 2 weeks of reaction time. Although sorption is rapid on untreated montmorillonite (Swy-2), on both kaolinite and montmorillonite, Cr(VI) fails to desorb at pH 10, even after several days. On kaolinite treated with HCl, hydroxylamine HCl or hydrogen peroxide, Cr(VI) sorption reaches steady state much more quickly, and more sorption occurs at pH 3-7 compared to the untreated kaolinite. These data point to the need for spectroscopic data to constrain SCMs describing Cr(VI) sorption on clay minerals.

Secondary Mineral Phases in a Uranium Mill Pilot Study

JOCELYN KOSHINSKY[1*], JOSEPH ESSILFIE-DUGHAN[2], M. JIM HENDRY[3]

[1]University of Saskatchewan, Saskatoon, Canada, jocelyn.koshinsky@usask.ca (* presenting author)

Introduction

The uranium milling process at Cameco's Key Lake operation in nothern Saskatchewan, Canada leaches untargeted elements of concern (EOC; e.g., arsenic, molybdenum, selenium, iron, radium-226) that have the potential to adversely impact local groundwaters and surface waters. [1] Studies at similar uranium milling operations indicate As concentrations are controlled by Fe oxide mineral phases such as ferrihydrite. [2-5] The environmental impact of EOCs in the Key Lake mill waste solution (raffinate) is mitigated by neutralizing the pre-discharge mine tailings with slaked lime, resulting in the formation of secondary As-, Mo-, Se-, and Fe-bearing mineral phases as well as co-precipitation of ^{226}Ra phases. This serves to control EOC concentrations at very low levels in the tailings porewater.

As part of an ongoing investigation into the long-term stability of EOCs in the Deilmann Tailings Management Facility (DTMF) at Key Lake, secondary mineral phases formed during the neutralization process must be characterized and the controls on the aqueous phase concentrations of EOCs defined for a variety of ore blends. A pilot-scale model of the Key Lake mill neutralization circuit was thus developed (Figure 1) to assist in quantifying the redistributon of EOCs during the milling process. Secondary precipitates and supernatants in the physical model are separated and analyzed using ICP-MS, XRD, and Raman spectroscopy. The results are compared to geochemical modeling of the mill neutralization process.

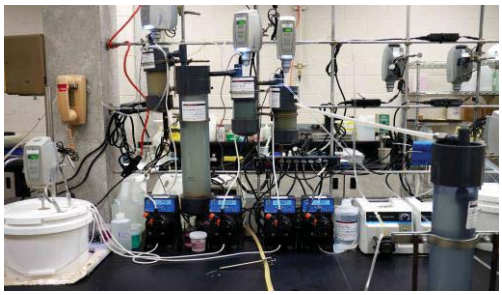

Figure 1: EOCs are removed from the raffinate by precipitation with slaked lime and thickener settling at pH set points.

Conclusions

A comparison of EOC percent removal efficiences from the pilot-scale model and the Key Lake milling process indicates that the model successfully reproduces conditions in the mill.

Prediction of B, Li and Si equilibrium isotope fractionation between minerals, aqueous solutions, melts and metals at high P and T

PIOTR M. KOWALSKI*, BERND WUNDER AND SANDRO JAHN

GFZ German Research Centre for Geosciences, Telegrafenberg, 14473 Potsdam, Germany; email: kowalski@gfz-potsdam.de

"Non-traditional" stable isotopes of light elements such as B, Li and Si are important geochemical tracers widely used in petrology. B and Li isotopes strongly fractionate between minerals and fluids during fluid-rock interaction. The fractionation of Si isotopes between silicate melt and iron-rich metal during Earth's core formation is assumed to produce the observed difference in isotopic signatures between the Bulk Silicate Earth and Chondrite meteorites. In order to understand the origin of these isotopic signatures we need to know the equilibrium isotope fractionation factors between the different materials of interest. They can be determined in high P/T experiments, which due to extreme conditions is often a difficult task, or computed. In order to deliver the required information we have developed an efficient *ab initio* based computational method for prediction of the equilibrium isotope fractionation factors between different phases at high P and T, including fluids and melts. We have tested our method by computing the B and Li isotope fractionation factors between complex B/Li-bearing crystalline solids (tourmaline, staurolite, spodumene and micas) and aqueous solution, and by comparison of the results with the existing experimental data. We show that we are able to reproduce correctly the experimental isotope fractionation sequences: fluid-tourmaline-mica for B and staurolite-fluid-mica-spodumene for Li and compute the fractionation factors with an uncertainty comparable to the experimental error [1]. In addition, we are able to get a valuable atomic-scale insight into the processes driving the fractionation of isotopes, such as coordination environment of cations, or speciation in fluids [1,2]. The computations also provide a better understanding of the experimental results such as "contradicting" measurements of B isotopes fractionation between mica and tourmaline [2]. With our method well tested on B/Li systems we attempt to derive the fractionation factors of Si isotopes between silicate melt and iron-rich metal fluid at the condition of Earth's core formation. We believe that the results of such theoretical investigation will help to better constrain the Si fractionation factors and address the question on the silicon content of the Earth's core.

Habitats worldwide have strongly been contaminated with industrial waste metals, such as Cd, which may potentially enter the food chain through plants. These contaminant metals have drastic effects on human and environmental health. Hence, there is a demand for the development and application of new techniques to efficiently remediate contaminated soils.

In the present study, we present a new Fe(III)-reducing *Geobacter* strain, isolated from a highly Cd-contaminated soil in Germany. This *Geobacter* strain reduces Cd-loaded Fe(III) hydroxide fast and to a large extent and thus mobilizes the Fe-mineral-bound Cd. Using X-ray diffraction we identified and characterized the Fe(III) minerals present during and after Fe(III) reduction. Synchrotron-based STXM-XRF analysis was used to locate Cd in the cell-mineral aggregates. Taking into account the data presented in this study, Fe(III)-reducing bacteria could potentially mobilize Cd in Cd-contaminated soils and make it more bioavailable. We are currently investigating whether the mobilized Cd is taken up and accumulated by the Cd hyperaccumulator plant Arabidopsis halleri, leading to the net removal of Cd from the contaminated site. Hence, combining enhanced natural attenuation and phytoremedation could potentially be a technique to remove metals from contaminated sites more time- and cost-efficiently. First studies in plant-microbe-soil microcosms showed that the presence of the naturally occurring microbial community compared to sterile conditions leads to a higher uptake of Cd into the plant A. halleri, potentially due to the presence and higher activity of Fe(III)-reducing bacteria.

Past changes in riverine input and ocean circulation in the Gulf of Guinea

STEFFANIE KRAFT[1*], SYEE WELDEAB[2], ED HATHORNE[1], MARTIN FRANK[1]

[1]GEOMAR | Helmholtz Centre for Ocean Research Kiel, Wischhofstr. 1-3, Kiel, Germany, skraft@geomar.de (* presenting author)
[2]University of California, Santa Barbara, USA

Large river systems draining the West African Monsoon area deliver sediments and dissolved trace elements into the Gulf of Guinea (GoG) in the easternmost equatorial Atlantic. The different catchment areas of these river systems are characterized by different geological ages and rock types releasing distinct radiogenic neodymium isotope compositions during weathering which are supplied to the GoG. The main rivers discharging into the GoG are the Niger, the Sanaga, the Nyong and the Ntem with present day εNd signatures of -10.5 [1], -12.3, -12.5 and -28.1 [2], respectively. These riverine inputs mix with the tropical Atlantic surface waters. At intermediate water depths Antarctic Intermediate Water (AAIW) prevails whereas the deep basin at this location is mainly filled with NADW.

We focus on a marine sediment core that was recovered off the Sanaga and Ntem Rivers and we reconstruct changes in riverine inputs and in mixing of surface and deep water masses over the past 140,000 years.

Changes in riverine inputs most likely reflecting latitudinal shifts of the rainfall zones across the different catchment areas were obtained from the Nd isotope signatures of the residual detrital fraction of the sediment. Sediment leachates of several GoG core top samples reflect the riverine input from nearby rivers indicating transport of particles coated in the rivers. Both the sediment leachates and the residual detrital fraction show similar patterns, with shifts towards radiogenic values during the interglacials and least radiogenic values during glacial periods. This shift in εNd values may be attributed to the migration of the rainfall zones towards the north during interglacial times and thus implies the increased influence of the northern rivers, the Sanaga and Nyong.

The oxidatively-reductively cleaned planktonic foraminiferal calcite of the core top samples in the GoG reflects surface seawater signatures. Non-reductively cleaned planktonic foraminiferal tests and cleaned shallow endo-benthic and epi-benthic foraminiferal tests were used to acquire information about past bottom waters. Difficulties in cleaning down core foraminiferal samples were experienced and these samples appear to be contaminated by secondary manganese and iron bearing phases, even after cleaning. Those phases may have overprinted the original surface water Nd isotope composition in the planktonic foraminiferal tests. As the planktonic and benthic foraminiferal values are overall similar to the sediment leachates, the foraminiferal isotope signatures are most likely overprinted by isotopic signals originating from the rivers due to remobilization processes in the sediments and formation of secondary phases such as Mn-carbonates, which are attached to the foraminiferal calcites.

Sulfate-reducing bacteria (SRB) have been identified to facilitate present-day dolomite formation under hypersaline conditions. Our laboratory study demonstrates for the first time, to our knowledge, primary Mg-rich dolomite formation in biofilms of the marine sulfate-reducing strain *Desulfobulbus mediterraneus,* under modern seawater salinity and Mg/Ca ratio. Spatial distribution of crystals within the biofilm was investigated using confocal laser scanning microscopy. Crystal morphology and mineralogy were examined with scanning electron microscopy, X-ray diffraction, and electron microprobe. Values of $\delta^{44/40}$Ca of crystals, biofilm, and bulk fluid were analyzed by double spike thermal ionization mass spectrometry. Mg-dolomite crystals precipitated in association with extracellular polymeric substances (EPS) in the biofilm. Three days after inoculation, nucleation of single nano-spherulites (~50 nm) was observed, subsequently aggregating to spherulites of ~2–3 μm in diameter after 14 days. Differences in Mg/Ca molar ratios and $\delta^{44/40}$Ca (‰) values between the biofilm material (including cells and EPS; 0.87 ± 0.01 [2 SD] and 0.48‰ ± 0.11 [2 SE], respectively), the crystals (1.02 ± 0.11 [2 SD] and <0.08‰ ± 0.24 [2 SE], respectively), and the liquid bulk medium were observed after mineral precipitation (4.53 ± 0.04 [2 SD] and 1.10‰ ± 0.24 [2 SE], respectively). These data indicate that the EPS bind relatively more Ca^{2+} than Mg^{2+}. We also propose a two-step fractionation process for Ca, shown by successive relative enrichment of ^{40}Ca in the biofilm and the crystals, compared to the bulk medium. Our results demonstrate the capability of EPS to overcome kinetic inhibition for dolomite, also suggesting contribution of SRB to dolomite deposition during periods of low oxygen concentration in the Phanerozoic.

Biogenicity of iron microfossils based on the morphology, physiology, and behavior of modern iron-depositing microbes

SEAN T. KREPSKI[1]*, PATRICIA L. HREDZAK-SHOWALTER[2], DAVID EMERSON[3], GEORGE W. LUTHER III[2] AND CLARA S. CHAN[1]

[1]Dept. of Geological Sciences, University of Delaware, Newark, DE 19716, USA (*krepskis@udel.edu)

[3]Bigelow Laboratory for Ocean Sciences, West Boothbay Harbor, ME 04575, USA

Many iron-depositing microorganisms make distinctive iron mineralized filaments, which form iron mats in oxic-anoxic transition zones. These organisms and their mineral byproducts are found in environments ranging from wetlands to deep-sea hydrothermal vents. Iron-depositing microbes have likely been significant biogeochemical agents throughout much of Earth's history (e.g. deposition of iron formations). Iron filaments, similar to those of modern iron-depositing microbes, are found in the rock record. If we can confidently determine biogenicity and interpret physiology, these structures could be powerful tools to understand the microbiological and redox history of Earth. In our research, we are developing quantitative biogenicity criteria, based on multiple extant organisms and environments, and linked to physiology.

We investigated growth and biomineralization by the marine *Mariprofundus ferrooxydans* PV-1, as well as *Leptothrix*-like organisms enriched from a freshwater iron seep. Microbes were grown in opposing O_2/Fe(II) concentration gradients in flat glass growth chambers, which allowed for direct microscopic observation of growth. We documented microbial biomineralization by time-lapse light microscopy, and measured filament widths and directionality (as circular variance) over space and time. Microscopy was also coupled with solid-state electrode voltammetry to pair imaging with *in situ* measurements of chemical microenvironments. Our results show that microbial iron filaments display a narrow range of widths, and strong directional formation (showing small circular variance values) parallel to redox gradients. Biomineralization occurred under low oxygen levels, indicating the oxygen microenvironment of iron-depositing microbes. Filament widths and directionality varied over space and time, reflecting microbial growth and chemotaxis. We also made similar measurements on putative iron microfossils and found that they showed quantitatively similar patterns with regard to filament width and directionality. This work shows that iron filaments with a narrow range of widths, and directional formation can form the basis for strong morphological biosignatures. These signatures can be indicative of microaerophilic iron-depositing microbial activity and physiology in ancient environments. Strong biogenicity criteria will aid in the interpretation of iron microfossils, and will help us to piece together the redox history of Earth.

New water column profiles of dissolved thorium and protactinium in the western North-Atlantic

SVEN KRETSCHMER[1]*, PERE MASQUE[2], WALTER GEIBERT[3], MICHIEL RUTGERS VAN DER LOEFF[1]

The strength of the Atlantic Meridional Overturning Circulation (AMOC) is a major factor in the global thermohaline circulation system. Because of this central role of AMOC in the global climate system, it is important to have reliable tools to reconstruct the strength of deep water ventilation in general and of AMOC in particular during major phases of past climate variability. The basin-wide Atlantic $^{231}Pa/^{230}Th$ signature in sediment archives has been identified as a powerful tracer for the intensity of the AMOC in the past. The information on ocean circulation arises from an overall higher export rate of ^{231}Pa over ^{230}Th within NADW from the entire Atlantic basin to the Southern Ocean due to the somewhat lower particle reactivity of ^{231}Pa.

A fundamental complication for reliable applicability of this tool arises from the fact that there is a severe lack of data of these isotopes in the critical areas of the modern AMOC. Only very few ^{230}Th and ^{231}Pa profiles in the Labrador Sea, in the NE Atlantic, and in the tropical and South Atlantic have been published [1, 2, 3, 4].

To remove this gap, 14 water column profiles were sampled under trace metal clean conditions during the expedition of RV Pelagia (GEOTRACES Cruise GA02) on a transect following the North Atlantic deep water (NADW). At all stations the deepest sample was collected within the bottom nepheloid layer, providing information on the latest stage of signal development in the water column. Here we will present the first results on 5 profiles of dissolved ^{230}Th and ^{231}Pa along NADW between 15 and 55°N including also the crossover station Bermuda Atlantic Time-Series (BATS). With this study we aim to provide missing information of the factors controlling signal generation in order to answer the questions: What is the $^{231}Pa/^{230}Th$ isotope composition of the main water masses of the AMOC and how do the ^{230}Th and ^{231}Pa activities in NADW evolve on its way south and east? Can they be explained by ventilation or are there other controlling factors to identify such as the composition of suspended particles?

[3] Oak Ridge National Laboratory, Oak Ridge, TN, USA, rotherg@ornl.gov
[4] Pacific Northwest National Laboratory, Richland, WA, USA, eugene.ilton@pnnl.gov

The interaction of CO_2 with Na-rich montmorillonite clay (Na-mont) as an analog for a clay-rich caprock was studied to better understand how CO_2 might interact with caprock at P-T conditions relevant to carbon capture and storage (CCS). Neutron diffraction, excess sorption and Attenuated Total Reflectance – Fourier Transform Infrared Spectroscopy (ATR -FTIR) analyses of Na-mont at 35°C and 50°C, and pressures relevant to CCS, were conducted.

Neutron diffraction and excess sorption measurements were conducted on Na-mont at CO_2 pressures from 0-200 bars. Neutron diffraction measurements show a shift in the d(001) spacing from 12.10 Å to 12.55 Å and a decrease in the intensity of the d(001) peak, both of which are consistent with CO_2 entering the interlayer region of the clay. Excess sorption isotherms were determined gravimetrically to provide a better understanding of changes in the density of CO_2 near clay surfaces. Maxima in the excess sorption isotherms were observed at a bulk density ≈0.15 g/cm^3 and pressures of 58 bars (35°C) and 64 bars (50°C). As the bulk density of the CO_2 increases, the amount of CO_2 sorbed to the clay decreases.

To better understand the specific structural locations of CO_2 interaction with the Na-mont, the same clay sample examined by neutron diffraction and excess sorption was studied using ATR-FTIR. Measurements were conducted on both dried and hydrated Na-mont from 1-82 bars at 35° and 50°C. ATR-FTIR data show that the asymmetric stretch and bending mode of sorbed CO_2 is impacted by the presence of interlayer water, but the absorption bands due to adsorbed water between 3564 and 2975 cm^{-1} are not affected by the presence of CO_2. Specifically, the frequency of the asymmetric sorbed CO_2 band is at 2339 cm^{-1} in dehydrated clay, but at 2344 cm^{-1} in hydrated clay. The sorbed CO_2 bands increase in intensity with increasing CO_2 pressure. The stretching mode for the isolated inner hydroxyl groups at 3623 cm^{-1} is present in both the hydrated and dehydrated clay and is not affected by the presence of CO_2.

Analysis of the data indicates that sorbed CO_2 enters the interlayer space and potentially sorbs onto the edges of octahedral sheets in the Na-mont structure. If CO_2 does enter the Na-mont interlayer it could affect the rheological properties of the caprock, but further work is needed to determine if this might lead to a degradation or enhancement of seal quality.

Origin of Q-gases in pristine meteorites: an experimental study

M. KUGA[1*], B. MARTY[1], Y. MARROCCHI[1], L. TISSANDIER[1] AND L. ZIMMERMAN[1]

[1]Centre de Recherche Pétrographique et Géochimique - CNRS, Nancy, France (* correspondence : mkuga@crpg.cnrs-nancy.fr)

Most of heavy noble gases (Ar, Kr and Xe) trapped in primitive meteorites are hosted in the so-called phase Q which is commonly thought to be part of the Insoluble Organic Matter (IOM) of primitive meteorites [1]. This enigmatic phase is found in many classes of meteorites, implying that it was widespread in the early solar system [2]. Q-gases are characterized by an important fractionation relative to solar composition in favor of the heavy elements and isotopes (up to 1.3%/amu for xenon isotopes, the least-prone to isotopic fractionation) [2]. Despite many effort, the origin of Q-gases and the nature of their carriers are still poorly understood. Several experiments performed in the past decades showed that Q-gas characteristics could be reproduced to some extent by trapping ionized noble gases in various solids [3-7]. It has been interpreted by [6-7] as evidence for anomalous adsorption of xenon on growing or crumbled surfaces. This process takes place at low ion energy (<10 eV) and involves chemical bonds between ionized xenon and reactive sites onto the surface. Such a process could have occurred in the outer part of the protoplanetary disk or in the parent cloud, where gases and organics are subjected to intense UV light from the young Sun or near-by stars [8]. However, it remains unclear whether this process controls the xenon isotopic fractionation and if it can account for the light noble gas fractionation reported in phase Q [2].

The goal of this study is to better constrain the trapping and the isotopic fractionation of noble gases under ionizing conditions. Thus, we investigated the synthesis of carbonaceous particles in presence of noble gas ions by dissociating CO in a microwave plasma, at low pressure and ambient temperature. Solid particles were characterized by SEM, TEM, Raman Microscopy and Infrared Spectroscopy. The abundances and the isotopic ratios of noble gases were analyzed by static Mass Spectrometry.

Xenon trapped in carbonaceous particles is enriched in heavy isotopes by a factor of 0.2 to 1.7%/amu, depending mostly on the duration of the experiment. Assuming Henry's law for xenon trapping in carbonaceous particles, the trapping yield of xenon ions is 12000 mbar.(cm^3.g^{-1})$^{-1}$ in average, which can largely account for the amount of xenon trapped in phase Q [2,7]. Preliminary element ratios Ar/Xe and Kr/Xe are in the range of those measured in meteorites [2]. Future investigations will focus on the role of plasma parameters on the trapping efficiency and isotopic fractionation of Ar, Kr and Xe.

Partial-equilibrium concepts to model trace element uptake

DMITRII A. KULIK[1*], BRUNO THIEN[1], ENZO CURTI[1]

[1]Paul Scherrer Institut, Villigen PSI, Switzerland, dmitrii.kulik@psi.ch (* presenting author)

Uptake of trace elements into host minerals involves various mechanisms - from ion exchange and inner-sphere adsorption via surface entrapment or in-diffusion to structural incorporation upon precipitation or recrystallization. Even at long reaction time, their interplay may result in a metastable distribution of minor elements that deviates from complete aqueous- solid solution thermodynamic equilibrium. Uptake processes may proceed at widely different rates, e.g. fast (minutes to hours) for ion exchange and slow for re-crystallization (days to years), with important consequences for the reactive transport of contaminants. In this work, we explored how the rate-dependent uptake and metastability can be implemented in geochemical models using the partial equilibrium principle.

Thermodynamic models cannot be directly related to particular molecular mechanisms or their locations. Yet, some information can be retained in the model by introducing (i) multiple metastability constraints; (ii) mineral surface areas and site densities; and (iii) a set of 'layered', intrinsically metastable solid phases. In particular, the additional time-step-dependent metastability constraints [1] can be imposed on the amounts of solid solution end members. Because the specific free energy of the solid-aqueous interface is usually positive, solids with large specific surface area are metastable relative to coarse-crystalline counterparts. The surface free energy decreases due to adsorption, the extent of which is limited by the site density and the solid surface area. The limited adsorption can be modeled using the activity coefficient terms [2] or, more commonly, by adding the mass balances for surface- or permanent charge sites [3,4].

In usual aqueous - solid solution (AqSS) models, metastability constraints can only be set on bulk amounts of host and trace end members. In the new aqueous – layered solid (AqLS) model, 'seed' grains with defined specific surface, representing metastable cores of the solid, are enveloped by layers of the overgrown (or re-crystallized) solid solution phase. This 'overgrowth' part has its own metastability constraints linked to the surface area of 'seed' phase. The 'adsorption solution' phase can be linked to the surface area of either the 'layer' (in AqALS) or the 'seed' phase (AqAS).

These partial equilibrium concepts, combined with different models of uptake kinetics [5], have been implemented in the GEM-Selektor code (http://gems.web.psi.ch) and tested in simulations of uptake into carbonates, sulfates, and goethite. Major trends in the experimental data were reproduced well in all cases. A more detailed time-dependent distribution of trace elements in AqLS and AqALS models could be reconciled with the inferred uptake mechanisms.

The research leading to these results has received funding from the European Atomic Energy Community's Seventh Framework Programme (FP7/2007-2011) under grant agreement n° 269688.

Use of metallic nanoparticles in the groundwater treatment is a relatively new concept. Due to their small size nanoparticles exhibit both the critical necessities, a large surface area to volume ratio and ability to transport through finest porosity. Zero valent iron nano particles (nFe°) are perhaps the most used and kinetically efficient reactive material for in-situ groundwater treatment. Effective treatment ability of any reactive material does not depend only on maintaining reactive surface area and oxidation but also on the mobility through the finest pores within the sediment to be able to reach the targeted contaminants. Although there have been several studies recently, discussing the transport of nanoparticles in model porous media but the behaviour and interaction in real sediment is poorly understood. Geochemical interactions, non-uniform porosity and aggregation and oxidation of particles make it difficult to predict the effectiveness of treatment systems. We setup several bench scale flow through columns in laboratory to investigate the behaviour of the nFe° in subsurface transport. Several organic coatings were tested for surface modification to improve dispersion in aqueous media and mobility in sediment. Different porous media i.e. model sand, contaminated sediment and interaction with iron oxides were also tested for possible impact on mobility of nanoparticles. Oxidation kinetics of nanoparticles in aqueous medium was followed using different analytical tools like XAS, TEM and XRD analysis.

Our results show that the transfer of nanoparticles was largely affected by the geochemical interactions within the transfer medium. Transport of iron nanoparticles in model sand media was found to be largely different from the real sediment given the similar physico chemical parameters. We observed upto 95% transfer of nano particles in sandy porous media and upto 64 % in real sediment. The oxidation kinetics of nanoparticles after suitable surface coating in aqueous media was found to be relatively slow (~14 days), which allowed a relatively complete decontamination when tested against TCE contaminated groundwater in our experiments. Latest results will be presented.

Killed by geochemistry: Mass extinction in toxic oceans

LEE R. KUMP[1*]

[1]Dept. of Geosciences, Penn State University, University Park, USA, lkump@psu.edu (* presenting author)

The boundaries between geological periods often mark major losses of biodiversity, i.e., mass extinctions. Geochemistry is used to investigate these events, both to determine the trigger for the event (asteroid/comet impact, volcanism) and the event's cause (abrupt warming, anoxia, trace metal poisoning, loss of habitat by sea-level fall, global wildfires, etc.). For the Cretaceous-Paleogene event, although the trigger is well established to be asteroid impact, the kill mechanism is less clear, and trace metal poisoning may have played a role. For the end-Permian, evidence for oceanic anoxia and the spread of sulfidic waters into the photic zone is widely associated with the extinction horizon in marine sedimentary rocks. Detailed studies of the spatio-temporal distribution of geochemical and isotopic proxies together with numerical simulations of these events is leading to a clearer picture of the cause and consequence of mass extinction in Earth history.

Super-high atmospheric oxygen levels during the Great Oxidation Event

LEE R. KUMP[1*]

[1]Dept. of Geosciences, Penn State University, University Park, USA, lkump@psu.edu (* presenting author)

A combination of geological and isotopic evidence demonstrates that the atmosphere became oxygenated for the first time in Earth history roughly 2.5 billion years ago. The proxies for atmospheric oxygen in the rock record are quite sensitive, though; an atmosphere sufficiently oxygenated to support animal life may not have been established for hundreds of millions of years after this initial rise.

A new repository of geological information has recently become available, the result of scientific continental drilling in Fennoscandia (FAR-DEEP). Kilometers of drill core potentially record a detailed history of the path atmospheric oxygenation took through the critical interval from 2.5 to 2.0 billion years ago. Preliminary analysis of these cores has revealed an excursion in the carbon isotope composition of the ocean/atmosphere system that is best explained by a massive oxidation of the continental crust. The event terminates a well-known, equally anomalous but oppositely signed carbon isotope excursion that likely reflects a large accumulation of oxygen in the atmosphere from about 2.2 to 2.0 billion years ago. The hypothesis that arises from these observations is that atmospheric oxygen levels built up to levels that may have exceeded modern during the earlier interval, leading to pervasive oxidative weathering of the continental crust, the first in Earth history, and a large consumption of atmospheric oxygen during the termination event. The suggestion that oxygen levels may have exceeded modern levels during the early stages of planetary oxygenation is provocative, but is consistent with singular geologic events that happened at this time, including the generation of natural nuclear reactors resulting from concentration of uranium by oxygenated groundwaters, and the enrichment in the iron content of banded iron formations by oxidative weathering into ore-grade deposits.

The oil-water-vapor three-phase systems are investigated by molecular dynamics methods. The line tension has been calculated directly from local pressure profile. In this work, the line tension of decane-water-vapor system is estimated to be around -8.2×10^{-12} N, while the line tension of decane/heptane/toluene multicomponent-oil-water-vapor system has been obtained to 9.1×10^{-12} N. We suggested that the precursor thin film of toluene, which spreads preferentially over the water ahead of the bulk oil, is responsible for the fact that the line tension of decane-water-vapor system have increased from negative to positive values by adding heptane and toluene.

Zn isotope composition of Paleoproterozoic carbonates, banded iron formation and manganese formation

MARCUS KUNZMANN[1*], PAOLO A. SOSSI[2], GALEN P. HALVERSON[1], AND JENS GUTZMER[3]

[1]Department of Earth & Planetary Sciences/GEOTOP, McGill University, Montréal, Canada, marcus.kunzmann@mail.mcgill.ca (* presenting author), galen.halverson@mcgill.ca

Previous studies of Zn isotopes in the modern open marine realm demonstrate a consistent biological control of the Zn isotopic composition of the surface ocean. The micronutrient Zn is assimilated in the surface ocean by primary producers and exported to the deep ocean, where it is released by remineralization. Preferential uptake of the light isotopes enriches the surface ocean compared to the source (river-derived Zn in surface ocean, hydrothermal mantle Zn in deep ocean), resulting in a surface-to-deep isotope gradient akin to that of $\delta^{13}C$ of dissolved inorganic carbon. Since Zn is incorporated in carbonates without significant isotopic fractionation, Zn isotope ratios of carbonates precipitated in the surface ocean should track fluctuations in primary productivity.

We analyzed the Zn isotopic composition of ~2.2 Ga old shallow and deep marine carbonates, banded iron formation (BIF) and manganese formation (MnF) from the Kalahari Manganese Field in South Africa, which formed in a small rift basin. The $\delta^{66}Zn$ ($^{66}Zn/^{64}Zn$) composition of the carbonate fraction of dolostones mainly ranges from 0.20–0.63‰ (vs JMC-Lyon) and systematically varies with inferred paleo-waterdepth. $\delta^{66}Zn$ of BIF samples range from -0.25–0.49‰ and MnF samples from -0.36–0.68‰.

The observed range in $\delta^{66}Zn$ cannot be easily explained by analytical artefacts, such as spectral interferences or diagenetic re-equilibration. Hence, we argue that these data represent the composition of the stratified seawater in a Paleoproterozoic rift. Whereas microbial carbonates deposited above the chemocline are enriched (up to 0.63‰) due to the biological pump, deep marine rhythmites are closer to the mantle value (0.2-0.3‰). Upward deepening of the succession, from intertidal microbialaminites to subtidal thrombolites, is accompanied by a gradual decrease in $\delta^{66}Zn$ values. The highest Zn isotope values are significantly lower than those reported from Neogene carbonates, which could be due to lack of eukaryotes in the 2.2 Ga old ocean. Eukaryotes have higher Zn requirements than cyanobacteria and, therefore, more efficiently deplete ^{64}Zn in the surface ocean. MnF and BIF likely owe their large variability to formation close to the chemocline, resulting in enriched $\delta^{66}Zn$ values if deposited above the chemocline and mantle values if formed below the chemocline. Values depleted with respect to the mantle signature might be due to preferential adsorption of light isotopes by Fe and Mn hydroxides as observed during previous reported experiments.

Combined Lu-Hf and Sm-Nd isotope systematics of Martian meteorites

E. KURAHASHI[1,2*], E. E. SCHERER[2], T. KLEINE[1] AND K. MEZGER[3]

[1]Institut für Planetologie, Westfälische Wilhelms-Universität Münster, Wilhelm-Klemm-Str. 10, 48149 Münster, Germany (*e.kurahashi@uni-muenster.de, thorsten.kleine@uni-muenster.de)
[2]Institut für Mineralogie, Westfälische Wilhelms-Universität Münster, Corrensstrasse 24, 48149 Münster, Germany (escherer@uni-muenster.de)
[3]Institute of Geological Sciences, University of Bern, Baltzerstrasse 1, 3012 Bern, Switzerland (klaus.mezger@geo.unibe.ch)

The radioisotope systems of ^{176}Lu-^{176}Hf ($t_{1/2}$ = 3.71×10^{10} yr) and ^{147}Sm-^{143}Nd ($t_{1/2}$ = 1.06×10^{11} yr) are well suited to investigating Martian mantle evolution. All four of these elements are refractory and lithophile, so they should not have been fractionated during planetary accretion or metal-silicate separation during core formation. In contrast, silicate differentiation, e.g., melt extraction from the mantle, produces melts and residual mantle whose Sm/Nd and Lu/Hf differ from those of the parental reservoir. Over time, these secondary reservoirs diverge isotopically from the parental reservoir. To gain a better understanding of Martian mantle evolution, we are conducting a systematic investigation on Martian meteorites and their minerals, measuring both isotope systems on the same sample aliquot. Eleven bulk Martian meteorites (5 shergottites, 4 nakhlites, and 2 chassignites) have been examined so far. For each, 70 to 240 mg of powder were spiked with ^{176}Lu-^{180}Hf and ^{149}Sm-^{150}Nd, then digested in a closed Teflon vial with HF + HNO_3 (2:1) overnight on a hot plate, and again in steel-jacketed Teflon bombs for 5 days at 180 C°. After ion exchange chemistry, Lu and Hf isotopic compositions were measured by MC-ICP-MS (Isoprobe, Münster), and Sm and Nd were analyzed by TIMS (Triton, Münster). Initial ε^{176}Hf and ε^{143}Nd values range from +49.0 to +51.3 and +34.7 to +47.8, respectively, for depleted shergottites, -13.3 to -17.4 and -6.3 to -6.5 for enriched shergottites, +1.8 to +14.5 and +13.4 to +15.6 for nakhlites, and +16.3 to +24.9 and +15.3 to +15.4 for chassignites. These values from unleached samples agree well with those of previous studies [e.g., 1-7]. The initial ε^{143}Nd values of nakhlites and chassignites exhibit low variation relative to ε^{176}Hf. The time-integrated ^{176}Lu/^{177}Hf and ^{147}Sm/^{144}Nd of all investigated source reservoirs define a narrow trend within the terrestrial MORB + OIB field, with the sources of nakhlites and chassignites falling between those of depleted and enriched shergottites. Shergottites themselves display a large range of ^{147}Sm/^{144}Nd, with higher values at a given ^{176}Lu/^{177}Hf relative to MORB + OIB. The constraints placed by these data on the differentiation history, mineralogy, and dynamics of the Martian mantle critically depend on the accuracy of the samples' crystallization ages. In particular, the ages of shergottites have been debated (e.g., [2,3,7]). Evidence for young (474-150 Ma) and old ages, and the implications for models of silicate differentiation on Mars will be evaluated.

Noble gas distribution and migration in the oceanic crust: new results from ODP Hole 1256D

MARK D. KURZ [1]*, JOSHUA CURTICE [1], DEMPSEY E. LOTT III[1] AND THE IODP EXPEDITION 335 SCIENCE PARTY

[1]Department of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts, 02543, USA, mkurz@whoi.edu

In an effort to understand the relative contributions of mantle, radiogenic, and atmospheric/hydrothermal noble gas components in the ocean crust, we have performed helium, neon and argon measurements on a suite of gabbros, granoblastic dikes, and diorite veins in Pacific oceanic crust. The samples were collected during IODP Expeditions 312 and 335 to Hole 1256D, a deep crustal borehole drilled into 15 Ma ocean crust formed at the East Pacific Rise during an episode of superfast spreading (>200 mm/yr). The measurements were carried out by coupled vacuum crushing and melting in order to determine the fraction of gases held by fluid inclusions. Total helium abundances in the whole rock gabbros range from 0.46 to 1.22 micro cc STP/gram, which is 2 to 5 times higher than literature data, all of which are from the slow spreading Southwest Indian Ridge (Kumagai et al., 2003; Moreira et al., 2003). These strikingly higher helium concentrations place constraints on the thermal crustal history (due to relatively rapid helium diffusivity) and are assumed to reflect fundamentally different emplacement/degassing processes within crust formed at a super-fast spreading rate. Contact metamorphosed granoblastic dikes have total helium contents lower than the gabbros (typically ~ 0.15 micro cc STP/gram), but significantly higher than the assumed degassed basaltic protolith, suggesting that metamorphism adds helium to the crust. The helium isotopes obtained by crushing of the gabbros and granoblastic dikes are dominated by mantle helium, with average ^{3}He/^{4}He = 6.5 ± .2 times atmosphere (Ra). This value is at the low end of the range for normal Pacific MORB helium data and is interpreted to represent the mantle source. Crushing in vacuum releases a larger fraction of total neon and argon (28 to 64 %), suggesting that atmospheric/hydrothermal/alteration neon and argon are loosely bound, most likely in secondary alteration minerals. Small mantle argon isotopic components are only found in a few samples, mainly during the heating experiments. These data suggest that the atmospheric noble gas components are most likely to be expelled during subduction of the ocean crust.

A transect across an amphibole diorite vein within granoblastic basalt reveals remarkable heterogeneity with respect to noble gases, on a centimeter scale. The amphibole and plagioclase at the vein center have 5-10 times higher abundances of He, Ne, and Ar, and slightly elevated ^{3}He/^{4}He and ^{40}Ar/^{36}Ar. The length scale of the variability, the age of the crust, and the present temperature of the hole, place an upper limit on the bulk helium crustal diffusion coefficient of ~2 x 10^{-14} cm^{2}/sec at 70 C. The abundances and isotopic compositions are consistent with hydrous melting models of ocean crust for production of diorite veins. The small He and Ar isotopic variations might be due to post emplacement radiogenic components, and distribution of K, Th, and U, suggesting possible applications to geochronology.

Comparing felsic and mafic volcanics along Central America with implications for interaction with continental crust

[1] GEOMAR, Kiel, Germany, skutterolf@geomar.de(*)
[2] IfG at university of Kiel, Germany

The subduction of the Cocos plate beneath the Caribbean plate has formed the Central American Volcanic Arc (CAVA) extending from Guatemala through central Costa Rica. We have analyzed all Pliocene through Holocene felsic tephras along the volcanic front, which we compare with mafic tephras and lavas in terms of major and trace element as well as Sr-Nd-Pb-Hf isotope compositions. Thus we extend previous geochemical studies that have largely focused on mafic rocks while attempting to constrain mantle-source conditions. In contrast, our mafic-felsic comparison aims to identify crustal influences on evolving magmas along the CAVA.

Along the southern CAVA, incompatible-element and isotope ratios of mafic and felsic rocks co-vary in a fashion expected from simple fractional crystallization of mantle-derived melts. However, felsic compositions along the northern CAVA, from central El Salvador through Guatemala, deviate from the associated mafic compositions particularly for radiogenic and some HFS elements in a way that suggests interaction with Mesozoic continental crust. Our observations have two implications:

(1) The onset of the geochemical deviation places the transition from mafic to continental crust between San Vincente volcano and Ilopango caldera in central El Salvador.

(2) The reason that crustal contamination has affected the cooler felsic rather than the hotter mafic magmas argues against partial melting of crustal rocks but rather favors hydrothermal interaction of magma reservoirs with host rocks such that contamination of felsic magmas benefits from their longer residence times allowing for longer-lasting interaction of hot fluids with both the resident magma and the host rocks.

210Pb and 137Cs in margin sediments of the Arctic Ocean: controls on boundary scavenging

ZOU ZOU KUZYK[1*], CHARLES GOBEIL[2], AND ROBIE MACDONALD[3]

[1]Department of Geological Sciences and CEOS, University of Manitoba, Winnipeg MB, Canada, umkuzyk@cc.umanitoba.ca (* presenting author)

Abstract

Scavenging and burial of particle-reactive elements along continental margins play important roles in the oceanic biogeochemical cycling of many elements and may be particularly important in the Arctic Ocean, where the shelves are disproportionally large and there are extreme contrasts in productivity, particle supply and sedimentation between the margins and interior ocean. Water-column distributions of radioisotopes have provided insight into scavenging processes in the interior Arctic Ocean but the importance of, and controls on, scavenging in margin areas, which are not dominated by vertical processes, remain poorly understood. In this study, we report new measurements of the naturally-occurring radioisotope 210Pb and the artificial radioisotope 137Cs in 25 sediment cores that were collected broadly along the North American Arctic margin, from the North Bering Sea eastward to Baffin Bay/Davis Strait. We apply sediment profiles and inventories of 210Pb and 137Cs to the dual objectives of (1) determining and validating the sediment accumulation rates in the cores; and (2) assessing the intensity of scavenging and burial of particle-reactive elements along the North American Arctic margin. Outside the North Bering and Chukchi Sea shelves, most sediments contain an actively mixed surface layer and a subsurface layer in which sediment mixing appears to be negligible relative to sediment accumulation. Variation in sediment accumulation rates among the cores explains much of the variation in sediment inventories of 137Cs but little of the variation in the sediment inventories of 210Pb, which everywhere meet or exceed the total supply of 210Pb to the ocean by atmospheric deposition and 226Ra decay. Although the data imply enhanced scavenging all along the North American arctic margin, relative to the interior Arctic Ocean, there are also pronounced regional differences in the accumulation of 210Pb. Geographic disparities in the distributions of 210Pb and 137Cs in margin sediments are examined with regard to regional variations in sea ice cover, degree of terrestrial influence, productivity and strength of lateral exchanges with the interior ocean.

Adding value to exploration and the mining environment with isotopes

KURT KYSER[1]

kyser@geol.queensu.ca

Isotopes in exploration

Elemental geochemistry has proven invaluable in exploring for undercover ore deposits using a multitude of surface media. The anomalous concentrations of metals and compounds in ore deposits will disperse with geologic time and may result in slight aberrations in the normal background levels in the environs of the deposit. The challenge in exploration geochemistry is in finding those particular elements that reflect this process when the ore deposits reside at some depth below the surface. Most elements of interest have more than one isotope whose ratios can provide the most sensitive and precise way to fingerprint the source of an element, even though the concentration may not differ from backgroud.

The use of isotopes as definitive tracers of the origin of an element is exemplified by radiogenic Pb that has migrated from uranium deposits and non-radiogenic Pb that has migrated from VHMS deposits. The $^{207}Pb/^{206}Pb$ ratios in permeable sandstones, along unconformities or in fractures of cemented lithologies several kms from known sandstone-hosted uranium mineralization are aberrantly low and unsupported by co-existing U. This indicates that radiogenic Pb was introduced from the deposits post-mineralization. Similar results are evident using H, Li, C, N and U isotopes from U deposits. Similarly, low $^{206}Pb/^{204}Pb$ ratios in soils and vegetation above VHMS deposits at depth discriminate mineralized bodies buried ca. 100m below cover from background signals. S, Cu and Zn isotopes have the same response, despite surface media over the deposits and the background having similar elemental concentrations.

Carbon, N, O and S isotopic compositions in conjunction with elemental concentrations differentiate the least-altered from moderately-altered rocks as well as the specific geochemical alteration associated with the ore stage. Isotopic compositions and trace elements of these fluids are recorded in the ores and concomitant alteration and can be used to guide exploration at both regional and local scales.

Use of isotopes in the mining environment

As in exploration, isotopes can be used in the mining environment to fingerprint the origin of elements. For example, explosives used in mining and residual sulfides are potential sources of nitrate and sulfate pollution in the environs mines in S. Africa and Chile. However, isotopes of B, C, N and S indicate that the mine sites contribute only minor amounts of these compounds to the environment, but anthropogenic and agricultural sources of nitrate and sulfates are substantial. Similarly, the isotopic compositions of Cu, Zn and Pb are distinct from mining and anthropogenic activities on local, regional and even global scales.

Conclusion

Isotopes can add value to exploration for all types of ore deposits and provide new avenues to move up learning curves for both effective exploration and targeting of remediation strategies for mining.

Access to the largest geosphere laboratory in the world – the Äspö Hard Rock Laboratory

MARCUS LAAKSOHARJU[1], IOANA GURBAN[2*]

[1]Nova, Oskarshamn, Sweden, marcus.laaksoharju@gmail.com
[2] 3D Terra, Montreal, Qc, Canada, gurban@videotron.ca (* presenting author)

Nova FoU (Nova R&D) www.novaoskarshamn.se is a joint research and development platform at Nova Centre for University Studies Research and Development in Oskarshamn, Sweden. The platform is a cooperation between the Swedish Nuclear Fuel and Waste Management Co (SKB) and the municipality of Oskarshamn. SKB has a general policy to broaden the use within society concerning research results, knowledge and data gathered within the SKB research program. Nova FoU is the organisation which implements this policy by facilitating access for external research and development projects to SKB's facilities in Oskarshamn, Sweden (Fig. 1 and 2). The facilities are: Äspö Hard Rock Laboratory Äspö HRL) (located 450 meters underground), the Bentonite Laboratory, the Canister Laboratory and Site Investigations Oskarshamn.

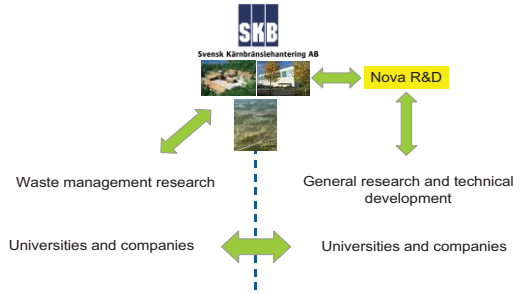

Figure 1: Nova FoU gives free access to the SKB facilities in Oskarshamn for general resarch and technical development within various geospehere projects and for technical development.

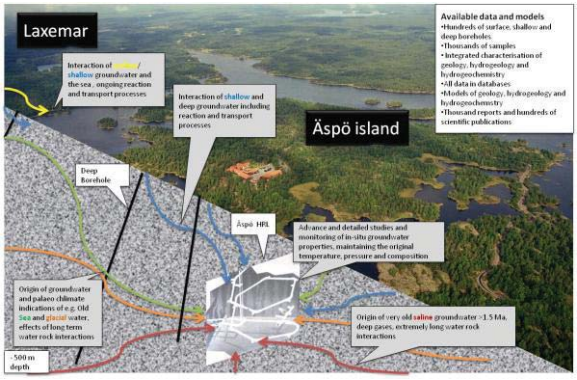

Figure 2: Research possibilities at Äspö HRL through Nova FoU

The unique Äspö Hard Tock laboratory is now open for new research outside the field of spent nuclear fuel. The present Nova status is that more than 20 projects are ongoing and engage 80 researchers. The total project value is 5 million USD. Major domestic universities and international universities are involved.

A new way to look at mantle heterogeneities : Multiple sulfur-isotope on Pacific Antarctic ridge

JABRANE LABIDI[1*], PIERRE CARTIGNY[1], CEDRIC HAMELIN[2], MANUEL MOREIRA[3], LAURE DOSSO[4] AND NELLY ASSAYAG[1]

[1]Stable isotope Laboratory, IPGP, Paris, France. (*labidi@ipgp.fr)

[4]CNRS, Domaines Océaniques, IFREMER, 29280 Plouzané, France.

On- and off-axis basalts have been collected along the Pacific-Antarctic Ridge (PAR) during the PACANTARCTIC cruises, between 65 and 40°S. The distance between this area and any of the numerous pacific hotspots (d>1000 km) allows determination of the average local upper mantle composition, undisturbed by any mantle plume [1]. Previous study [2] has revealed a subtle but significant Sr-Nd-Hf-Pb-He isotope variability for on-axis samples, mostly seen as the consequence of a large-scale melting process of a marble-cake assemblage. The off-axis samples, collected between 50 and 40°S, show more radiogenic $^{87}Sr/^{86}Sr$, $^{206}Pb/^{204}Pb$, and $^{4}He/^{3}He$ ratios, varying between the local mean MORB value and 0.703065, 20.2 and 180 000 respectively. Such values reflect an increased contribution of the marble-cake enriched component.

In order to better assess the nature of the local components and their distribution in the Pacific Antarctic mantle, we conducted a Sulfur multi-isotopes study on 29 on-axis and 8 off-axis samples from the PAR. Using an improved method allowing quantitative recovery of sulfur from basaltic glasses, we report data with external precision to be ± 0.005‰, 0.10‰ and 0.10‰ in 1σ for $\Delta^{33}S$, $\delta^{34}S$, and $\Delta^{36}S$ respectively.

All our samples are homogeneously ^{33}S and ^{36}S slightly depleted compared to the theoretical mass-dependent prediction, with a mean $\Delta^{33}S$ of -0.015 ± 0.004 (1σ) and a mean $\Delta^{36}S$ of -0.186 ± 0.046 (1σ). Besides, almost all the basalts are ^{34}S depleted when compared to the Canyon Diablo Troilite (CDT) standard. Their mean $\delta^{34}S$ is -0.68 ± 0.42 ‰ (1σ), varying between -1.2 and +0.6‰. $\delta^{34}S$ of our samples appears constant over lengthscales of several hundred kilometers with localized spikes of ^{34}S-enriched values, recorded mainly in on-axis samples. The $\delta^{34}S$ background of on-axis samples is constant at -0.8‰ from 65 to 46°S and reaches -1.2 ‰ northward. The off-axis basalts are equally ^{34}S depleted and also record the $\delta^{34}S$ background transition at 46°S.

We interpret the spike-like ^{34}S enrichments as the result of oceanic crust assimilation, in agreement with their high Cl/K ratios (>0.2) typical of fast-spreading ridge context. Taken together, the negative $\delta^{34}S$ recorded in the on- and off-axis basalts show that the local depleted mantle is statistically distinct of the chondrite reservoir ($\delta^{34}S$ = 0.0 ± 0.4 ‰), from the sulfur isotopes point of view. Finally, along ridge variation in the $\delta^{34}S$ background at the northern end of the area is concomitant with a Pb isotopic evolution toward less radiogenic values. This illustrates the isotope variability of the local enriched component, revealing that the marble-cake assemblage may contain more than one recycled constituent.

Marble with brucite and calcite is commonly the result of metamor-phism of dolomite rock in the presence of an H_2O-rich fluid through the reaction dolomite = periclase + calcite + CO_2 with subsequent replacement of periclase by brucite. We have conducted laboratory experiments to determine the rate and mechanism of the breakdown of dolomite and have found that dolomite converts to the product assemblage by the shrinking-core process, in which H_2O and CO_2 diffuse through a reaction rim of calcite and periclase. The reaction rate is diffusion controlled with an average rate given by $\langle d\xi/dt \rangle = 0.01\ t^{-0.75}$ (μmol/mm^2·s). The rate is a function of the composition of the fluid and approaches zero at the equilibrium value of x_{CO_2}, which is about 0.23 at the conditions of the experiments, 700 °C, 100 MPa. With these data, we can construct a kinetic model for metamorphism of dolomite rock in an infiltration system, as might occur in contact-metamorphic aureoles. The goal of the model is to compare the extent of reaction accounting for the finite reaction rate with the extent expected simply by assuming local equilibrium only. The model is isothermal and isobaric, to use the kinetic parameters determined by our experiments, and one-dimensional. Adjustable parameters include the flux at the inlet, the composition of the infiltrate, and the initial hydraulic conductivity of the dolomite. The model accounts for the production of porosity during reaction and the fluid pressure resulting from the change in composition during reaction. As an example, Figure 1 shows the composition of the fluid after infiltration of 1 mol H_2O/m^2·y for three times. For a dolomite rock with 1.52×10^4 mol dolomite/m^3, two orders of magnitude more time are required for the downstream fluid composition to change, and reaction is confined to the first meter. Even though the rate of dolomite breakdown is fast, its finite value can result in reaction over a zone a few meters wide.

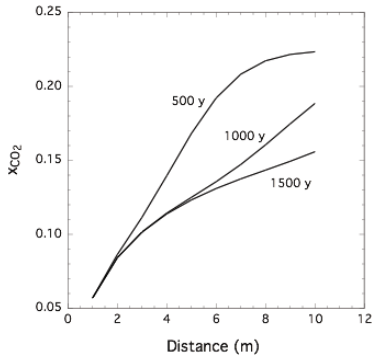

Figure 1: Fluid composition during infiltration with a flux at the inlet of 1 mol/m^2·y

Experimental study for determination of trace element sequestration in chrysotile

Introduction

Olivine alteration by serpentine is crucial to understand the fluid-mobile-elements cycle in geological systems. However, few hydrothermal experiments have quantified the partitioning of trace elements during serpentine precipitation is still poorly known and new experimental data are required.

Experimental protocols

In this study we characterized the trace elements (B, Li, As, Sb, Cs) partitioning between serpentine and alkaline fluids using two distinct experimental protocols. Alkaline conditions were choosen for the fast kinetic of reaction and the formation of few secondary phases. First, chrysotile nanofibers were synthetized from H_2SiO_3-$MgCl_2$-NaOH "silicagel system" at 300°C, Mg/Si=1.5, P_{sat}, (pH=13.5 at 25°C) in presence of a single trace element (5 to 200mg/L in solution in the starting fluid) to model equilibrium isotherms (Fig.1b). The second protocol, "alteration system", consists in serpentinisation of olivine grains at 200°C, fluid/rock=15, (pH=13.5 at 25°C), 3h<t<6 months with three olivine starting grain size. Serpentinisation reaction was characterized using XRD, FESEM (Fig.1a,c) and FTIR. Thermogravimetric analyses (TGA) was used as an inovative method to determinate kinetic of serpentinization.

Results

Fast serpentinization is observed in this "alteration system" leading to full olivine replacement by a porous assemblage of chrysotile nanotubes and Fe-rich hexagonal brucite in less than 30 days (for <30µm grain size). Chrysotile fibrous growing from "silicagel system" are very homogeneous and the presence of trace elements influence the size and morphology of partiles.

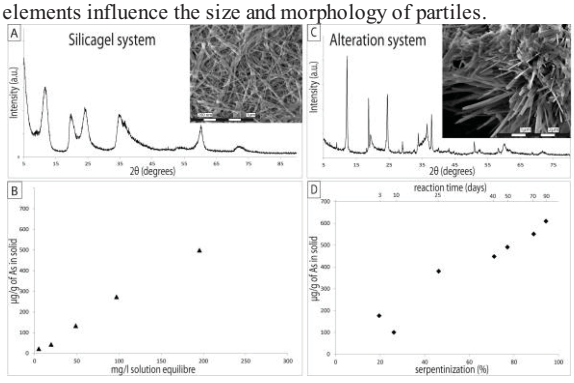

Figure 1: Exemple of results obtained in the two protocols

Results indicate that trace elements are significantly sequestreted by chrysotile in the both systems (e.g. up to 2000 ppm for Sb). Surprisingly, boron is the element with the lowest partitioning in serpentine in alkaline condition. In alteration systems, As (Fig.1d) and Cs incorporation follow rationally serpentinization advancement, Li and B seems not only controlled by chrysotile growth.

5f. Characterizing mid- to lower-crustal flow related to orogenic processes

The Repulse Bay block of Melville Peninsula, Nunavut, is hypothesized to be a crustal block that accreted to the Rae craton prior to terminal collision of the Superior craton during the Trans Hudson orogeny. The block consists primarily of Archean granitoid lithologies with interleaved sedimentary sequences that were deformed and metamorphosed at amphibolite to granulite facies. Within what is known as a central granulite facies domain, two different units were chosen for this study: a 2670 Ma enderbitic intrusion and a younger migmatitic metapelitic gneiss. The timing of 1) prograde and peak metamorphism, 2) deep crustal residence and 3) subsequent uplift of the Repulse Bay block are constrained using *in situ* LA-(MC)-ICPMS studies of Sm-Nd in apatite, and U-Pb in apatite and monazite from the study units. Within the migmatitic metapelitic gneiss, the timing of muscovite dehydration is well constrained by ca. 1847 Ma monazite and zircon in leucosomes, and the timing of biotite dehydration, interpreted to represent peak metamorphism having reached 800˚C and 9.5 kbar, is constrained by **ca.** 1811 Ma large monazite grains partially enclosed by peritectic garnet. The duration of deep crustal residence is documented by *in situ* Sm-Nd analyses on 50-200 μm magmatic apatite grains in the enderbite that reveal complete resetting of the Sm-Nd system during peak Trans-Hudson metamorphism. Based on the experimental diffusion data for Nd in apatite of Cherniak (2000), complete loss of radiogenic ^{143}Nd is expected to occur over a crustal residence time >2 myr for temperatures of 800˚C; quantitative accumulation of radiogenic ^{143}Nd is not expected until cooling below 725˚C for the apatite diameters we encountered. The decompression path is also recorded in the metapelitic gneiss by cordierite + spinel coronas surrounding garnet, indicative of near-isothermal decompression. Abundant small (< 10 μm) monazite inclusions within these coronas have a ^{207}Pb/^{206}Pb age of ca. 1770 Ma, interpreted to represent the timing of near- isothermal uplift to 4.5 kbar. Finally, preliminary U-Pb apatite geochronology demonstrates that the granulite facies domain then cooled to 450˚C by ca. 1700 Ma.

Results and Conclusions

These results suggest that the Repulse Bay block encountered a classic Himalayan-style orogenic cycle that was marked by relatively rapid burial followed by slow cooling during subsequent uplift. The sub-horizontal ductile fabrics preserved in the block are interpreted to have formed during granulite-facies mid-crustal flow between 1840-1810 Ma. The block was then uplifted to upper-crustal levels by 1700 Ma before final exhumation along major terrain-bounding shear zones.

Re-suspension of lead-contaminated soils a major health burden in cities

M.A.S. LAIDLAW[1], S. ZAHRAN[2], H.W. MIELKE[3], M.P. TAYLOR[1], D. MORRISON[4], AND G.M. FILIPPELLI[4*]

[1] Environmental Science, Macquarie University, North Ryde, Sydney NSW 2109, Australia

[2] Department of Economics and Center for Disaster and Risk Analysis, Colorado State University, Fort Collins, CO 80523-1784, USA

[3] Department of Chemistry and Center for Bioenvironmental Research, Tulane University, New Orleans, LA 70118, USA

[4] Department of Earth Sciences and Center for Urban Health, Indiana University - Purdue University Indianapolis (IUPUI), Indianapolis, IN 46202, USA, gfilippe@iupui.edu

Introduction

Soils in older areas of cities are highly contaminated by lead, due largely to past use of lead additives in gasoline, the use of lead in exterior paints, and industrial lead sources. Soils are not passive repositories and periodic re-suspension of fine lead contaminated soil dust particulates (or aerosols) may create seasonal variations of lead exposure for urban dwellers.

Results and Discussion

Atmospheric soil and lead aerosol data from the Interagency Monitoring of Protected Visual Environments (IMPROVE) database were obtained for Pittsburgh, Detroit, Chicago, and Birmingham (Alabama), USA [1]. The temporal variations of atmospheric soil and lead aerosols in these four US cities were examined to determine whether re-suspended lead contaminated urban soil was the dominant source of atmospheric lead. Soil and lead-in-air concentrations were examined to ascertain whether lead aerosols follow seasonal patterns with highest concentrations during the summer and/or autumn. Atmospheric soil and lead aerosol concentrations on weekends and Federal holidays were compared to weekdays to evaluate the possibility that automotive turbulence results in re-suspension of lead contaminated urban soil. The results show that the natural logs of atmospheric soil and lead aerosols were associated in Pittsburgh from April 2004 to July 2005 (R^2=0.31, $p < 0.01$), Detroit from November 2003 to July 2005 (R^2=0.49, $p < 0.01$), Chicago from November 2003 to August 2005 (R^2=0.32, $p < 0.01$), and Birmingham from May 2004 to December 2006 (R^2=0.47, $p < 0.01$). Atmospheric soil and lead aerosols followed seasonal patterns with highest concentrations during the summer and/or autumn. Atmospheric soil and lead aerosols are 3.15 and 3.12 times higher, respectively, during weekdays than weekends and Federal Government holidays, suggesting that automotive traffic turbulence plays a significant role in re-suspension of contaminated roadside soils and dusts.

Conclusions and Recommendations

To decrease urban atmospheric Pb concentrations, subsequent Pb-rich dust deposition and penetration into homes, and its consequent deleterious effect in childhood Pb levels, it is necessary to remediate and or isolate urban soils contaminated with Pb. While the US Federal Government has enacted legislation covering clean air and clean water, there is no universal clean soil act, although there are several standards pertaining to acceptable values. These guidelines are inconsistent across the US and in light of the evidence, they need to be harmonized and re-evaluated so as to develop a unified strategy to mitigate an unnecessary and preventable exposure pathway.

The mechanism for inhibition of calcite recrystallisation by organic molecules

LAKSHTANOV L.Z. [1,2,*], BELOVA D.A.[1], AND STIPP S.L.S.[1]

[1]NanoGeoScience, Dept of Chemistry, Copenhagen Univ, Denmark, leonid@iem.ac.ru (* presenting author), bd@gmail.com, stipp@nano.ku.dk

[2]Institute of Experimental Mineralogy, Chernogolovka, Russia.

The inhibitory effect of biopolymers, particularly by polysaccharides, could explain the extremely slow recrystallization rates of biominerals such as the calcite coverings on some species of algae that make chalk. Recrystallization can be considered as a series of simultaneous and consequent elementary events of dissolution and precipitation that leads to the diagenetic phenomenon known as grain coarsening. A driving force of recrystallization in geological environments is usually either the difference between lithostatic and hydrostatic pressures or the dependence of the chemical potential of the interface on the grain size. This coarsening process, where larger particles grow at the expense of smaller ones, is called Ostwald ripening.

It is well known [1] that the presence of aqueous organic anions (such as alginate) negligibly affects calcite dissolution rate. On the other hand, there is evidences that alginate significantly inhibits calcite precipitation [2]. Thus, it can be supposed that precipitation is the rate-limiting stage of the overall process of recrystallization, which, in turn should be affected by the presence of alginate. This conclusion is supported by our experimental study of ^{14}C isotope uptake during calcite recrystallization in a pure system and in the presence of alginate. Isotope concentration was monitored during the experiment, yielding the total amount of isotope uptake into the solid phase. An assumption about the mechanism of isotope uptake (i.e. burial into calcite layers newly formed during recrystallization) allows us to quantify the amount of newly formed material. Extent of inhibition of the calcite recrystallization rate because of alginate adsorption is comparable with that of calcite precipitation. This inhibition would take place as long as alginate is present in the solution. If there is no effective alginate supply, inhibition would sooner or later be decreased by exhausting the solution and burying the alginate molecules under the newly formed calcite layers, the more so, because adsorbed alginate could function as a substrate for calcite growth, initiated by the interaction of Ca with the negative end of the –C=O bond of the alginate functional group.

Organic matter (OM) depleted in $\delta^{13}C$, is considered an excellent tracer for terrestrial OM in aquatic systems. As a bulk measurement, it was also thought that $\delta^{13}C$ is less susceptible than molecular biomarker proxies toward bacterial reworking and degradation. It has been shown however, that $\delta^{13}C$ in total dissolved organic matter (DOM) can change as a result of photochemical reactions, with coloured, aromatic-rich terrestrial OM most susceptible to these reactions [1,2]. Here we further assess the viability of $\delta^{13}C$-DOM as a tracer for terrestrial OM in coastal systems by assessing the susceptibility of this proxy to UV radiation, which causes the photochemical destruction of chromophoric DOM. Our data set comprises 10 large rivers, which cumulatively account for approximately 1/3 of the world's freshwater discharge to the global ocean. We show that irradiation causes a 1.5‰ enrichment in $\delta^{13}C$ in almost all riverine DOM samples, demonstrating that riverine DOM, almost entirely terrestrial in nature, can artificially be branded as a mixture of terrestrial and marine DOM due to photochemical reactions. Photochemical alterations in $\delta^{13}C$ therefore bias mass balance calculations of terrestrial OM discharge and degradation in coastal oceans towards the marine end-member.

Germanium and silicon isotopic evolution of seawater inferred from Precambrian Iron Formations

STEFAN V. LALONDE[1*], KURT O. KONHAUSER[2], AND OLIVIER J. ROUXEL[3]

[1]European Institute for Marine Studies, UMR 6538 Domaines Océaniques, Plouzané, France, stefan.lalonde@univ-brest.fr (* presenting author)
[2]University of Alberta, Edmonton, Canada, kurtk@ualberta.ca
[3]IFREMER, Dept. Géosciences Marines, Plouzané, France, olivier.rouxel@ifremer.fr

The metalloid germanium behaves as silicon's geochemical twin as the result of their near-identical ionic radii and coordination environments, and the behaviour of Ge and Si in modern seawater are tightly correlated. However, two important exceptions exist: (1) in hydrothermal systems where Ge/Si is elevated due to Si uptake during quartz precipitation, and (2) in continental runoff, where Ge/Si is depressed due to Ge retention during clay formation. Contrasting Ge/Si of these two major marine Ge and Si inputs has led to the suggestion that Ge/Si ratios of siliceous sediments may be used as a paleo-proxy for evolving marine Si sources and sinks. Germanium has five stable isotopes (^{70}Ge, ^{72}Ge, ^{73}Ge, ^{74}Ge, ^{76}Ge), and natural Ge stable isotope variations stand poised to provide additional constraints on marine Ge and Si cycling past and present [1]. In this work, we examine secular changes in Ge/Si and the Ge and Si isotopic compositions of Si-rich metalliferous deposits to better understand their inter-relationship and implications for the evolution of marine silicon cycling. We focus on Precambrian iron formations as they predate the modern biological silicon pump and represent >3 Gyr of inorganic marine Si cycling that remains largely unexplored. Both $\delta^{74/70}$Ge and $\delta^{30/28}$Si data demonstrate a nearly 3‰ variation over geological time and Archean IF that are isotopically light relative to later deposits. A heavy excursion in Ge isotopes alone appears to coincide with atmospheric oxygenation ca. 2.5-2.3 Ga. This new dataset will be discussed in light of the proposal that silicon isotopes in Precambrian cherts record waning hydrothermal input and cooling seawater over geological time [2].

Size-fractionated particle mass and composition during the U.S. GEOTRACES North Atlantic Zonal Transect

PHOEBE J. LAM[1*], MAUREEN E. AURO[1], DANIEL C. OHNEMUS[1,2]

[1]Department of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, USA, pjlam@whoi.edu
[2]MIT-WHOI Joint Program in Oceanography, Woods Hole, USA

Particles are a key parameter for the international GEOTRACES program because of their role in mediating the cycles of so many trace elements and isotopes (TEIs). For example, the atmospheric or margin input of lithogenic particles is a source of many TEIs to the ocean; primary producers and consumers (biogenic particles) mediate the internal cycling of TEIs; and particles of all compositions are the vector for the scavenging removal of particle-reactive TEIs to the sediments. One of the key recommendations to emerge from the 3rd GEOTRACES Data-Model Synergy Workshop was the importance of measuring total suspended mass and major particle composition for GEOTRACES. These parameters are crucial for understanding the scavenging behaviour of many TEIs.

Here we present the major particle composition and the chemically-derived particle mass of the suspended (<51μm) and sinking (>51μm) size fractions for particles collected by in-situ filtration on the U.S. GEOTRACES North Atlantic Zonal Transect in occuppied in 2010 and 2011 (NAZT'10 and NAZT'11). Results from NAZT'10 Stn 10 in the eastern tropical Atlantic, 500 km away from the Mauritanian coast, show that particulate organic matter accounts for over 80% of suspended particle mass in the euphotic zone, declining to 25% near the seafloor at 3300m. The opal and $CaCO_3$ contributions at this station were less than 8% and 27%, respectively, of the suspended particle mass. The lithogenic fraction increased with depth until it accounted for 41% of suspended particle mass by 3300m. We will contrast this station with profiles from a selection of stations that represent a wide range of particle compositions, including the oligotrophic gyres, the TAG hydrothermal site, and the western and eastern margin stations.

Identification of trace amounts of H_2O in CO_2-rich fluid inclusions in granulite facies rocks

HECTOR LAMADRID[1*], ROBERT J. BODNAR[1], WILLIAM LAMB [2] AND M. SANTOSH [3]

[1] Department of Geosciences, Virginia Tech, Blacksburg, VA, USA, (lamadrid@vt.edu*)

[2] Department of Geology and Geophysics, Texas A&M University, College Station, TX, USA, (lamb@geo.tamu.edu)

[3] Department of Interdisciplinary Science, Faculty of Science, Kochi University, Kochi, Japan, (santosh@cc.kochi-u.ac.jp)

Granulite facies metamorphism is characterized by mostly anhydrous mineral assemblages that include orthopyroxene, plagioclase, garnet and quartz. It has been proposed that granulites are generated during dry melting of the deep crust at ultra high P-T conditions. The role of the fluids during granulite formation has been the subject of debate for decades. The debate is centered on whether or not low a_{H2O} fluids were present during metamorphism [1]. Numerous workers have reported high density "pure" CO_2 fluid inclusions as evidence that granulite facies fluids are carbonic and do not contain H_2O. However, silicate minerals show low solubilities in CO_2 and the poor wetting ability at grain boundaries inhibits infiltration, making it more difficult to dissolve silicate minerals and transport elements such as U and Rb out of the lower crust [1].

We show that H_2O is a common but minor fluid component in "pure" CO_2 fluid inclusions from various previously well-studied granulites. The inclusions were analyzed at 150°C using a recently developed technique that involves a Raman microprobe coupled with a Linkam THSG 600 heating/cooling stage [2]. Over a wide range of temperatures, CO_2 and H_2O are largely immiscible. Because of this, and because H_2O is the "wetting" phase, at room temperature small amounts of H_2O in CO_2-rich fluid inclusions will be present as a thin film wetting the walls and will be optically unresolvable [3]. In this study, fluid inclusions were heated from room temperature (~25°C) to a temperature above the one-phase / two phase boundary (≈150°C), and the liquid H_2O phase that occurs as a thin film at room temperature evaporated into the CO_2 phase. Raman analysis of this homogeneous phase at elevated temperature revealed the presence of H_2O, as evidenced by a small but sharp peak at ~3641 cm^{-1}. H_2O was detected in all primary-appearing fluid inclusions in quartz that formed at peak metamorphic conditions. In secondary fluid inclusions in garnet from Southern India, H_2O was not detected. Rather, hydrogarnet was found covering the walls of inclusions in this phase, as evidenced by a peak at ~3661 cm^{-1}. The hydrogarnet is interpreted to be a "step-daughter" phase that was formed by reaction of the H_2O in the fluid with the garnet host during retrogression. These observations suggest that granulites may not be as dehydrated as previously thought, and provide evidence for an H_2O-bearing fluid that could transport LILE out of the lower crust.

[4]Department of Earth and Environment, Franklin and Marshall College, Lancaster, Penn., stan.mertzman@fandm.edu

Late Mesozoic magmatic belt stretches north- south in the central Vietnam to the northern part of southern Vietnam. In the central Vietnam, at the eastern part of the Dalat zone, the Late Mesozoic plutonic and contemporaneous volcanic rocks are widespread, and are interpreted as subduction-related products (Nguyen Thi Bich Thuy et al., 2004a, b). The Late Mesozoic granitic rocks are divided into three suites: the Dinhquan, the Deoca and the Ankroet suites. The Dinhquan and Deoca suites are widely developed as a northeast-southwest trending belt south of the Kontum Massif and along the coast. The Dinhquan and Deoca granitic rocks are crosscut by Ankroet granitic rocks. The Ankroet suite is more quartz-rich with predominantly leucocratic sub-alkaline granites. Beside the main granitoid suites of Dalat zone, there are few scattered igneous bodies, especially the southwest corner of southern Vietnam, such as That Son and Ba Den batholiths. The Dinhquan, the Deoca and the Ankroet suites are also given for these batholiths although they are separated over 400 to 500 km from the Dalat zone. Our previous studies indicate the late Mesozoic granitic rocks of Dalat zone can be divided into two suites: the Dinhquan-Deoca I-type granite and the Ankroet A-type granite suites. In the field, mafic microgranular enclaves are rather common in late Mesozoic granitic rocks of Dalat zone. However, enclaves are less common in late Mesozoic granitic rocks in SW corner of southern Vietnam. We will present in-situ U-Pb zircon dating and Lu-Hf isotopic analyses, and whole rock geochemical and Nd-Sr isotopic analysis of Dinhquan, Deoca and Ankroet suites in SW corner of southern Vietnam in order to compare the characteristics of these granites suites with those from the Dalat zone.

Deciphering sedimentary recycling via multiproxy *in situ* analyses

PENELOPE J. LANCASTER*, SHANE TYRRELL AND J. STEPHEN DALY

University College Dublin, School of Geological Sciences, penelope.lancaster@ucd.ie (* presenting author); shane.tyrrell@ucd.ie; stephen.daly@ucd.ie

Sedimentary rocks and modern sediments sample large volumes of the Earth's crust, and preserve units that vary greatly in age and composition. Determining the provenance of component minerals is complicated by the ability of some minerals to be recycled through multiple sedimentary cycles, so minerals from completely unrelated sources may end up in the same sedimentary basin. To untangle these multi-stage signals, two or more chemical signatures measured in minerals with different stability are required. For instance, labile minerals, such as feldspar, can break down rapidly during sedimentary transport, while refractory minerals, such as zircon, can be much more resilient and survive repeated recycling.

One sedimentary succession suitable for testing this hypothesis is the Upper Carboniferous Millstone Grit Group, a fluvio-deltaic, upward-coarsening sequence of mudstones, sandstones and conglomerates deposited in the Pennine Basin of northern England. New data from throughout this sequence clearly indicate two main feldspar populations, consistent with previous work [1], but also a minor third group which may represent an additional source. Since rocks of similar ages typically describe overlapping domains on a $^{207}Pb/^{204}Pb$ vs. $^{206}Pb/^{204}Pb$ plot, the addition of zircon U–Pb and Hf measurements from the same sediments may help to discriminate between possible source areas.

Previous zircon U–Pb analyses in parts of the sequence have identified three main zircon populations at c. 500, 1000–1800 and 2700 Ma, with the proportion of young to old ages increasing up section [2]. This data set has now been extended to the rest of the sequence to create a statistically significant database covering c. 14 Ma of deposition in the Pennine Basin. With the addition of new Hf isotope data from the same zircons, the combination of all three isotope systems from the same units should fingerprint discrete source terrains within potential source areas, such as Greenland, north-west Scotland and the Southern Uplands of Scotland. As such, these data have significant implications for transport distances of both labile and refractory minerals.

Introduction

Reconstruction of past temperature from water isotopic records in deep ice cores in remote East-Antarctica is limited by several artefacts such as precipitation seasonality, limited knowledge of water isotopic fractionation at low temperature, temporal changes in hydrological cycle , post-deposition effects and possible input of stratospheric water. In order to address these issues, we present new combined measurements of all water stable isotopes ($\delta^{18}O$, δD and $\delta^{17}O$) at the remote East Antarctica site of Vostok (78°27 S, 106° 50 E) at three timescales: seasonal, interannual and over the last 150 kyears Before Present. Indeed, the combination of water isotopes such as d-excess ($\delta D - 8\times\delta^{18}O$) and ^{17}O-excess ($\ln(\delta^{17}O+1) - 0.528\times\ln(\delta^{18}O+1)$) are especially sensitive to organisation of the hydrological cycle, changes in kinetic vs. equilibrium fractionations and post-deposition effects.

Results and Conclusion

The relationships between $\delta^{18}O$, d-excess and ^{17}O-excess display very different patterns on the three different timescales. The results on the seasonal cycle suggest a much more important influence of temperature on d-excess and ^{17}O-excess than previously assumed which is helpful to constraint fractionation conditions at very low temperature. It also shows that seasonality should be taken into account when interpreting deep ice cores isotopic records.On the opposite to seasonal cycle variations, we show that the strong variations of $\delta^{18}O$, d-excess and ^{17}O-excess observed at interannual timescale can not be explained only by temperature effects but that processes such as post-depositionnal effects or hydrological cycle reorganizations should be invoked. Finally, we compare these different results with general circulation model outputs including water isotopes to test the capacity of such models to represent water isotopic composition in remote regions of East Antarctica.

Measurement of the reactive surface area relevant to CO_2 mineralization in a reservoir sandstone

GAUTIER LANDROT*, JONATHAN B. AJO-FRANKLIN, STEPHANO CABRINI, CARL I. STEEFEL

Lawrence Berkeley National Laboratory, Berkeley, USA, gjlandrot@lbl.gov (* presenting author)

Introduction

The accessible surface area of reactive minerals considered in reactive transport models are needed to multiply rate constants associated with the reactive minerals, since the latter are typically normalized to a unit surface area. An experimental approach is developed and applied in this study that enables the measurement of the surface area of each reactive mineral located within the connected pore network of a sandstone from a carbon sequestration pilot site in Cranfield, Mississippi [1]. Several analytical techniques are used that probe the sample at different scales and dimensions, including X-ray based micro-tomography (u-CT), Energy Dispersive X-ray Spectroscopy-Scanning Electron Microscopy (SEM-EDX), Backscattered Electron Microscopy (BSE-SEM), and Focus Ion Beam-Scanning Electron Microscopy (FIB-SEM). In contrast to the methods commonly employed to measure mineral surface areas, our approach accounts for the fraction of the mineral surface that is accessible to transport. Our method thus may help minimize the discrepancy often observed in the literature between the rates predicted by models and those measured in the field, and could be used in reactive transport models that would accurately predict the fate of CO_2 in the deep subsurface.

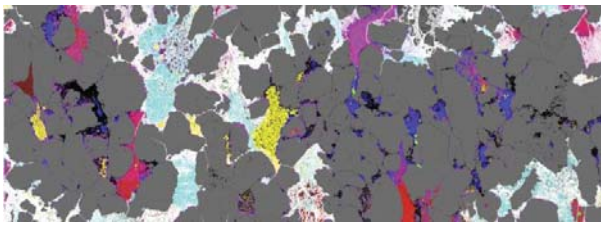

Figure 1: Mineral accessibility mapping

Results and Conclusion

The accessible surface area of each reactive mineral present in the sandstone is inferred, in m^2/g, by multiplying the fraction of each reactive mineral next to the connected pore network, measured in 2D (Figure 1), with the surface area of the connected pore network in the rock, which is measured in 3D from u-CT tomography images.

The characterization approach employed in this study is suitable for mapping the mineral distribution and pore structure found in a reservoir sandstone currently being considered as a sequestration site. Our approach could be also employed to characterize the physical and chemical properties of the rock after CO_2 injection. This would be useful in determining where precisely carbon dioxide is trapped in the rock and in identifying the CO_2 sequestration mechanisms.

The density, thermal expansion and compressibility of FeO in model basalts (An-Di-Hd) and a lunar basalt: Fe^{2+} in 6-fold coordination

REBECCA A. LANGE[1*], XUAN GUO[1], QIONG LIU[1], YUHUI AI[1]

[1]University of Michigan, Ann Arbor, USA, becky@umich.edu (* presenting author)

FeO is an important component in both terrestrial and lunar basalts and yet its partial molar volume at one bar is not well known because of the difficulty of performing double-bob density measurements under reducing conditions. Moreover, there is growing evidence from spectroscopic studies that Fe^{2+} occurs in 4, 5, and 6-fold coordination in silicate melts, and it is expected that its partial molar properties will vary accordingly. We have conducted both density and relaxed sound speed measurements under reducing conditions on four liquids in the An-Di-Hd ($CaAl_2Si_2O_8$-$CaMgSi_2O_6$-$CaFeSi_2O_6$) system: (1) Di-Hd (50:50), (2) An-Hd (50:50), (3) An-Di-Hd (33:33:33) and (4) Hd (100), as well as a lunar basalt. All the multi-component (model basalts and lunar basalt) liquid density data were combined with published density data on SiO_2-Al_2O_3-CaO-MgO-K_2O-Na_2O liquids (Lange, 1997), and CaO-Al_2O_3-TiO_2-SiO_2 liquids (Lange and Carmichael, 1987) in a fit to a linear volume equation; the results lead to a partial molar volume for FeO = 12.2 (± 0.1) and TiO_2 = 23.9 (± 0.1) cm^3/mol at 1723 K, and dV/dT for FeO = 3.45 (± 0.62) 10^{-3} and TiO_2 = 3.88 (± 1.43) 10^{-3} cm^3/mol-K. The partial molar volume for FeO is similar to that for crystalline FeO at 298 K (halite structure; 12.06 cm^3/mol), which suggests an average Fe^{2+} coordination of ~6 in these model basalt and lunar basalt compositions. In contrast, the fitted partial molar volume of FeO in pure hedenbergite liquid is 14.6 ± 0.3 at 1723 K, which is consistent with an average Fe^{2+} coordination of 4.3 derived from EXAFS spectroscopy (Rossano, 2000). Similarly, the compressibility data for the three model basalt and lunar basalt liquids were combined with compressibility data on SiO_2-Al_2O_3-CaO-MgO liquids (Ai and Lange, 2008) and new sound speed data on CaO-MgO-TiO_2-SiO_2 liquids in a fit to an ideal mixing model for melt compressibility; the results lead to a partial molar compressibility (± 1 σ) for FeO = 3.25 (± 0.15) 10^{-2} and TiO_2 = 8.67 (± 0.06) 10^{-2} GPa^{-1} at 1723 K. In contrast, the compressibility of FeO in pure hedenbergite liquid is significantly larger than that in the basalts: 6.3 (± 0.2) 10^{-2} GPa^{-1}. When these results are combined with density and sound speed data on CaO-FeO-SiO_2 liquids at one bar (Guo et al., 2009), a systematic and linear variation between the partial molar volume and compressibility of the FeO component is obtained, which appears to track changes in the average Fe^{2+} coordination in these liquids. Therefore, the three most important conclusions of this study are: (1) ideal mixing of volume and compressibility does not occur for all FeO-bearing liquids, owing to changes in Fe^{2+} coordination, (2) the partial molar volume and compressibility of FeO varies linearly and systematically with Fe^{2+} coordination, and (3) ideal mixing of volume and compressibility does occur among the three multicomponent An-Di-Hd liquids and extends to lunar basalt compositions, presumably because of a common, average Fe^{2+} coordination of ~6.

The Arctic Ocean is one of the most intense CO_2 sinks of the oceanic realm due to the low temperature and relatively high primary productivity of its waters [1]. Nevertheless, the Arctic Ocean is prone to rapid transformations in response to climate change, such as changes in sea-ice melt and freezing rates, increased freshwater, nutrient, and particulate input due to higher riverine discharge, as well as changing carbon and sediment fluxes caused by coastal erosion and permafrost thawing. Given the complex interplay between these factors, predicting how the strength of the Arctic Ocean atmospheric CO_2 sink will vary in the future is still a matter of debate [2]. In this context, we address how CO_2 in the surface mixed layer (SML) of the Arctic Ocean may change in response to increased sea-ice melt and riverine inputs.

During the summer of 2009, we conducted high resolution water column sampling on the Mackenzie and Beaufort Shelves (Canadian Arctic) to examine the impact of sea-ice melt and river runoff on surface ocean CO_2 chemistry. We used a combination of natural tracers (salinity, total alkalinity (TA) and stable oxygen isotopic composition ($\delta^{18}O$-H_2O)) to distinguish between sea-ice melt (SIM) and meteoric water (MW) [3]. SIM is characterised by a low TA (415 ± 35 μmol kg^{-1}), a relatively high $\delta^{18}O$-H_2O (-2.0 ± 0.5‰) and relatively low CO_2 partial pressure (pCO_2≈300 μatm). MW is characterised by a high TA (1618 ± 55 μmol kg^{-1}), low $\delta^{18}O$-H_2O (-18.9 ± 0.1‰), and relatively high pCO_2 (>450 μatm). In addition, we analysed the stable carbon isotopic composition ($\delta^{13}C$) of dissolved inorganic carbon (DIC) to determine the origin of the CO_2, i.e. metabolic or atmospheric.

During the study period, significant contributions of MW (>50%) to the SML were only observed on the inner Mackenzie Shelf. In contrast, SIM contribution to the SML reached 30% close to the ice pack, located beyond the shelf break. The admixture of SIM to the SML may therefore allow for the absorption of atmospheric CO_2. A preliminary analysis of the $\delta^{13}C$-DIC data reveals two distinct patterns indicating that CO_2 was either taken up from the atmosphere or produced *in situ* by microbial respiration.

[1]Laurentian University, Sudbury, Canada, amcdonald@laurentian.ca

Elevated concentrations of metal(loids) in silica rich alteration layers has recently been described for altered surfaces at the solid-water and solid-atmospheric interfaces in tailings, and in the vicinity of smelters, respectively. To determine if similar coatings occur in acidic soils, samples were taken from unlimed areas around three major smelting centers in Sudbury, Ontario, Canada. Coated grains were extracted from these samples and individually mounted to be analysed with SEM, Micro-raman spectroscopy, Laser Ablation ICP-MS and XPS. Preliminary results indicate that coatings are mainly composed of Fe and Si, and that trace elements seem to be associated primarily with coatings having Si : Fe ratios greater than 1, whereas coatings with Si : Fe ratios less than 1 have lower concentrations of associated trace elements. The silica-rich coatings were most likely formed through the precipitation of amorphous silica in iron hydroxide. Their higher metal concentrations with respect to Fe-rich coatings can be explained either by the promoted growth and encapsulation of jarosite group minerals by a silica matrix, or by higher sorption of metal(loids) by iron hydroxide minerals with high silica content which have a lower positive surface charge, lower crystallinity and number of polymerized polyhedra, as well as a higher reactivity than Si-depleted Fe-hydroxides. In conclusion, micro-coatings are capable of taking up and in some cases preserving metal(loid)s such as As,Pb,Se,Cu and Zn among others, and therefore play an important role in the interaction of trace elements with soils, and may affect their behaviour within the soil environment.

Soil grain with multiple coatings

A record of Northern Hemisphere climate variability during the Penultimate Glacial from high resolution speleothem data

ZACHARY LAPOINTE[1*], YEMANE ASMEROM[1], VICTOR POLYAK[1], MATTHEW LACHNIET[2]

[1]Department of Earth and Planetary Sciences, Albuquerque, USA, zoneldc@unm.edu

[2]Department of Geoscience, University of Nevada, Las Vegas, USA, matthew.Lachniet@unlv.edu

Numerous paleoclimate records have contributed to our understanding climate change during the Last Glacial. Data for previous glacial cycles are rare however, due to the lack of absolutely dated continuous records. Here we present stable isotope and elemental data of an absolutely dated stalagmite (FS-TR3) from Fort Stanton Cave, New Mexico, that reveal the character and timing of Northern Hemisphere (NH) climate variability during the Penultimate Glacial (MIS 6). These data show links to summer insolation, rapid North Atlantic cold/warm anomalies or lack thereof, and climatic oscillations resembling the 1500-year cycle.

Previous results from the study area showed that δ18O values from stalagmite FS2 mimic the δ18O record of the Greenland Ice Core in both general trends and higher frequency variations such as the Dansgaard–Oeschger (DO) and Heinrich events (HEs) (Asmerom et al., 2010 ref 1) . The new FS-TR3 stalagmite extends our record to the Penultimate Glaciation. Stalagmite FS-TR3, based on high-resolution U-series chronology, grew continuously from 165 to 130 ka. At the orbital scale, the trend is dominated by insolation, upon which are superimposed millennial scale variations. The millennial scale variations are more muted than HE and DO events during the Last Glacial. In contrast to the millennial scale variability, the transition to peak cooling during MIS 6 was abrupt and pronounced, and followed by a very rapid Termination II. Time series analyses of the stable isotope and elemental data show climatic oscillations similar to those exhibited by NH Last Glacial records, such as the 1500-yr cycle. A growth hiatus at 130.3 ka is coincident with the termination of NH Glacial-II from other records. Our record is comparable to that of stalagmite SB11 from Sanbao Cave, China (Wang et al. 2008 ref 2), and this comparison shows that the atmospheric teleconnections between Greenland, the SW USA, and China are likely hemispherical in scale through the Penultimate NH Glacial.

Whilst nanomaterials are employed in an increasing range of commercial and industrial products, analytical difficulties obstruct the scientific understanding of their toxicological properties and environmental fate. ZnO nanomaterials (NMs) are of particular interest as these are used in sunscreens and cosmetics as a UV filter, and reach the biosphere through a variety of routes. Due to the high natural background levels of Zn, the detection of ZnO NMs in ecotoxicologically relevant exposures cannot be attained through concentration data alone. However, highly sensitive detection can be achieved using purpose-made ZnO nanoparticles (NPs) labelled with a stable Zn isotope [1]. This approach also negates handling difficulties and time restrictions associated with radioactive tracing. Even with relatively inexpensive ^{68}Zn as the isotope label, ZnO nanoparticle concentrations as low as 5 ng/g can be precisely quantified against a background of 100 μg/g Zn when measured using MC-ICP-MS.

ZnO NPs (30 nm, TEM) labelled with ^{68}Zn were synthesized by hydrolysis from an acetate precursor [2]. Parallel 10-day exposures of *Corophium volutator* to labelled ^{68}ZnO NPs, bulk ^{68}ZnO and soluble $^{68}ZnCl_2$ were performed in artificial seawater in the presence of sediment [3]. Dialysis experiments were used to determine the rate and extent of dissolution for both bulk and nanoparticulate ^{68}ZnO in the test medium. The subsequent analyses of organisms, sediment and water samples for Zn isotope compositions and concentrations were carried out by MC-ICP-MS following preconcentration of Zn by anion exchange chromatography [4].

For all exposures, including those utilizing dissolved $^{68}ZnCl_2$, the sediments accumulated the largest pool of the ^{68}Zn label. This finding and the low final ^{68}Zn contents of the aqueous media are indicative of significant Zn transfer from the water column to sediments, presumably as a result of Zn sorption [5]. The observations that (i) the ^{68}Zn levels determined for the organisms were approximately scaled in proportion to the dissolved ^{68}Zn concentrations that are expected based on the dialysis experiments and (ii) the organisms featured $^{68}Zn/^{66}Zn$ isotope ratios lower than those measured for the corresponding water samples, suggest that the uptake of ^{68}Zn by the organisms from ^{68}ZnO NPs occurred through the dissolved state.

Fingerprinting Himalayan convergence accommodation processes

KYLE LARSON [1*], LAURENT GODIN[2], AND JOHN COTTLE[3]

[1]University of Saskatchewan, Department of Geological Sciences, Currently at University of British Columbia Okanagan, Department of Earth and Environmental Science kyle.larson@ubc.ca (* presenting author)
[2]Queen's University, Department of Geological Sciences and Geological Engineering, godin@geol.queensu.ca
[3]University of California, Santa Barbara, Department of Earth Science, cottle@geol.ucsb.edu

Conceptual models of convergence accommodation processses that operated during the Tertiary evolution of the Himalayan orogen have commonly been examined from an 'end member' point of view. Many previous studies have used geologic data to attempt to characterize these processes in terms of either channel flow or wedge taper models. These models, however, are not mutually exclusive [1] as supported by recent field-based research that demonstrates they are intrinscially related both spatially and temporally [2,3]. Key to undertanding the relationship between channel-type mid-crustal flow and wedge taper processes is appreciating the spatial variation in displacement and distortion throughout a large, hot orogen. Moreover, it is also critical to recognize how initially spatially and deformationally distinct domains may be later juxtaposed.

The exhumed metamorphic core of the Himalaya is well exposed in the Manaslu-Himal Chuli region of central Nepal. This transect has been subject to much geologic research including spatially expansive P-T determinations and new geochronologic controls. These data, coupled with detailed mapping that covers most of the exhumed metamorphic core, provide the constraints necessary to characterize the convergence accommodation processes that imparted those characteristics. The lower portion of the exhumed mid-crust is characterized by structurally-downward decreasing P-T conditions and monazite ages interpreted to reflect subcretion of material to the base of the mid-crust as it was exhuming, consistent with wedge taper processes in the shallow foreland [2]. The upper portion of the exhumed mid-crust, however, preserves a condensed right-way up pressure gradient, an invariant temperature gradient, and monazite ages that are consistent with ductile mid-crustal flow in the deep hinterland [3]. The present-day juxtaposition of these two contrasting domains and the characteristics they record is compatible with the crustal scale channel flow models of Jamieson et al. [4]. Channel flow and wedge taper processes are, therefore, not mutually exclusive.

Mercury exposure in a sub-arctic population 80 years ago

THORJØRN LARSSEN[1*], MARTHE T.S. JENSSEN[1], HANS FREDRIK BRAATEN[1], AND INGER NJØLSTAD[2]

[1]Norwegian Institute for Water Research, thorjorn.larssen@niva.no (* presenting author)
[2]Department of Community Medicine, University of Tromsø

Mercury exposure to humans from consumption of fish and sea food is a global concern. Mercury releases to the environment from human activities have increased over the past several hundred years. Along with the historical increase in releases, concentrations of mercury in the environment has also increased. As mercury undergo long range transport, elevated concentrations can be found in the environment far from the sources, including in the Arctic. Samples from museum collections, such as, teeth from humans and marine mammals, hair from polar bears and feathers from birds, have shown that mercury concentrations increased rapidly from around 1900 [1].

Historical samples of biological material are scarce and usually only available from a very limited number of individuals . We have come across a set of several hundred human hair samples from a remote population in sub-arctic Norway (a coastal village in Finnmark County) collected as part of a tuberculosis study in the period 1928-1932. A sub set of 218 samples covering all age groups and both sexes was analysed for methyl mercury.

Mean hair methyl mercury concentration was 1.5 mg kg^{-1} (median 1.3 mg kg^{-1}; range 0.3-6.1 mg kg^{-1}). A compareable modern day population (sampled in Tromsø in 2007-2009) had mean hair mercury concentration 1.3 mg kg^{-1} (median 1.0 mg kg^{-1}; range 0.02-11.9 mg kg^{-1}; n=4973) [2]. The relatively similar mean concentrations in the data from around 1930 and from 2007-2009, despite that concentrations of mercury in fish around 1930 were considerably lower than today, are probably due to higher fish intake and hence similar total mercury exposure 80 years ago.

Contrary to the modern day population, the data set from around 1930 shows no differences between age groups or sexes. Modern day data typically show increasing concentrations with age and higher concentrations in men than women. The differences between age groups and sexes in the modern day population can be explained by food consumption habits. The lack of differences between sub groups in the old data probably shows that there were minor differences in food consumption habits, related to high dependency on local fish and limited choice of food due to poverty and relative geographical isolation at the time.

Sorption of vanadate(V) to iron (hydr)oxides is one of the most important processes affecting vanadium bioavailability and transport in soils. We characterised vanadate(V) adsorption to 2-line ferrihydrite by means of batch experiments, EXAFS spectroscopy, and surface complexation modeling using the CD-MUSIC model for ferrihydrite [1, 2].

Vanadate(V) sorption was strongest at low pH, and it decreased in the presence of *o*-phosphate, as expected. Results from EXAFS spectroscopy showed that vanadate(V) is sorbed primarily as an edge-sharing bidentate complex with a single V···Fe distance of ~2.87 Å. Our conclusion differs from earlier work on vanadate(V)-sorbed goethite, for which a corner-sharing bidentate complex with V···Fe distances of ~3.25 Å was identified [3].

The CD-MUSIC model could describe vanadate(V) sorption well when two surface complexes were considered. One of them was a bidentate $\equiv FeO_2VO_2^{1.5-}$ complex (in line with the EXAFS results), which dominated vanadate(V) sorption under most conditions. The best modeling results were obtained when one of the surface oxygens of this complex was assumed to be singly coordinated to iron, whereas the second one was doubly coordinated. At low pH and at low Fe:V ratios the modeling exercise suggested the additional presence of another complex, which may be an outer-sphere surface complex involving $H_2VO_4^-$ and a diprotonated $\equiv FeOH_2^{½+}$ surface group. The implications of these results are that vanadate(V) may be strongly sorbed to iron (hydr)oxides in acid to neutral environments; however, the sorption affinity is related strongly to, e.g., competition with *o*-phosphate.

Summary

Geochemical and geological inferences have suggested, based on analysis of chemical gradients in biodegraded oil reservoirs that the site of microbial activity must be largely focussed at the oil-water-transition zone (OWTZ) at the base of the oil column[1]. Using a combined geochemical, geological and microbiological analysis of an actively biodegrading Canadian heavy oil reservoir shows that petroleum degrading microorganisms are indeed focussed in a zone of high water saturation at the base of the oil column in the OWTZ but that surprisingly, it is much thicker than expected, occupying a zone of active biological activity exceeding 10 meters. Through the oil column, gradients in biodegradation related oil physical and chemical properties are driven from this OWTZ with chemical gradients in, for example, concentrations of alkylaromatic hydrocarbons and aromatic heterocompounds significantly steepening in this "biological burn out zone". 16S rRNA gene qPCR data suggest on the order of 10^6 to 10^7 cells/gm of sediment are present in the burn out zone, numbers that are consistent with an active biological system and around 10^4 to 10^5 cells/gm outside the burnout zone. The bacterial abundances in the OWTZ are in line with the trend of bacterial abundance with depth that has emerged from extensive analysis of microbial cells in deep subsurface sediments [2], implying that in terms of the deep biosphere, oil reservoirs are nothing special! The bacterial abundance is about 2 orders of magnitude higher within the burnout zone than within the oil leg, consistent with the notion that microbial activity and abundance in the deep subsurface is elevated at geochemical interfaces[3]. This broad result appears to support the original hypothesis that microbial activity must be largely focussed at the oil-water-transition zone (OWTZ) at the base of the oil column. We discuss the impact of these results on both the uniformity of processes in the deep biosphere and the substantial challenges this imposes on engineering accelerated microbial conversion of liquid petroleum to methane or hydrogen on production timescales.

Introduction: The possible transfer of engineered nanoparticles (ENPs) into plants should be evaluated in the perspective of human exposure through ingestion of crops. The mechanisms of ENPs transfer and on their fate inside plants are poorly understood, particularly for the foliar pathway [1]. The fate of TiO_2 and Ag^0 ENPs in lettuce leaves was studied after foliar exposure by wet deposition. The localization of ENPs and the speciation of Ti and Ag were studied by SEM- and TEM-EDX, micro X-ray fluorescence (μXRF) and micro X-ray absorption spectroscopy (μXAS) based on synchrotron radiation.

Results and Conclusion: TiO_2 exposure did not induce any visible toxicity symptoms, whereas Ag (both ionic and nano) induced some necroses on leaves. Imaging techniques show the presence of large agglomerates of Ti or Ag both on the surface of the epidermis and inside leaves (Figure 1). No sign of TiO_2 dissolution was observed by μXAS whereas Ag ENPs are partially dissolved with the formation of secondary Ag species (Ag^+ bound to organic ligands). These results suggest that crops exposed to atmospheric deposition of ENPs may undergo contamination due to foliar transfer of ENPs.

Introduction

Lithium interest for industrial production has been increasing during the last few years. This alkali metal is of primary importance in the battery production for electricity storage, in vehicles and electronic devices. Because of very high solubility of lithium in water, the chemical behaviour of lithium minerals – brines systems is highly non-ideal and very complex. Its characterization requires specific approaches. The ion-specific interactions model developed by Pitzer [1] is particularly well suited for dealing with ionic strengths ranging from low up to very high salinities, i.e. above several tens of moles per kg of water [2].

Description of the work

In this work, we studied the H-Li-Na-K-Cl-H_2O chemical system, and determined new relevant Pitzer interaction parameters using the recent procedure developed by André et al. [3]. In the binary LiCl-H_2O system, this set of parameters, together with the aqueous complexation constant of the $LiCl^0$ aqueous species, allows the description of the phase diagram for temperatures ranging from 0 to 250°C and for salinities up to saturation, i.e. up to 40 mol/kgw. The presence of the $LiCl^0$ aqueous species has been investigated by NMR (Nuclear Magnetic Resonance) as described in a companion communication [4]. Using this parametrization (which includes the $LiCl^0$ aqueous species) in the ternary LiCl-KCl-H_2O, LiCl-NaCl-H_2O, and LiCl-HCl-H_2O systems, phase diagrams can be satisfactorily described up to 30 mol/kgw, and 150°C.

The set of new interaction parameters determined in this study should allow the description of the chemical behaviour of the quinary LiCl-KCl-NaCl-HCl-H_2O system over a wide range of salinities (0.001 to 40 molal) and temperatures (0 to 250°C). The model presented here is a continuation of the previously established model for lithium hydroxide systems [5], and is consistent with the related set of specific interaction parameters. This extension is of great importance to better characterize the chemical behaviour of complex systems like natural Li-bearing brines found in hydrothermal systems (e.g., Soultz-Sous-Forêt, Salton Sea, etc.).

Evaluation of sources of error in $^{186}Os/^{188}Os$ measurements via NTIMS

JOHN C LASSITER[1]*, RUDRA CHATTERJEE[1], SHUANGQUAN ZHANG[1], STACI LOEWY[1]

[1]University of Texas, Jackson School of Geosciences lassiter1@mail.utexas.edu (* presenting author)

The ^{190}Pt-^{186}Os decay system may be useful for monitoring signals of core/mantle interaction in plume-derived lavas [c.f., 1]. However, the total natural variation in $^{186}Os/^{188}Os$ is small (~150 ppm), requiring the highest levels of accuracy and precision in $^{186}Os/^{188}Os$ measurements to discern natural variations that may reflect such interaction. Previous studies have examined several potential sources of systematic and non-systematic error in $^{186}Os/^{188}Os$ measurements deriving from uncertainties in the O-isotope composition of OsO_3^-, potential interferences from PtO_2^-, PtO_3^-, and WO_3^-, and departures from exponential mass fractionation [2]. We have undertaken a $^{186}Os/^{188}Os$ study of both laboratory Os standards and natural samples to better quantify the primary sources of analytical error in $^{186}Os/^{188}Os$ measurements and refine analytical procedures to minimize these errors.

Inter- and intra-run variations in oxygen isotope composition of measured OsO_3 peaks produce correlated errors in $^{186}Os/^{188}Os$, $^{189}Os/^{188}Os$, and $^{190}Os/^{188}Os$ ratios. Although significant O-isotope variation is observed between analyses, intra-run variation is sufficiently small that O-isotope composition determination through pre- and post-run measurement of $^{192}Os^{16}O_2{}^{18}O$ and other high-mass oxide peaks is suffiicent. Uncertainties derived from oxide corrections can be further reduced by utilizing the $^{189}Os/^{188}Os$ ratio for mass fractionation corrections rather than $^{192}Os/^{188}Os$, but the reduced error from oxygen isotope uncertainties is offset by increased error in the fractionation factor. However, the excellent reproducibility of $^{189}Os/^{188}Os$ measurements (<10ppm 2σ) using $^{192}Os/^{188}Os$ for mass fractionation indicates that these uncertainties are not the primary sources of error in $^{186}Os/^{188}Os$ measurements.

For the quantities of Os and beam intensities utilized in previous $^{186}Os/^{188}Os$ studies (several 10s of ng Os, ~80-120 mV ^{186}Os with a 10^{11} ohm resistor), the largest source of analytical error is shown to be Johnson Noise on interblock baseline measurements, which significantly exceeds error derived from counting statistics. Because ^{186}Os is a relatively minor isotope of Os (~1.6%), it is affected by Johnson Noise error propagation to a much greater extent than higher abundance isotopes. Analytical precision on the smaller Os-isotope peaks can be significantly improved without increasing sample size simply by increasing the duration of baseline measurements in proportion to signal measurement time [3]. Further improvement is obtained by utilizing a 10^{12} ohm resistor for measurement of $^{184}OsO_3$ and $^{186}OsO_3$ peaks. Finally, several $^{186}Os/^{188}Os$ analyses previously reported in the literature appear to be compromised by an as-yet unidentified, possibly organic interference that impacts both the $^{186}Os/^{188}Os$ and $^{184}Os/^{184}Os$ ratios. We present an improved method for monitoring potential interferences in future $^{186}Os/^{188}Os$ studies.

Reduction of U^{VI} to U^{IV} through coupled biotic-abiotic processes can significantly decrease uranium mobility in subsurface environments. To understand the abiotic factors contributing to this process, we investigated the reduction of U^{VI} to U^{IV} by magnetite, a common rock forming mineral and product of microbial Fe^{III} respiration. U^{VI} reactivity with pure, stoichiometric magnetite ($Fe^{II}Fe^{III}{}_2O_4$, $Fe^{2+}/Fe^{3+} = 0.5$) is compared to that with a series of oxidized ($Fe^{2+}/Fe^{3+} < 0.5$) and Ti-substituted magnetites. Ti^{4+}-for-Fe^{3+} substitution is common in natural magnetite [1, 2] and results in a solid solution ($Fe_{3-x}Ti_xO_4$, $0 < x < 1$) where Ti^{4+} incorporation is charge balanced by proportional increases in Fe^{2+}.

Using x-ray absorption spectroscopy (XANES and EXAFS) at the U L_{III}-edge we observe that the Fe^{2+}/Fe^{3+} ratio in magnetite is a major control on its ability to reduce U^{VI}. Stoichiometric and partially oxidized magnetites ($Fe^{2+}/Fe^{3+} \geq 0.38$) reduce U^{VI} to uraninite ($U^{IV}O_2$) nanoparticles, whereas more oxidized magnetites ($Fe^{2+}/Fe^{3+} < 0.38$) adsorb U^{VI} as an inner-sphere complex without transferring electrons. The observed redox reactivity between magnetite and U^{VI} can be correlated with measured reduction potentials for magnetite and with published thermodynamic parameters for U^{IV}/U^{VI} redox couples [3].

Titanomagnetite nanoparticles with Ti formula contents up to $x = 0.5$ and Fe^{2+}/Fe^{3+} ratios between 0.5 and 1.2 can also reduce U^{VI} to U^{IV}. EXAFS spectra indicate that the reduced U^{IV} atoms are *not* incorporated in uraninite. The speciation of U^{IV} appears to be controlled by Ti-content and not by the Fe^{2+}/Fe^{3+} ratio, as the reduction of U^{VI} by partially oxidized $x = 0.5$ titanomagnetite results in the same non-uraninite U^{IV} species.

This work highlights previously unexplored thermodynamic and geochemical factors that may influence the speciation and solubility of uranium in the subsurface. The observation of non-uraninite U^{IV} species in this study, as well as in carbonate and phosphate bearing systems in previous studies [4-6] suggests the need for a better understanding of the stability of reduced U^{IV}.

Mobility of nanoscale zero-valent iron in quartz and carbonate sands

SUSANNE LAUMANN[1], VESNA MICIĆ[1], THILO HOFMANN[1,*]

[1]Department of Environmental Geosciences, University of Vienna, Vienna, Austria, susanne.laumann@univie.ac.at, vesna.micic@univie.ac.at, thilo.hofmann@univie.ac.at (*presenting author)

Abiotic dechlorination of chlorinated solvents by nanoscale zero-valent iron (nZVI) is an alternative remediation technology for deep aquifers or those underneath infrastructures. Its effectiveness depends on the nZVI properties and concentration, as well as concentration and distribution of contaminats. One prerequisite for a succesfull application of this technology is the delivery of nZVI particles to the contaminats [1]. Delivery is limited by nZVI mobility due to aggregation and deposition, all depending on water chemistry, nZVI properties, and aquifer surface properties.

Adsorbed anionic polyelectrolyte coatings provide electrostatic double layer repulsions between negatively charged nZVI particles [2], hindering their aggregation and also deposition on the negatively charged quartz surfaces (prevailing in aquifers). However, it is shown that the presence of surface charge heterogeneities in the aquifer, such as carbonates, effects the particle mobility [3].

Hereby we evaluated the mobility of commercially available nZVI particles in porous media that have different surface charges, namely quartz and carbonate sands.

Column experiments showed that the mobility of nZVI was reduced by ~45% in pure carbonate sand, compared to that in pure quartz sand. These results revealed substantially different attachment efficiencies of nZVI to these aquifer solids with different surface charges. The zeta potential varied from -40.6 mV in pure quartz sand to -13.6 mV in pure carbonate sands at pH value of 9.1 and 9.6, respectively. The results demonstrated the influence of surface chemistry of the two often encountered aquifer matrices on the mobility of nZVI particles. Further experminets are carried out aiming to evaluate the influence of other surface charge heterogeneities (such as presence of NOM and iron oxides) as well as of different groundwater chemistry on nZVI mobility.

The diversity of granitoids in the northern Kaapvaal craton records late-Archæan geodynamic changes

OSCAR LAURENT[1*], HERVE MARTIN[1], REGIS DOUCELANCE[1], JEAN-FRANÇOIS MOYEN[2] AND JEAN-LOUIS PAQUETTE[1]

[1]Clermont Université, Université B. Pascal, Laboratoire Magmas et Volcans (CNRS-UMR6524), BP10448, F-63000 Clermont-Ferrand, France. O.Laurent@opgc.univ-bpclermont.fr (* presenting author)

[2]Université Jean Monnet, Département de Géologie (CNRS-UMR6524), 23 rue Dr. Paul Michelon, F-42043 Saint-Étienne, France.

We studied the emplacement ages (LA-ICP-MS dating on zircons) and petrogenesis (major- and trace-elements, Nd isotopes) of granitoid rocks along a cross-section in South Africa, from the Murchison greenstone belt in the Kaapvaal craton to the Central Zone of the Limpopo mobile belt.

The 'basement' of the northernmost Kaapvaal craton is made up of deformed and variously migmatized granitoid gneisses of TTG affinity that emplaced as discrete events, in the time range of 3.20 to 2.85 Ga. The peraluminous biotite granites from the Turfloop batholith and Duiwelskloof area, located between the Murchison and Pietersburg belts, emplaced at ~2.78 Ga and have a crustal origin (TTGs, possibly metasediments). At the suture between the Kaapvaal craton and the Limpopo Belt, several metaluminous, high-K calc-alkaline granitoids intruded at ~2.69 Ga (Mashashane, Matlala, Matok, Moletsi). Their geochemical features indicate that they are composite complexes, whose genesis involved melts derived from both the reworked TTGs and mantle-derived intermediate to mafic material. Finally, the Bulai pluton (~2.59 Ga) emplaced in the Central Zone of the Limpopo belt further north. It shares unequivocal affinities with sanukitoids. It was generated by differentiation of primary monzodiorites [1], themselves deriving from a mantle source previously enriched by a sediment-derived felsic melt [2].

Therefore, while 'classical' Archæan petrogenetic mechanisms prevailed until ~2.85 Ga (protracted generation and recycling of TTG), the late-Archæan evolution is marked by a diversification of granitoid sources and crustal growth processes. In addition, whereas TTGs of all ages are randomly distributed throughout the whole area, younger magmatism shows a strict structural control: from south to north, emplacement ages decrease while mantle contribution increases.

This spatial and temporal evolution of granitoid magmatism in the northern Kaapvaal records fundamental geodynamic changes. In particular, while typical Archæan TTGs are only derived from meta-basalts at various depths [3], the magmas emplaced at the Archæan-Proterozoic transition involved a greater range of sources (from recycling of various crustal lithologies up to inputs of juvenile, mantle-derived material), thus resulting in a wide range of medium- to high-K granitoids. As the distribution, geochemistry and temporal evolution of granitoids in the northern Kaavaal recall those of post-Archæan late-orogenic settings, we propose that these rocks witness the progressive initiation of modern-style geodynamic processes.

The influence of temperature on carbon chemistry of organomineral complexes

JOCELYN M. LAVALLEE [1]*, RICH T. CONANT[1], MARTIN OBST[2], THOMAS BORCH[3], AND TOM REGIER[4]

[1]Natural Resource Ecology Laboratory, Colorado State Univervity, Fort Collins, USA, jocelyn.lavallee@colostate.edu (* presenting author) , rich.conant@colostate.edu

[2]Center for Applied Geoscience Eberhard Karls University Tuebingen, Tuebingen, Germany, martin.obst@uni-tuebingen.de

[3]Department of Soil and Crop Sciences, Colorado State University, Fort Collins, USA, thomas.borch@colostate.edu

[4]Canadian Light Source, Saskatoon, Canada, Tom.Regier@lightsource.ca

Soil organic matter can interact with soil mineral surfaces to form stable organomineral complexes. These organomineral complexes effectively protect carbon compounds against microbial decomposition and play a large role in regulating global carbon cycling rates. Because the interactions between the organic matter and mineral surfaces are chemical reactions, there is reason to believe that they are regulated by temperature, but this remains unknown. As part of an ongoing study, we are investigating the impact of temperature on the rates of formation of organomineral complexes and the chemical properties of the carbon within those complexes. We are employing scanning transmission X-ray microscopy (STXM) and carbon near edge X-ray absorption fine structure (CNEXAFS) to map the spatial distribution of carbon forms in organomineral complexes at different temperatures. We are also using CNEXAFS with a spot size of 1000µm x 100µm to gather comprehensive chemical data on the effect of temperature on organic matter fractionation. We will present data from ongoing experiments utilizing two types of samples: synthesized iron oxide-organic matter complexes and soils gathered from field climate manipulation experiments. The climate manipulation experiments are part of the Old-field Community Climate and Atmospheric Manipulation Experiment carried out in Oak Ridge, Tennessee from 2003 to 2005. We fractionated the climate manipulation soils by density prior to measurement. The laboratory experiments provide the benefit of control over the materials used, while the climate manipulation soils are more representative of the effects of temperature that we would see in the field. Thus far, results suggest that temperature can impact organic matter fractionation at mineral surfaces. Of particular interest, we see an influence of temperature on the absorption peak at 290.2 eV, which under our experimental conditions may be caused by Fe-O-C bonds rather than carbonates. We also present methodological considerations for CNEXAFS measurements, as well as plans for future experiments.

Multiple glass transitions in natural volcanics: a demonstration of shallow magma mixing during Strombolian eruptions at Yasur Volcano, Vanuatu

YAN LAVALLÉE[1*], SIMON KREMERS[1], JONATHAN HANSON[1,2], KAI-UWE HESS[1], MAGDALENA ORYAËLLE CHEVREL[1], JOACHIM WASSERMANN[1], DONALD B. DINGWELL[1]

[1] Ludwig-Maximilians-University Munich, Earth and Environmental Sciences, lavallee@min.uni-muenchen.de (*presenting author)

[2] University of Bristol, Department of Earth Sciences

Introduction

Strombolian activity is often regarded as a product of the rapid ascent of gas slugs entraining a deep magma [1], which mingle with a batch of shallow magma upon eruption [2]. The presence of a range in crystallinities as well as bimodal bubble-size distributions, in the eruptive products, generally support this view. The regular intervals of strombolian activity suggest a continuum in an open system [3], where the surface activity is inferred to reflect the ascent of magma batches at various rates, driven by the relative buoyancy of bubbles with contrasting sizes [4,5]. Mt. Yasur volcano (Vanuatu) has been increasingly recognized for its high-frequency Strombolian eruptions, where three active vents display eruptions of different intensities at contrasting intervals of minutes to tens of minutes. Here, we constrain this range of behaviour using information locked in at the glass transition.

Result and conclusion

A rheological investigation of the eruptive products indicates that basaltic-andesitic eruptive products containing an apparently homogeneous glass phase exhibit evidence of a distinct range of glass transition temperatures with multiple peaks occurring in individual samples. Such anomalous behavior, is proposed to result from the mingling of magmas with contrasting oxidation state. We resolved this hypothesis through complementary calorimetric analyses on remelted rocks prepared under different oxigen fugacities, which attest of the range in glass transitions with oxidation states as well as reveal the instability of such basaltic-andesitic melts in the reduced state. The anomalous nature of the measured glass transition behavior of eruptive products leads us to the inference that mingling is located in the shallow parts of the eruptive conduits, in parts due to rejuvenation of material slumped from the crater walls into an open conduit system. The dynamics of this process may reflect the periodicity of the eruptions themselves.

[4]Karlsruhe Institute of Technology, Institut fur Nukleare Entsorgung, Karlsruhe, Germany

Neptunium is a key risk-driving radionuclide in geological disposal and is predicted to be the most mobile transuranic in the subsurface at nuclear contaminated sites. However there is a lack of information concerning Np environmental behavior; notably in relation to manganese, a ubiquitous element in any geological setting that has been implicated in actinide beogeochemical cycling [1]. To explore this relationship further, we have characterised Np biogeochemical behaviour in: (i) a ^{237}Np(V) amended δMnO_2-rich sediment treatment where we have poised the system at Mn-reducing conditions; and (ii) a range of ^{237}Np(V) amended synthetic Mn mineral systems (pure-phase δMnO_2, tri-clinic and acid birnessite, todokrokite, hausmennite and rhodochrosite).

In the sediment system, acetate addition stimulated microbially-mediated bioreduction and the rate of Np sorption to sediment increased during both Mn-reduction and Fe(III) reduction. By the onset of sulfate reduction, all (>99 %) of the added Np(V) (~0.3 μM) had been removed from solution. Parallel XAS experiments (Np(V) ~ 0.3 mM) underwent a similar biogeochemical evolution and data collection is ongoing. In the pure-mineral systems, Np(V) (0.3 μM – 0.3 mM) rapidly (minutes – hours) sorbed to each mineral phase except rhodochrosite, which showed more limited Np sorptive potential. XAS analysis of each mineral phase is ongoing and we expect a range of Np speciation and co-ordination environments related to the Mn-mineral structure and average oxidation state.

Modeling the influence of organic acids on soil weathering

COREY R LAWRENCE[1*], KATE MAHER[2], MARJORIE SCHULZ[1], AND JENNIFER HARDEN[1]

[1]USGS, Menlo Park, USA, clawrence@usgs.gov (* presenting author)

[2]Stanford University, Stanford, USA, kmaher@stanford.edu

The potential infuences of low molecular weight organic acids (LMWOA) on the dissolution of soil minerals and, conversly, the stabilization of organic compounds by complexation with minerals or weathering products are well characterized. Mineral weathering is enhanced through several processes including: ligand promoted dissolution; the influence of organic-metal comlexation on dissolution reaction affinity; and/or the changes in soil pH resulting from organic acid dissociation and the production of CO_2 through the decomposition of organics [1]. Protection of organic matter occurs through adsorption of organics on mineral surfaces, complexation of organics with metals in solution, the formation of soil aggregates and/or other processes that limit the microbes access to organic compounds or increase the energy required to initiate decomposition [2]. Although these processes are well documented, the net influence of these interactions in a natural soil weathering system has yet to be quantified.

Reactive transport modeling of soils provides a viable framework for examining the organic-mineral interactions at the field scale. The inclusion of LMWOA in simulations of soil development at the Santa Cruz Marine Terrace Chronosequence yields supprising results with regard to mineral weathering. Our work suggests that inclusion of reactions describing the complexation of organic acids and aqueous Al species does not dramatically alter the spatial extent of primary mineral dissolution (and hence the overall weathering rate), but has a comparativly greater influence on seondary mineral precipiation (e.g. kaolinite). In our model system, complexation of organic acids with trace metals competes with kaolinite precipitation as a sink of Al^{3+}; effectively reducing precipiation in the top 0.5 m of the study soils but not leading to large enough changes in the saturation state of albite or K-feldspar to increase the dissolution rate of those minerals. Furthermore, our results show how the spatial extent of weathering fronts may control the distribution of organic substrates. Several other processes linking organic acids to mineral weathering still need to be encorporated into this model framework, but these results demonstrate that our understanding of organic-mineral interactions in soils may be advanced through consideration of these processes in natural systems.

Oxygen Isotope Proxies of Tropical Cyclones: Suitable Species

JAMES LAWRENCE[1], ROSALIE MADDOCKS[1], NIALL SLOWEY[2], AND BRENDAN ROARK[2]

[1]University of Houston, Earth and Atmospheric Sciences, Houston, Texas, USA, jimrslawrence@gmail.com*
[2]Texas A&M University, Geosciences, College Station, Texas, USA

Results

The human experience of climate change is not one of gradual changes in seasonal or yearly changes in temperature or rainfall. Despite that, most paleoclimatic reconstructions attempt to provide just such information. Humans experience climate change on much shorter time scales. We remember hurricanes, weeks of drought or overwhelming rainy periods

Tropical cyclones produce very low isotope ratios in rainfall. Thus, climate proxies that potentially record these low isotope ratios offer one of the most concrete records of climate change to which humans can relate.

The oxygen isotopic composition of tropical cyclone rainfall has the potential to be recorded in fresh water carbonate fossil material, cave deposits and corals. The waters in ephemeral ponds in Texas have been shown to contain anomalously low isotope ratios following the passage of tropical cyclones. The Class of carbonate organisms known as Ostracoda (Arthropods) form their carapaces very rapidly and have been shown to provide an isotopic record of the storm passage [1]. The Class of organisms known as Charophyceae (specialized algae) form desiccation resistant ooganis ("carbonate fruits") on their stems in response to the sudden appearance of water in dry ponds. Thus fresh water ephemeral ponds in the subtropics are ideal locations for isotopic studies.

A region that shows considerable promise is South Texas /Northeast Mexico. In 2010 rains from Hurricane Alex, Tropical Depression 2 and Tropical Storm Hermine flooded ephemeral ponds in south Texas. Isotopic analysis of water and fossil Ostracoda and Charophyceae from ephemeral ponds in south Texas are planned. A core (50 cm in length) was taken in one of these ponds where living Ostracoda and Charophyceae were found and collected.

Biogeochemical Dynamics of Aqueous Fe and Mn in Soil Pore-Waters and Stream with Respect to Dissolved Organic Matter (DOM) Quantity and Quality

O. LAZAREVA[1*], D.L. SPARKS[1], W. PAN[1], J. KAN[2], A. AUFDENKAMPE[2]

[1]University of Delaware Environmental Institute, Newark, USA, olazarev@udel.edu*, dlsparks@udel.edu, wpan@udel.edu
[2]Stroud Water Research Center, Avondale, USA, jkan@stroudcenter.org, aufdenkampe@stroudcenter.org

Iron (Fe) and manganese (Mn) oxides, hydroxides and oxyhydroxides are well known redox-sensitive and reactive mineral components of environmental systems. Soil horizons with abundant Fe and Mn oxides/hydroxides have high mineral surface area and thus a high capacity to complex carbon (C), reducing susceptibility of C to microbial degradation. At the same time, Mn and Fe oxides are strong oxidizing agents under anaerobic conditions and could facilitate the microbial degradation of organics and formation of humic compounds.

The National Science Foundation (NSF) Critical Zone Observatory program is a system of six environmental observatories in the USA within a growing network throughout the world. The Christina River Basin-Critical Zone Observatory (CRB-CZO), located in the Piedmont region of Southeastern Pennsylvania and northern Delaware, is a partnership between the University of Delaware and the Stroud Water Research Center. At the White Clay Creek Watershed (WCCW) of the CRB-CZO we study how biogeochemical dynamics of Fe- and Mn- along redox gradients affect the C cycle within a floodplain forest.

We investigated the composition of soil pore-waters and stream over a 9 month-period with respect to the concentration of dissolved organic carbon (DOC) and the quality of dissolved organic matter (DOM) coupled with aqueous Fe and Mn, pH, temperature, alkalinity, conductivity, major anions, major cations, δD, and δ18O. DOM quality was characterized using UV-visible absorbance and fluorescence metrics such as absorption coefficient at 254nm (a_{254}), specific-UV absorbance ($SUVA_{254}$), slope ratio (S_r) humification index (HIX), fluorescence index (FI), protein-like and other indices obtained from PARAFAC modeling of fluorescence excitation-emission matrices (EEMs). The biogeochemical approach above was combined with an advanced in-situ monitoring of biogeochemical parameters including redox, soil moisture and temperature. The sensors are being used to characterize geochemical gradients and how they change over time, and to enable targeted sampling at hot spots and during hot movements.

Our preliminary results demonstrated a significant redox gradient across the interface between anoxic wetland soils and valley-bottom gravel layers within a floodplain forest. Variations in redox gradients near the streambed may drive changes in Fe- and Mn-oxide precipitation and dissolution affecting C complexation or destabilization. DOM quality fluctuated in time and space indicating the existence of humic, microbial, or protein regions depending on the redox envirоinment.

Erebus is an intraplate volcano associated with extensional tectonics, mantle upwelling and high heat flow. It is famous for its long-lived lava lake, a rare phenomenon seen at just a few other volcanoes. Such lava lakes imply steady-state magma input, convection and degassing. They represent particularly convenient "windows" into the behaviour of magma plumbing systems. The Erebus lava lake is further distinguished by its phonolitic composition, with abundant megacrysts of anorthocolase feldspar. The eruptive activity is characterised by two kinds of behaviour: (i) passively degassing lava lake, and (ii) intermittent Strombolian eruptions. An important question to address is what physico-chemical mechanisms drive these contrasting styles of eruption. One hypothesis is that the lava lake activity is associated with open-system degassing, while the Strombolian phases are related to closed-system degassing.

Observations of the emissions of passive and explosive degassing and analysis of the sulfur contents of melt inclusions from the Erebus magmatic lineage are both consistent with a reducing-upwards redox trend in the magma system. Oxygen fugacity changes, occuring between the magma chamber and the lava lake surface, will control the redox state of sulfur and iron, impacting both the melt's thermodynamic and rheologic properties.

The next key step is to make direct measurements of redox conditions in Erebus samples to test model results. Moreover, no rheological data exist on Erebus lava. Therefore, we performed X-ray absorption spectroscopy (XAS) at the iron K-edge experiments under controlled atmosphere at high temperature, and viscosity experiments on the lava. The obtained data bring informations about the oxygen fugacity evolution of the lava between the magma chamber and the surface, and its rheology in the superficial lava lake. These data will constrain the existing eruptive models, and allows to better understand the Erebus dynamic and behavior.

Holocene deposition of atmospheric REE in Europe

Abstract

Three peat bogs from Eastern French Pyrenees, German Black Forest and Swiss Jura provide three parallel records of REE deposition in Europe. The Swiss site shows considerable variation in dust deposition during the past 15,000 years with abrupt changes in fluxes at 12 k.y. cal. BP, 9.2 k.y. cal. B.P., 8.4 k.y. cal. B.P., 7.2 k.y. cal. B.P. and 6 k.y. cal. B.P [1]. Using Nd isotopes and Rare Earth Elements, it is possible to clearly distinguish between volcanic inputs and those driven by climate change such as the long-term aridification of the Sahara and regional erosion due to forest clearance and soil cultivation. Our results indicate that a major dust event in Central Europe precedes the 8.2 k.y. cold event by 200 years. The French and German sites show also considerable variation in dust deposition but represent only respectively 10,000 and 8,000 years of peat accumulation. Unlike the French and Swiss sites located on a limestone plateau, the German peat bog is located on a granite massif, which strongly influences the chemical composition of aerosols falling into the peat. These findings show that the inorganic fraction of high-resolution peat records can provide remarkably sensitive indicators of dust load and its local and remote sources. Our study supports the priority to better identify the impact of dust cycles during the Holocene in terms of direct and indirect impacts on environmental and climate changes.

Scaling and nature of melting processes in the mantle wedge: a record from the Josephine Peridotite (Klamath Mountains, USA)

VERONIQUE LE ROUX[1*], HENRY DICK[1], NOBUMICHI SHIMIZU[1]

[1]Woods Hole Oceanographic Institution, Woods Hole, USA, vleroux@whoi.edu (* presenting author)

The selected peridotite samples come from the Josephine ophiolite, emplaced 157 My ago and now part of the western Jurassic belt of the Klamath Mountains in Northern California and Southwest Oregon [1]. The ophiolite is partly dismembered but presents a complete ophiolitic section from mantle peridotites in the lower part (our samples) to pillow lavas at the top. The Josephine peridotite extends over >800km^2 and has most likely originated in a fore-arc or back-arc setting [1]. It is mostly composed of massive harzburgites, believed to be the residue of partial melting processes, crosscut by several generations of dykes and veins of variable lithologies [2]. Previous studies have mainly focused on the dunite bodies because of their importance as melt extraction channels in the upper mantle. They are believed to have formed through melt-rock reactions between depleted melts and the mantle wedge [3-6].

However, large areas of the Josephine peridotite have yet to be investigated. Here we propose to focus on the compositional variability of harzburgites and lherzolites, which likely represent the protolith of mantle wedge before the diking and veining events that later affected the massif. Our goal is to constrain the scale of melting processes in the upper mantle in subduction environments and better assess the role and distribution of subduction-derived fluids in the melting process. In order to achieve this, our study is based on the observation of geochemical gradients (major, minor and trace elements in minerals and whole-rocks) throughout the selected harzburgites and lherzolites. Based on major elements and most minor and trace element trends (e.g. HREE, Ti, Ni versus MgO wt%) we find that harzburgites and lherzolites are genetically related by a partial melting event, as suggested in previous studies [2]. However the concentrations of the most incompatible elements (e.g. LREE) and fluid-mobile elements (Ba, Rb, Sr) cannot result from a partial melting process but require the later addition of fluids and/or melts superimposed to the partial melting features recorded by the Josephine peridotites.

Mapping out the melting and melt percolation processes that took place in the Josephine Peridotite should shed a new light on the extent and nature (dry or hydrous) of melting in the upper mantle from subduction environments.

The nanoSIMS as a tool to study zonation around/in melt inclusions

MARION LE VOYER[1, 2*], MEGAN NEWCOMBE[1], EDWARD M. STOLPER[1], AND JOHN M. EILER[1]

[1]California Institution of Technology, Pasadena, CA, USA, mlevoyer@caltech.edu (* presenting author).
[2]Presently at Carnegie Institution, Washington DC, USA.

Melt inclusions preserve geochemical records of magmatic processes and can provide windows into melt composition prior to near-surface fractionation processes such as degassing, crystal fractionation, and mixing that can influence the compositions of erupted magmas. The compositions of melt inclusions are usually measured near their centers using in-situ analytical techniques such as electron microprobe, ion probe, or LA-ICPMS. However, melt inclusions can experience post-entrapment modifications through crystallization or exchange with the host mineral or the outside melt via diffusion through the host mineral. For example, water loss (or gain) can occur by diffusion of H-bearing species through the host mineral toward (or from) the enclosing melt. Zonation in melt inclusions and their host minerals provide information on such post-entrapment modifications. We present a new approach to the study of such zonation using the nanoSIMS Cameca 50L high-resolution ion microprobe. Our data document mechanisms of chemical evolution of melt inclusion after entrapment and can constrain the nature and timescales of syn-eruptive processes.

The distinctive capabilities of the nanoSIMS are (1) small spot sizes – typically as small as ~0.2 μm for major elements, 1 μm for minor elements, and several microns for trace elements (including H in nominally anhydrous minerals); and (2) multicollection with large mass range, permitting simultaneous analysis of low- and high-mass elements.

We characterized H and F gradients in olivine around volatile-rich melt inclusions from two arc basalts. The H gradients are anisotropic and can be modeled by diffusion by the proton-polaron mechanism (D_a=100D_b). The length scales of these gradients (from < 20 μm to > 125 μm) indicate that diffusion from the melt inclusion to the olivine produced these gradients on timescales of a few hours,.

We also discovered concentric major and volatile element concentration gradients inside melt inclusions (i.e., zonation within the glass) from various geological settings. Given the high rates of chemical diffusion in silicate melts, the preservation of these gradients implies that these gradients formed during or just prior to eruption on timescales on the order of 0,1-1 hour. For example, gradients in MgO and Al_2O_3 in inclusions from the Siqueiros fracture zone can be modeled as due to coupled olivine growth on inclusion walls and diffusion in the melt inclusion on timescales of ~10 min, presumably in the last stages of eruption. Gradients in H and F inside melt inclusions are more complex, likely reflecting the coupling of olivine crystallization with loss of H and F from the melt inclusion into the host olivine.

POTENTIAL ENVIRONMENTAL FATE AND BEHAVIOUR OF INORGANIC MANUFACTURED NANOPARTICLES IN THE AQUATIC ENVIRONMENT

J.R. LEAD*[1],

[1] School of Geography, Earth & Environmental Sciences, University of Birmingham, Birmingham, UK, j.r.lead@bham.ac.uk (presenting author)

Introduction

Manufactured nanoparticles are usually defined as materials between 1 and 100 nm. They are widely used industrially and in consumer products because of their novel properties and ease of use; metals (e.g. Ag, Au, Fe) and their oxides (e.g. Ti, Zn and Fe) are of particular ubiquity and are produced in high volumes. It is certain that these nanoparticles are entering the aquatic environment in large volumes and are present in low but increasing concentrations. Once in the environment, these nanoparticles are subject to transformations due to alterations in the physical and chemical environment. Potentially the nanoparticles are subject to interactions with salts, natural organic macromolecules (NOM) such as humic substances and polysaccharides and are potentially altered by pH variation. Changes include surface alterations such as oxidation followed by dissolution and possibly regrowth and sulfidation followed by reduced dissolution especially for Ag, shape changes and coating or corona formation often leading to reduced aggregation or even diaggregation. Microbiological effects are also observed.

This paper will discuss these changes in relation to NP properties such as core material type, capping agent and size with particular examples drawn form ceria and silver. Both natural aquatic and toxicological media will be considered.

The sulfur isotope fractionation of dissimilatory sulfite reductase (Dsr)

WILLIAM D. LEAVITT*[1], ALEXANDER S. BRADLEY[1], INÊS C. PEREIRA[2], RENATA CUMMINS[1], AND DAVID T. JOHNSTON[1]

[1]Harvard University, Cambridge, MA, USA, wleavitt@fas.harvard.edu (*presenting author), johnston@eps.harvard.edu

[2]Instituto De Technologia Quimica E Biologica, Oeiras, Portugal

The sedimentary sulfur isotope record is an integrator of biochemical processes, among the most quantitatively important of which is microbial sulfate reduction (MSR). Interpretations of the sedimentary sulfur isotope record rely largely on our understanding of the fractionation associated with MSR. This has been empirically determined by numerous cellular-scale studies [1, 2]. Still, a mechanistic understanding of the controls on this fractionation has proven elusive. Here, through whole-cell (*in vivo*) and pure-enzyme (*in vitro*) experiments, we provide the next generation of quantitative constraints on the fractionation capacity of a key reductive step in the MSR metabolic network. We present data from experimental work with purified dissimilatory sulfite reductase (Dsr) protein, from which we can extract enzyme-specific isotope fractionation factors. These data represent the first enzyme level constraints on isotope fractionation during MSR, and serve as a template for evaluating the other prominent enzymatic reduction steps within this metabolic process. Akin to the early carbon isotope work on RuBisCO and its importance to the carbon cycle [3], the work presented herein will help to unlock the secrets of the sulfur cycle and ultimately allow for the full isotopic interpretation of Earth's sulfur isotope records.

Metabolic isotope models of MSR are at the heart of interpreting modern and ancient sulfur isotope records [2], but models require a quantitative understanding of the magnitude of fractionation at each node within the metabolic network. To provide fundamental boundary conditions for the metabolic fractionation models of MSR [2, 4], we measured the enzyme-specific (*in vitro*) isotope fractionation factors for the key enzyme Dsr ($^{34}\alpha_{Dsr}$) which catalyzes sulfite reduction. Our pure Dsr enzyme fractions are from the model bacterial sulfate reducer *Desulfovibrio vulgaris* Hildenborough (DvH). In replicate closed-bottle experiments, Dsr catalyzed sulfite reduction at the expense of molecular hydrogen. After freeze-quenching the reaction, products and residual reactant were collected and quantified. In all cases, elemental and isotopic mass balance was satisfied. Individual sulfur pools were isolated from the bulk solution by sequential precipitation. To support the novel *in vitro* experiments, we also performed a set of continuous culture controls and classical *in vivo* closed bottle growth experiments. During closed bottle experiments, MSRs were grown first utilizing sulfate, then sulfite or thiosulfate. These later experiments represent an attempt to get whole-cell quantification of the same reductive process that the pure enzyme experiments facilitated.

Taking an enzyme-level approach to understanding isotopic fractionation in MSR provide the most fundamental constraints on the biogeochemical sulfur cycle. It is through coupled biochemical and physiological observations that we are able to better quantify the key fractionations during MSR. As a result, we gain insight into the physicochemical controls on the directionality of sulfur flow through a bacterium and resulting net sulfur isotope fractionation signatures.

Carbon and nitrogen isotopes cycling recorded in sediments from anoxic and ferruginous Lake Pavin

OANEZ LEBEAU[1]*, VINCENT BUSIGNY[1], DIDIER JEZEQUEL[1] AND MAGALI ADER[1]

[1]Univ. Paris Diderot-IPGP, Sorbonne Paris Cité, UMR7154 CNRS, Paris, France, olebeau@ipgp.fr

Over geological timescale, the Earth's oceans were affected by several periods of total or partial anoxia. Timing, causes and consequences of the ocean oxygenation can potentially be better understood from past C and N cycles. Studies on modern analogues are essential for interpreting the biogeochemical signal recorded in ancient sediments. Lake Pavin (French Massif Central) is permanently stratified with anoxic Fe-rich deep waters (from 60 to 92m depth) overlain by oxic shallow waters (from 0 to 60m depth) and can be regarded as an analogue for the ocean during periods of redox stratification with ferruginous deep water column.

In order to determine if the primary C and N isotope signatures are preserved or modified in this type of environment, we analyzed bulk C and N isotope compositions in 3 sediment cores from different depths in Lake Pavin: in the oxic zone (31.5m depth), at the oxic-anoxic boundary (60m depth), and the last one at the peak of H_2S production from SO_4^{2-} reduction (65m depth). For the cores of the anoxic layer the C and N isotopic compositions show little variability: $\delta^{13}C_{org}$ = -26.8±0.4‰ (1σ) and $\delta^{15}N_{tot}$ = -1.1±0.2‰ (1σ). Such $\delta^{15}N$ values suggest a dominance of N_2-fixers in the water column, which is expected in stratified system where nitrates are strongly denitrified at the redox boundary. For the core of the oxic layer, both $\delta^{13}C_{org}$ and $\delta^{15}N_{tot}$ increase with depth, from -28.6 to -25.3‰ and -3.4 to -1.7‰, respectively. This variation indicates either a modification of the primary signal by oxic early diagenesis or a change of the biomass contributing to the isotopic signal. Further investigations are still needed to explain this variability.

Preliminary analytical approaches to investigate the biogeochemical role of selenomethionine in aquatic ecosystems

KELLY LEBLANC[1]*, AND DIRK WALLSCHLÄGER[1]

[1]Trent University, Peterborough, ON, Canada,
* kellyleblanc@trentu.ca, dwallsch@trentu.ca

Recent changes to legislation relating to acceptable environmental selenium (Se) concentrations in North America have provided an increased need to better understand the element's natural biogeochemical cycle. Although toxicity tests modeling parts of this cycle generally expose organisms to the organic Se species selenomethionine (SeMet), to our knowledge it has not been shown that this form of Se is present in the abiotic compartments of the natural environment for uptake in real ecosystems.

It is well established that algae, the lowest trophic level in most aquatic systems, have the ability to uptake inorganic Se and metabolize it into SeMet – as both free and proteinaceous forms.[1] For this reason, as a preliminary investigation into the ability of SeMet to be released from organisms (upon their death) back into their surrounding environment, we have grown algal cultures (3 species of *Chlorophyta* and 1 *Cyanobacterium*) in the presence of selenate and examined the resulting metabolites that are present both within the cells and released into the growth media.

For the analysis of SeMet and other metabolites we have optimized existing anion-exchange chromatography inductively-coupled plasma mass spectrometric (AEC-ICP-MS) methods to allow for baseline resolution between various organic Se species of similar retention, while still allowing for quantitative analysis of inorganic metabolites such as selenite and selenocyanate. Using this method it has been observed that free SeMet is one of the main Se species within algal cells though only trace amounts are found in the growth media; potentially due to efficient re-uptake after this metabolite is released. To further confirm the identity of SeMet in algal growth media, electrospray tandem mass spectrometry (ES-MS/MS) was used and characteristic fragmentation patterns of the molecular ion were observed for various isotopes of Se.

The overall goal of this work involves determining whether SeMet is present in the abiotic compartments of the natural environment, which would make it available for uptake into the lowest tropic level of aquatic food webs and likely play a vital role in the initial stages of Se toxicity in these ecosystems. Preliminary evidence of discrete organic Se species in an impacted river system, as well as the potential implications of this will be discussed.

Carbon isotope clues on the origin of Frere granular iron formation from the Paleoproterozoic Earaheedy Basin

JACQUES L. ERFFMEYER[1*], DOMINIC PAPINEAU[1,2], AND FRANCO PIRAJNO[3]

[1] Department of Earth and Environmental Sciences, Boston College, United States.
[2] Geophysical Laboratory, Carnegie Institution of Washington, United States.
[3] Geological Survey of Western Australia, Perth, Australia.

The rocks of the late Paleoproterozoic Earaheedy Basin in Western Australia were deposited on a continental passive margin between the Pilbara and Yilgarn Craton and preserve a prominent horizon of granular iron formation (GIF). A drill core through the 1.83 to 1.79 Ga Frere Formation intersects the iron-rich horizon and was investigated for possible biological activity using carbon isotopes, which may provide clues on the origin of GIFs. Microbial involvement in the formation of granules is a possibility that remains to be demonstrated. The lowermost part of the studied section of the core consists of stromatolitic dolomite of the Yelma Formation, with mm- to cm-thick layers and veins of pyrite and galena. The lack of weathering and low metamorphic grades experienced by these rocks yield a particularly interesting suite of rock samples to investigate the local carbon cycle.

Granules with sizes between ~100 to ~500 microns were observed to be composed of chert associated with variable assemblages of microplaty hematite, magnetite, greenalite, sulfides, and organic matter. In a few samples, granules are exclusively composed of chert and organic matter, which forms rounded sub-structures, of possible diagenetic origin, a few tens of microns in size inside the granules. Initial results indicate large ranges of $\delta^{13}C_{org}$ values ranging from -14.0 to -33.1‰ for generally low total organic carbon contents between 0.01 to 0.50%wt. However, organic carbon could not be detected in all samples and many also contain carbonate carbon. Current work is focused on expanding the carbon isotope dataset of both organic and carbonate carbon, which will allow for a better characterization of the original depositional environment and of diagenetic and possibly metamorphic alteration.

The tracer-dependence of biodiffusion coefficients

PASCAL LECROART[1*], OLIVIER MAIRE[1], SABINE SCHMIDT[1], ANTOINE GREMARE[1], PIERRE ANSCHUTZ[1], FILIP J.R. MEYSMAN[2]

[1] Universite de Bordeaux, laboratoire EPOC, Talence, France p.lecroart@epoc.u-bordeaux1.fr (* presenting author)
[2] Netherlands Institute of Ecology (NIOO-KNAW), Department of Ecosystem Studies, Yerseke, The Netherlands

Bioturbation refers to the mixing of sediment particles resulting from benthic faunal activity. It is the dominant particle mixing process in most marine sediments and exerts an important control on biogeochemical processes. In models, bioturbation is usually treated as a diffusive process where the biodiffusion coefficient (Db) characterizes the biological mixing intensity. Biodiffusion coefficients are classically computed by fitting a diffusive model to vertical profiles of particle-bound radioisotopes.

One peculiar observation is tracer-dependence: Db values from short-lived tracers tend to be larger than those obtained from long-lived tracers from the same site. Recent theoretical work, based on random walk theory and Lattice Automaton Bioturbation Simulations (LABS), has suggested that this tracer-dependence is simply a model artifact and has concluded that the biodiffusion model is not applicable to the short observational time scales associated with short-lived radioisotopes.

Here we have compiled a global dataset of Db values obtained from different radiotracers to assess tracer-dependence from a data perspective. Tracer-dependence is significant in low-mixing environments like slope and deep-sea sediments, but is not present in intensely mixed coastal areas. Tracer-dependence is absent when the number of mixing events is larger than 20, or the potential length scale is greater than 0.5 cm. Roughly this comes down to tracer-derived Db values greater than 2 $cm^2\ yr^{-1}$. This condition is met for 68%, 50%, and 8% of published Db values obtained from coastal, continental slope, and abyssal environments, respectively.

These results show that short-lived radioisotopes are suitable to quantify biodiffusion mixing in sedimentary environments featuring intense bioturbation.

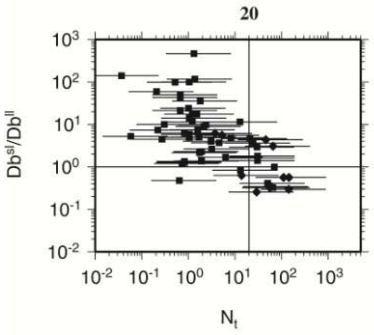

Fig. Evolution of the ratio between Db derived from short-lived tracers (Db^{sl}) and Db derived from long-lived tracers (Db^{ll}) as a function of the number of mixing events (Nt).

Characterization of fluids in the transition from deep porphyry Cu to shallow high-sulfidation epithermal mineralization at Red Mountain, AZ

PILAR LECUMBERRI-SANCHEZ[1*], ROBERT J. KAMILLI[2], ROBERT J. BODNAR[1]

[1]Virginia Tech, Blacksburg, USA, pilar@vt.edu*
[2]U.S. Geological Survey, Tucson, USA, bkamilli@usgs.gov

In recent years, significant efforts have been made to better understand the genetic relationship between deeper porphyry and shallower epithermal ore-forming systems [1,2,3]. Advanced argillic alteration is frequently associated with high-sulfidation epithermal systems and is typically absent in porphyry copper systems from the southwestern US. However, Red Mountain (AZ) has experienced relatively little erosion, leading to the occurrence of a well-preserved transition between a deep porphyry and a shallow high-sulfidation epithermal system. Hypogene mineralization at Red Mountain occurs as chalcopyrite-bornite ore at depth and transitions gradually to shallow chalcocite-enargite mineralization.

Early fluids in the deep part of the system are represented by chalcopyrite-bearing fluid inclusions that typically homogenize to liquid at 350-380 °C and have salinities of 2-5 equivalent wt% NaCl. For this range of salinity and Th the slope of the isochore is about 6 bar/°C so that the trapping temperature may be significantly greater than Th depending on the pressure of entrapment.

Later fluids in the deep part of the system are represented by halite+chalcopyrite-bearing fluid inclusions with consistent Th but variable halite dissolution temperatures of 350-420 °C within fluid inclusion assamblages. The consistent Th and variable Tm indicates that, unless necking down occurred after halite precipitation and before bubble nucleation, the fluid entrapped by this inclusions was halite saturated and therefore provides a constraint on the pressure and temperature of entrapment. The halite-bearing fluid inclusions are in secondary trails with chalcopyrite blebs. Therefore, these inclusions represent the mineralizing fluid and the trapping conditions represent the mineralization conditions.

Towards the surface and the high sulfidation epithermal system, the fluid inclusions are generally less saline and evidence of boiling is more frequent. Fluid inclusions spatially related to enargite-chalcocite mineralization have homogenization temperatures above 480 °C.

How to recognize and use primary cherts for studying Archean seawater?

MORGANE LEDEVIN[1*], NICHOLAS ARNDT[2] AND ALEXANDRE SIMIONOVICI[3]

[1*]ISTerre, OSUG, Grenoble, France, morgane.ledevin@ujf-grenoble.fr (* presenting author)
[2] ISTerre, OSUG, Grenoble, France, nicholas.arndt@ujf-grenoble.fr
[3] ISTerre, OSUG, Grenoble, France, Alexandre.Simionovici@ujf-grenoble.fr

Archean cherts are a powerful tool for studying physico-chemical conditions at the seafloor during the early history of the Earth. Numerous studies use geochemistry to infer the characteristics of Archean seawater (e.g. temperature, salinity, composition), but surprisingly few use rigorous petrological and field observations which are critical to understand the origin of analyzed cherts, their environmental context of emplacement, and their diagenetic history.

We sampled four sites in the Archean (3.5 – 3.2 Ga) Barberton Greenstone Belt in South Africa and identified three types of chert. Primary cherts are directly precipitated on the seafloor, secondary cherts come from the silicification of any kind of protolith, and fracture-filling cherts are precipitated from fluids circulating through the crust. Using field and petrological observations, we define reliable criteria to identify primary cherts, which are most likely to represent Archean seawater geochemistry.

Our field observations focus on the depositional environment and particularly on evidence of direct deposition on the seafloor. Several criteria are defined: (1) First, primary cherts are homogeneous and translucent, concordant with surrounding sedimentary rocks and they lack well-developed internal sedimentary structures (i.e. layering). (2) They contain recurrent undulating surfaces with troughs filled by the overlying sediment (i.e. load casts). (3) The presence of microbial mats on bedding surfaces indicates shallow-water deposition. (4) Slab conglomerates are interpreted as tempestites composed of angular fragments of reworked chert representing material that was precipitated and indurated on the sea floor.

When those criteria are absent, we use petrological observations to distinguish primary and secondary cherts. We show that primary cherts are exclusively made of microcrystalline quartz (<200µm in size), with little porosity (<1%) and without any internal sedimentary-like structures (i.e. layering). This homogeneity is inherited from early chert deposition as a colloidal silica phase. Cathodoluminescence and X-ray microfluorescence mapping confirm the homogeneity of primary chert which are composed also entirely of silica and contain extremely low concentrations of other elements. The very good preservation of Barberton samples is shown by an absence of major recrystallization and lack of metamorphic and/or alteration minerals.

Finally, we tested the validity of geochemical criteria to identify the primary oceanic signature in cherts. We show that such proxies are extremely dependent on the environmental context of deposition, and that no conclusions can be made without careful field and petrologic studies.

Metal stable isotopes for sediment core GC-99 from Lake Baikal

DER-CHUEN LEE[1,*], HSIN-TING LIU[2], SHUN-CHUN YANG[3]

[1]Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan, ROC, dclee@earth.sinica.edu.tw (* presenting author)
[2]Dept. of Earth Sciences, Nat. Normal Univ., Taipei, Taiwan, ROC, 49444039@ntnu.edu.tw
[3]Dept. of Geological Sciences, Nat. Taiwan Univ., Taipei, Taiwan, ROC, d98224001@ntu.edu.tw

Metal stable isotopes, e.g., Fe, Zn, Mo, and Cd, have been analyzed for the authigenic portion of a sediment core, GC-99, of Lake Baikal, Russia, in order to study the sources and sinks for these trace metals in the Lake Baikal, the largest fresh water lake in the world, as well as potential proxy for the past climate changes in this region. Lake Baikal is located in the southern region of the Siberia of Russia, and was formed through rifting. It has very thick sediments, and is relatively undisturbed due to its high latitude and isolation, and hence may provide a complete record of the local geological history [1]. In this study, a ~ 3 meters gravity core (GC-99; 52°05'23"N, 105°15'24"E) sampled near the bore hole of BDP-99 in Lake Baikal is used. Samples are taken continuously every cm interval for the entire core. For the initial test, one sample is selected for every 10 cm interval continuously throughtout the entire core. In order to extract the authigenic portions, a series of leaching procedures were used to remove the carbonates, and to collect the authigenic fractions, while leaving the lithogenic sediments unaffected. Double spike technique is used for all four metal stable isotopic measurements in this study.

Initial results showed that there are significant isotopic variations for all four isotope systems, and in general, the data are plotted away from the bulk silicate Earth (BSE). For Fe isotope, the $\delta^{56}Fe/^{54}Fe$ varies from the BSE at 0 to -2, while most of the sample centering around -1. For Zn isotope, the $\delta^{66}Zn/^{64}Zn$ is noticeably lighter than the BES, varying from -0.6 to 0 in the top 50 cm. In contrast, the $\varepsilon^{114}Cd/^{110}Cd$ varies from the BSE at +2 to +6 in the top 50 cm, and the observed +6 $\varepsilon^{114}Cd/^{110}Cd$ is most likely the results of bio-activity, e.g., diatom. For the top 50 cm, if the top surface sample is discarded, there seems to be a general positive correlation among the Fe, Zn, and Cd data, and if these correlations are real, they probably reflect a mixing relationship between the dissolved portions from the sources and the isotopic signature that had experienced the uptake of bio-activity. More data, for the extire sediment core and other biological indicators and mineralogical compositions, are needed in order to test if this is correct. Unlike the other metals, Mo data are more of an indicator for the sediment source and/or redox condition of the lake. Preliminary data for the top 50 cm also show observable variations. Although preliminary, the results seem to indicate evidence of source variations and biological activities in the sediment core of Lake Baikal. More data and, in particular, the chronology of the sediment core are needed in order to better constrain the relationship between the Lake Baikal and regional climate changes in the past.

Distribution of lead and lead isotopes in the Indian Ocean: data from the Japanese Indian Ocean GEOTRACES transect

JONG-MI LEE[1*], YOLANDA ECHEGOYEN-SANZ[2], EDWARD A. BOYLE[1], TOSHITAKA GAMO[3], HAJIME OBATA[3] AND KAZUHIRO NORISUYE[4]

[1]Massachusetts Institute of Technology, Cambridge MA, USA, jm_lee@mit.edu (*presenting author)
[2]University of Zaragoza, Zaragoza, Spain
[3]University of Tokyo, Tokyo, Japan
[4]Kyoto University, Kyoto, Japan

Anthropogenic Pb inputs have altered distributions of Pb and Pb isotopes in the modern ocean, but the impact of anthropogenic Pb inputs to the Indian Ocean has been unknown due to the lack of data. Here we discuss the distribution of Pb from 11 deep stations from the Japanese Indian Ocean GEOTRACES cruise (2009 Nov-Dec), from the Bay of Bengal and Arabian Sea to the Antarctic (18degN to 65degS). We will also show the Pb isotopic composition ($^{206}Pb/^{207}Pb$ and $^{208}Pb/^{207}Pb$) of these waters for the first time.

Because of the later industrialization and a delayed phase out of the leaded gasoline in the African and South Asian countries (and limited convection in the north), Pb concentrations in the surface waters of the Indian Ocean are higher (40-80 pmol/kg) than in the present-day North Atlantic and North Pacific (20-30 pmol/kg). The anthropogenic Pb has not penetrated deeply in the Indian Ocean yet; high Pb is confined to the upper 2000m and deep waters have low Pb (<10 pmol/kg, and as low as ~3 pmol/kg at some stations). Pb at the surface has low isotopic ratios ($^{206}Pb/^{207}Pb$ ranging 1.141-1.151 and $^{208}Pb/^{207}Pb$ ranging 2.417-2.429), and the ratios generally increase with depth due to the mixing with Pb of higher isotopic ratios in deep waters. The low isotopic ratios of the surface Pb reflect the anthropogenic origin of the Pb in the Indian Ocean: they fall onto the range of Pb isotopic ratios found in the aerosols collected from the major cities around the Indian Ocean [1]. The Pb isotopic ratios are lower in the northern stations (>20degS) than in the southern stations due to their proximity to anthropogenic Pb sources. The southernmost station (65degS) appears to be least affected by anthropogenic Pb inputs given the low Pb concentrations (4-9 pmol/kg) and distinctively high Pb isotopic ratios ($^{206}Pb/^{207}Pb$ =1.17-1.19; $^{208}Pb/^{207}Pb$ =2.44-2.46).

Analysis of Carbon Cycling Within a Malaysian Watershed

KERN LEE[1*], JAN VEIZER[1] AND IAN CLARK[1]

[1]University of Ottawa, Dept. of Earth Sciences, Ottawa, Canada klee029@uottawa.ca (* presenting author), jveizer@uottawa.ca, idclark@uottawa.ca

Introduction and Objectives

Carbon cycling in Southeast Asian watersheds remains poorly understood, and has been addressed by only a handful of studies. With regards to the stable carbon isotope systematics of these areas, the paucity of information is even greater. Such studies can help clarify the nature of carbon inputs into these fluvial systems, in addition to constraining sources and sinks of carbon in the associated watershed [1]. This information can then shed light on the importance and role of tropical rivers within the global carbon cycle.

Results and Conclusion

Initial results indicate that the dissolved organic carbon (DOC) within Langat River is sourced predominantly from C3 type vegetation, with an average $\delta^{13}C$ value of -27.4 ± 3.1 ‰. DIC $\delta^{13}C$ averages about -12.7 ± 2.4 ‰, which suggests that weathering of mineral substrates by soil-derived carbonic acid plays a central role in riverine DIC. Further ^{13}C enrichment may occur *in situ*, due to CO_2 outgassing from the river surface. Measured concentrations of DIC and DOC showed greater variance, averaging 3.5 ± 2.1 ppm and 5.3 ± 3.5 ppm, respectively. These concentration data plot negatively and positively with $\delta^{13}C$, respectively. The negative correlation is consistent with the proposition that biologic activity plays an important role in DIC generation. The factors behind the DOC $\delta^{13}C$ relationships are less certain, but could be indicative of external inputs of more ^{13}C enriched carbon relative to C3 plants sources.

Using the pH and DIC data, averaged values of -18.5 +/- 2.8 ‰ and 2958 +/- 2475 ppm were calculated for $\delta^{13}C_{CO2(g)}$ and [pCO_2], respectively. Throughout the year, the Langat River is supersaturated with respect to CO_2 in the overlying air. Atmospheric CO_2 has therefore a minimal impact on the riverine carbon budget. Instead there is a net efflux of carbon from the river surface, in accord with the proposition based on carbon isotope data implying that the fluvial CO_2 is predominantly sourced from biologically-respired carbon [2].

A rough, low-end estimate of evasion flux of carbon from the river to the atmosphere is about 3.8 kg C m^{-2} yr^{-1}, comparable to the world-average value of 2.7 kg C m^{-2} yr^{-1} for tropical streams [3]. This suggest that a minimum of 8.5 kt C yr^{-1} is being outgassed, approaching the magnitude of the total carbon export of 20 kt C yr^{-1} to the sea, as estimated based on river flow and DIC/DOC concentration data. These results confirm previous studies that highlight the active role of rivers in global carbon cycling, beyond that of simple conduits of carbon transport from land to sea.

Experimental evidence that redox state influences amino acid stability under hydrothermal conditions

NAMHEY LEE[1,2], DIONYSIS I. FOUSTOUKOS[2], DIMITRI A. SVERJENSKY[1,2], GEORGE D. CODY[2], ROBERT M. HAZEN[2]

The stability of amino acids under hydrothermal conditions is of great interest to geochemists and biochemists in understanding the metabolic cycles of the biosphere near deep-sea hydrothermal vents and potential mechanisms for the origin of life in such environments. Thermodynamic calculations suggest that amino acid stability is sensitive to both temperature and the redox state of the environment [1]. Previous experimental studies have shown that parameters such as temperature and catalytic reactor surfaces strongly affect the stability of amino acids under hydrothermal conditions [2]. However, despite the potential relevance, the redox state of amino acid systems has never been controlled experimentally. Here experiments were conducted to investigate the influence of redox conditions on the stability of glutamic acid under hydrothermal conditions in a flow-through cell with temperatures from 150 ^{o}C to 250^{o}C at 136 bars. The redox state was controlled by equilibrating ~14 mmolal $H_{2(aq)}$ in solutions containing glutamic acid with varying pHs. Results indicate that under hydrothermal conditions glutamic acid is converted to the cyclic pyroglutamate, a redox neutral reaction, following first-order kinetics. Other reaction products including $CO_{2(aq)}$, NH_4^+, formate, and succinate are formed through redox controlled reactions. The concentrations of the reaction products are observed to be strongly dependent on the redox state of the system. This finding indicates that redox state defined by aqueous H_2 is an essential variable in determining the stability of biomolecules under hydrothermal conditions.

Laboratory TIR Emission Spectroscopy of Silicic Melts

R. J. LEE[1*], M. S. RAMSEY[1], AND P. L. KING[2]

[1]University of Pittsburgh, Pittsburgh, PA USA, rjl20@pitt.edu (* presenting author)

Introduction

Silicic glass is ubiquitous in volcanic environments, and is known to affect TIR remote sensing data. Glasses display similar TIR spectral features regardless of composition, making them difficult to distinguish spectrally [3,4], and their features vary with physical state [1,2]. To quantify these spectral changes, and provide calibrated laboratory melt data, a custom-built micro-furnace has been developed for use with a Nexus 670 FTIR spectrometer. It has been used to collect the very first *in-situ* laboratory TIR emissivity spectra of actively melting/cooling rhyolitic to dacitic compositions.

Methods

Absolute emissivity spectra were acquired using an empty Pt-lined furnace cavity as the blackbody calibration source. Crushed synthesized glass (1 to 2g) was placed into Pt crucibles in the micro-furnace. Emissivity spectra were acquired in 100°C intervals to the melting point temperature (MPT). To mimic the cooling behavior of lava, data were also acquired at 100°C intervals as the melt cooled. Spectra of seven glasses were taken at 20°C intervals from MPT to ~1100°C, to determine the approximate glass transition (Tg).

Results and Conclusions

Changes in the position, depth and spectral morphology of the absorption band with physical state have been quantified. Significant findings include a reduction in average melt emissivity, and identification of ~ Tg. Preliminary results show this approach is applicable to melt petrology and could be used with remote sensing data to better characterize and map glassy volcanic environments.

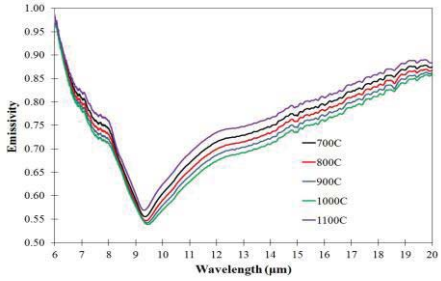

Figure 1: Glass emissivity spectra from 700C to 1100C, showing changes in spectral morphology with physical state.

In-situ observations of the formation of a single-layer gibbsite-like phase on the muscovite (001) surface

SANG SOO LEE[1*], MORITZ SCHMIDT[1], KATHRYN L. NAGY[2], AND PAUL FENTER[1]

[2]University of Illinois at Chicago, Earth and Environmental Sciences, Chicago, IL, USA

Hydrolysis of a multivalent cation in aqueous solutions often precedes secondary reactions such as oligomerization. It is known that such reactions can be controlled by the presence of solid surfaces [1]. Previous work showed that crystalline Al-hydroxide phases formed on the surface of muscovite mica with an apparent epitaxial relationship to the underlying surface [2], but the molecular-scale interfacial processes that initiate the reactions are not well understood. We investigated the formation of an Al-hydroxide phase on the basal surface of single crystal muscovite by monitoring changes in muscovite-solution interfacial structure using in-situ high resolution x-ray reflectivity. Experimental solutions were prepared with a fixed total Al content (1 mM) as a function of pH. At pH 4, we observed sorbed Al^{3+} species formed an approximately 2Å thick film. The thickness and the vertical structure of the film matches those of a single Al dioctahedral sheet, i.e., gibbsite, $Al(OH)_3$, phase. The films formed at lower pH (2 and 3) are structurally more disordered and are less dense (i.e., covered a smaller fraction of the surface) than that formed at pH 4. These observations can be attributed to decrease in the concentration of hydrolyzed Al species with decreasing pH, both in the solution and at the surface. No film formation was observed at alkaline conditions (pH 9-12) where Al^{3+} occurs primarily as an anionic species, $Al(OH)_4^-$. The difference implies that the formation of the film is initiated by adsorption of positively-charged Al species at the negatively charged surface.

The results demonstrate that the growth of secondary minerals and the structural control of underlying substrates can be investigated in situ, in real time, and with a molecular-scale resolution. The results also suggest a new capability to characterize the reactivity of nanomineral films [3] with a high resolution.

Biogenic and abiogenic nucleation of uranium in anaerobic environments

SEUNG YEOP LEE[1*], JONG MIN OH[1], MIN HOON BAIK[1], AND JONG WON CHOI[1]

[1]Korea Atomic Energy Research Institute, Daejeon, Korea, seungylee@kaeri.re.kr

Biogenic uranium transformation

Biogenic UO_2 (uraninite) nanocrystals may be formed as a product of a microbial reduction process in urnaium-enriched environments near the Earth's surface [1]. We investigated the size, nanometer-scale structure, and aggregation state of UO_2 formed by iron-reducing bacterium, *Shewanella putrefaciens*, from a uranium-rich solution. The UO_2 nanoparticles were highly aggregated by extracellular polymeric substances (EPS) (Figure 1), which limited a dispersal of the nanoparticulate uranium phase. Nearly all of the nanocrystals were networked in more or less 100 nm diameter spherical aggregates that displayed some concentric UO_2 accumulation with heterogeneity.

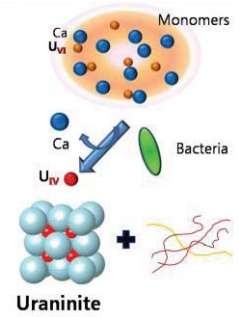

Figure 1: The microbial UO_2 formation and aggregation by EPS

Abiogenic U(IV) phase catalyzed by a biogenic sulphide mineral

Sulphate-reducing bacteria (SRB) and their by-products, such as iron sulfides, are widely distributed in subsurface environments, and can affect subsurface chemisty. There was a catalytic reduction and nucleation of uranium by fast-growing biogenic mackinawite (FeS), which is a common iron monosulphide observed in the anaerobic subsurface. The formed uranium phase was a nanoparticulate U(IV) phase. However, the U(IV) nanoparticles were easily released and dispersed without aggregation. It shows that a mobility of the reduced uranium phase might exist and be influenced by the ways that it was reduced in a heterogeneous microbial system.

Introduction

Dongrae and Haeundae hot springs are one of the representative hot springs with water temperatures more than 58°C in South Korea. Both hot springs occur in Mesozoic granite area which is located in the Busan city at the margin of southeastern coastal side of the Korean peninsula, and have been used for spa for the past 1,000 years. Here we report ^{14}C, ^{3}H, $\delta^{18}O$, $\delta^{2}H$ and $^{87}Sr/^{86}Sr$ isotopic data for the Haeundae and Dongrae hot spring waters, which were collected for 2004-2011. Based on the geochemical data mentioned above, the groundwater cycle between hot spring waters and shallow graoundwaters, and heat source of the hot springs in Busan area will be discussed.

Results and Discussion

Geochemically, both of the hot spring waters are of Na-Cl type. The result of stable isotope compositions of O and H suggested that both of the hot spring waters should be derived from meteoric water. Furthermore, the chemical components of the hot spring waters indicate that they all were derived from hot spring water-rock interaction rather than through anthropogenic input. The $^{87}Sr/^{86}Sr$ ratio in Dongrae hot spring waters during the past 8 years ranges from 0.705632 ± 0.000012 to 0.705694 ± 0.000010. And the $^{87}Sr/^{86}Sr$ ratio in Haeundae hot spring waters ranges from 0.706023 ± 0.000011 to 0.706082 ± 0.000011. The ^{14}C ages in Dongrae hot spring waters ranged from 1,271 to 2852 years(BP) whereas those from the Haeundae from 2037 to 6687 years(BP). Such age difference corresponds well with aquifer depth of hot spring waters.

Conclusion

In this study, we could observe that there was no variation in the $^{87}Sr/^{86}Sr$ ratio from both hot spring waters during last 8 years. The chemical component also does not show significant variaton in their compostion. These all indicate that the hot spring waters in Busan area might be a product of long-term water-rock interaction rather than short-term water-rock interaction due to the input of recent meteoric water. In this research, we could confirm that $^{87}Sr/^{86}Sr$ ratio in the groundwater can be used as a tracer for monitoring the groundwater mixing history among several different aquifers such as shallow and deep groundwaters.

Abstract

Bioreduction of U(VI) to U(IV) is considered a promising strategy for immobilizing U in the subsurface. Until recently, the product of U(VI) reduction was considered to be crystalline uraninite (UO_2). Recent studies have shown that other non-UO_2 phases may also exist including monomeric U(IV) which is presumed to be more labile relative to UO_2 [1]. Manganese oxides (MnO_2) which can be formed microbially even under low oxygen concentrations, can oxidize U(IV) to U(VI), and thereby jeopardize the stability of U(IV) [2]. Once oxidized by biogenic MnO_2, the resulting U(VI) can sorb to the MnO_2 surface. As the presence of MnO_2 can greatly impact the fate and transport of U in the subsurface, it is imperative to understand the effect a variety of common groundwater constituents may have on microbial Mn(II)-oxidation rates and the structure of the biogenic manganese oxides which in turn potentially affect the stability of U(IV).

In this study, the effects of common groundwater constituents, O_2 (0-5 %), Ca^{2+} (5 mM), Mg^{2+} (5 mM), and HCO_3^- (1 mM), on the coupled Mn/U processes were investigated. A model Mn(II)-oxidizing microorganism, *Bacillus* sp. SG-1 spores, was incubated with Mn(II) in the presence and absence of the above solutes and U(IV) as either biogenic UO_2 or monomeric U(IV). It is hypothesized that conditions that stimulate microbial Mn(II)-oxidation or lead to the formation of U(VI) complexes will lead to faster Mn(II) and U(IV) oxidation rates. In contrast, constituents that provide more stability for U(IV) species or sorb strongly to the MnO_2 surface and reduce its ability to oxidize U(IV) will decrease or have little impact on the rate of U(IV) oxidation. As expected, increasing O_2 concentration led to increased Mn(II)-oxidation rates. Addition of Ca^{2+} stimulated Mn(II)-oxidation while Mg^{2+} inhibited Mn(II)-oxidation in the presence of U(IV). Specific experiments probed the biological and chemical basis for the stimulatory and inhibitory effects of individual groundwater constituents on Mn(II)-oxidation in the presence of U(IV).

Cyanide (CN) has been the subject of interest due to its heavy toxicity on humans and ecosystems. Carbons such as charcoal and granular activated carbon (GAC) are commonly used to remove contaminants in environments. Despite the popular usage of carbon, cyanide uptake by GAC has not been systematically adressed yet. In addition, effects of UV-light on cyanide attenuation are barely studied over a wide range of physicochemical conditions. Thus, in this study, we investigate cyanide sorption on GAC and its attenuation by UV-light over a wide range of conditions such as different pHs and concentrations through batch experiments.

Cyanide uptake by GAC is effective at $[CN]_{initial} < 2$ mg/L. At pH 7.0, the sorption of cyanide on GAC is greater than that of pH 9.0. It is also found that the ratio of CN uptake by GAC increases at pH 9.0 whereas the ratio decreases at pH 7.0, suggesting that reactivity of GAC would increase as a function of pH. The cyanide uptake by GAC rapidly increases during the first 30 min, followed by sharp desorption until 3 hr, and then the sorption increases and reaches the maximum sorption during the duration of experiments, implying that the sorption mode could be changed. Total amount of cyanide desorbed from the GAC during the duration of the desorption is less than 1.5% of total sorbed cyanide, indicative of strong and stable sorption of cyanide on the GAC. It is noted that UV-light is much effective on the attenuation of cyanide but also the attenuation is achieved until $[CN]_{total}$ is up to 10 mg/L. Our findings demonstrate that both GAC and UV-light are very effective on the attenuation of cyanide over a wide range of environmental conditions.

Abstract

Assessing the distribution of groundwater inflow to small watersheds is of utmost interest to appreciate the sensitivity of humid zones to environmental changes. However, this distribution is poorly constrained because the resolution on river flow measurements is generally low. Different environmental tracer experiments have been proposed during the last decade [1]. In this work, we investigate the significance of $\delta^{18}O_{water}$, $\delta^{2}H_{water}$, $\delta^{13}C_{TDIC,}$ $A^{222}Rn$ coupled with *in situ* measurements (Q, T°, EC, pH, alcalinity) to better understand groundwater inflow to rivers. These tracers have been chosen as they may depict signals significantly different from groundwater to surface water. Here, we focus on processes and kinetics that sustain tracer evolution in surface waters.

The experimental site is a small watershed (219 km²) located in northern France. The Hallue River is 15 km long and flows over the Chalk aquifer. Stream flow was measured manually using a velocimeter and reflects variations in groundwater discharge along the river length. T, EC, pH and alkalinity were measured *in situ* at 11 locations along the Hallue River. Sampling for $\delta^{18}O_{water}$, $\delta^{2}H_{water}$, $\delta^{13}C_{TDIC}$ and $A^{222}Rn$ was performed in different glass bottles on the 11 locations with a peristaltic pump. Analyses of $\delta^{18}O_{water}$ and $\delta^{2}H_{water}$ were done in the IDReau laboratory (University Paris Sud, France) whereas the others were made at the "Département des sciences de la Terre et de l'atmosphère de l'UQAM" and at the GEOTOP (laboratory). The results of $\delta^{18}O_{water}$ and $\delta^{2}H_{water}$ show that there is no evaporation of the river water. The correlations between ^{222}Rn, CE and $\delta^{18}O_{water}$ and between $\delta^{13}C_{TDIC}$ and pH are high. ^{222}Rn and $\delta^{13}C_{TDIC}$ are anti-correlated and respond rapidly to groundwater inflow to the river. As a result, ^{222}Rn and $\delta^{13}C_{TDIC}$ processes are modeled using a diffusion exchange approach discretized along the river, as suggested by Cook et al. (2006) for ^{222}Rn [2]. The model fits very well the evolution of ^{222}Rn. Yet, the sensitivity of the model is too low for $\delta^{13}C_{TDIC}$.

The Lower St. Lawrence Estuary: A suitable analogue for OMZs?

STELLY LEFORT[1*], YVES GRATTON[2], ALFONSO MUCCI[1], DENIS GILBERT[3] AND ISABELLE DADOU[4]

When the rate of oxygen consumption in water exceeds the rate of supply, the oxygen concentration decreases and may reach levels that threaten the survival of many aquatic organisms. Waters with such low oxygen levels are termed severely hypoxic ($[O_2] < 62.5$ μmol L^{-1}).

The dissolved oxygen concentration in the deep water of the Lower St. Lawrence Estuary (Eastern Canada) has progressively decreased during the last century, concomitent with an increase in temperature. The severely hypoxic threshold was reached in the early 1980s where it has hovered ever since [1].

Using a 2D diffusion-advection model for oxygen, we examined the causes of large-scale hypoxia in the bottom waters (> 150 m depth) of the Lower St. Lawrence Estuary [2] and estimated the volumetric evolution of these hypoxic waters in response to further changes in the boundary conditons (biogeochemical properties of the waters that enter the estuary from the North Atlantic Ocean). The physics of the system and the source water properties were identified as the main cause of oxygen depletion and shown to control the oxygen distribution pattern in the deep water column [2]. Preliminary results on the evolution of hypoxia reveal that a ~2°C increase of the bottom water temperature would cause widespread anoxia throughout the Lower St. Lawrence Estuary and into the western Gulf.

Remediation of Coal-Mine Drainage by Sulfate-Reducing Bioreactor

LILIANA LEFTICARIU[1,2,*], PAUL T. BEHUM, JR[2], CHARLES W. PUGH[3] AND KELLY S. BENDER[3]

[1]Southern Illinois University, Department of Geology, lefticar@siu.edu (*presenting author)
[2]Southern Illinois University, Environmental Resources and Policy, pbehum@siu.edu
[3]Southern Illinois University, Department of Microbiology, bender@micro.siu.edu

Acid mine drainage (AMD) associated with abandoned coal mines is produced by biochemical weathering of organic (e.g., macerals) and inorganic (e.g., pyrite and other sulphides, clays, carbonates) components found in coal, overburden, and mine waste piles [1, 2]. Hydrologic conditions allow most coal mines in the Illinois Basin to be reclaimed without deleterious drainage problems. However, localized AMD from historic surface and underground mining within the basin have required remediation.

A passive-treatment system constructed in 2006 at one of these sites, the Tab-Simco mine near Carbondale, Illinois, remediates AMD characterized by low-pH (~2.9) and high-metal concentrations. Over the past five years the treatment system has increased the median pH of the AMD to ~6.0 and decreased the median acidity to 22.7 mg/L CCE, SO_4^{2-} from 2,981 to 1,750 mg/L, Fe from 450.6 to 3.76 mg/L, Al from 113 to 3.42 mg/L, and Mn from 36.4 to 23.3 mg/L. Continuous monitoring over the past five years has revealed significant temporal trends, including (1) seasonal variations in acidity, dissolved SO_4^{2-} and metals, (2) a general decline in the amount of alkalinity produced, and (3) an overall decline in the efficiency of the of treatment system in removing sulphate and metals. Bacterial community analyses targeting 16S rRNA and dsrAB genes indicated that the pre-treated samples were dominated by bacteria related to iron-oxidizing Betaproteobacteria, while the post-treated water directly from the reactor outflow was dominated by sequences related to sulfur-oxidizing Epsilonproteobacteria and complex carbon degrading Bacteroidetes and Firmicutes phylums. While initial microbiological results indicated that the passive treatment system was successful in stimulating sulfate-reducing bacteria to a certain extent, the algae and bacteria related to sulfur and iron oxidizers dominated the system. Cultures capable of sulfate-reduction have been enriched from the bioreactor and isolates are being used to determine optimal growth substrates. Molecular analysis targeting the 18S rRNA gene is also being used to characterize the algal and microscopic eukaryotic communities present in order to determine their metabolic contribution to the site chemistry. The geochemical and biological trends suggest that the AMD treatment system has to be modified in order to both stimulate sulfate-reducing bacteria and inhibit sulfur-oxidizing bacteria.

Our study demonstrates that passive treatment is an important technology for remediation of streams impacted by coal mining. This result is significant because it provide evidence that reclamation of abandoned coal mines can reduce significantly the environmental impact to water quality degradation.

Street sediment and lichen as proxies to constrain source of urban lead pollution using lead isotopes

ERIN LEGALLEY[1*], ELISABETH WIDOM[1], MARK P.S. KREKELER[1], AND DAVID C. KUENTZ[1]

[1]Department of Geology and Environmental Earth Science, Miami University, Oxford, Ohio 45056, U.S.A., legallem@muohio.edu (* presenting author)

Introduction and methodology

Street sediment and lichen samples were used as proxies to investigate the source of urban lead (Pb) pollution in Hamilton, Ohio. Pb is a well-known environmental pollutant that poses a significant risk to human health and the greater environment. The study area includes a coal-fired power plant, the Great Miami River, athletic fields, industry, residential neighborhoods, and roadways.

Previously studied street sediment samples exhibit high concentrations of heavy metals (Pb, Zn, Cr, Cu, and Ni) and contain evidence of coal-derived pollution such as fly ash spherules.[1] Lichens are extensively used as bioindicators of atmospheric pollution[2,3] and have not been previously investigated in this study area. Heavy metal concentrations and Pb isotopic compositions of street sediment and lichen samples are combined to develop a more complete picture of local pollution. Major potential sources of Pb pollution in the study area include road paint containing $PbCrO_4$ as a yellow pigment and emissions from the coal-fired power plant.

Samples of local coal, fly ash from an anonymous coal-fired power plant in Kentucky, local road paint, lichen, and sieved (<38 μm) street sediment were analyzed. Two soil samples and one glacial till sample representing regional background were also analyzed. Elemental concentrations were determined by ICP-MS and Pb isotope ratios were determined by either TIMS or MC-ICP-MS.

Results and discussion

Street sediment samples exhibit highly variable Pb concentrations ranging from 130 to 1398 ppm. Pb concentrations in lichen range from 11 to 54 ppm. Pb concentrations range from 17 to 94 ppm in coal and fly ash samples and from 14 to 18 ppm in regional background samples. Road paint samples contain up to 0.63 wt% Pb. Pb isotope ratios in sample materials also exhibit substantial variability and potential pollution sources are isotopically distinct.

Street sediment and lichen samples exhibit strong positive correlations of $^{206}Pb/^{204}Pb$ vs. $^{208}Pb/^{204}Pb$ and $^{208}Pb/^{206}Pb$ vs. $^{207}Pb/^{206}Pb$, consistent with two-component mixing between regional background and road paint samples. In $^{206}Pb/^{204}Pb$ vs. $^{207}Pb/^{204}Pb$, coal and fly ash samples fall distinctly off this mixing trend, confirming the dominant contribution of Pb from road paint. Electron microscopy investigations of street sediment and the utilization of lichens as bioindicators of atmospheric pollution demonstrate the fine particulate nature of Pb pollution, and efforts to reduce health and environmental risks are encouraged.

Metals in black shales

BERND LEHMANN[1*]

[1*]Technical University of Clausthal, Mineral Resources, bernd.lehmann@tu-clausthal.de

Post-Archean marine black shales with organic carbon content of several wt% have long been known to be enriched in a broad metal spectrum. These metals reflect accumulation of biogenic matter with a composition relatively close to that of planktonic organisms. A suite of redox- and particle-sensitive metals also accumulates through precipitation/adsorption from seawater and reflects the environmental conditions of the ocean bottom water as a function of bacterial respiration/organic matter degradation. Oxic conditions are characterized by enrichment of Mn and locally Ba, whereas suboxic (also denitrifying) conditions typically have high P, and in places high V or Cr concentrations; anoxic and euxinic conditions (both sulfate reducing) may display V, U, Mo, and Ni enrichments..

Advanced organic matter decay under reducing conditions will release Ni, Cu, Zn from biogenic matter which may be incorporated in pyrite or in other sulfides. Consequently, Ni, Cu, Zn may indicate the original presence of organic matter even if partially or totally lost after deposition. Lateral facies variation with distinct metal zoning between these different depositional environments corroborates the general model, which, at very advanced reaction progress, is best preserved in restricted and stratified Early Cambrian basins on the Yangtze Platform of South China. Hydrodynamically induced winnowing of hardground with oolithic Mo-S-C and Ni sulfide compounds has here produced spectacular metal tenors in the % range in euxinic portions, grading into suboxic V-rich black shale (V in illite), with huge stratigraphically equivalent phosphorite deposits in oxic/suboxic settings, as well as 10s of meter thick "stone coal" (sapropelite).

Anoxic/euxinic marine environments may also provide the reducing milieu for focussed seafloor metal precipitation from hydrothermal fluids related to sediment-hosted massive sulfide systems (Cu-Pb-Zn-Ag-Ba), as documented by the presence of host basal black shale units in many SEDEX massive sulfide ore deposits (such as Rammelsberg, Germany; HYC, Australia; Howards Pass and Sullivan, Canada; Red Dog, USA). Basal black shale is also found related to Late Archean/Early Proterozoic banded iron formation (Minas Gerais and Carajás, Brazil).

Black shales preserve their reducing lithology with geological time and may then act as epigenetic traps for redox-sensitive metals in a broad hydrothermal ore deposit spectrum. Examples are orogenic gold and Carlin-type gold deposits where gold deposition is controlled by carbonaceous host rocks, or unconformity-related uranium deposits which are controlled by graphite-rich basement rocks. Roll-front/sandstone-hosted uranium deposits are also controlled by reducing host rocks within a much wider oxidizing depositional environment. The same applies to the European Kupferschiefer and Central African copper shale deposits where basinal brines leach postorogenic red bed/molasse basins and Cu (Co) + other minor redox-sensitive elements are deposited at thin carbonaceous rock units.

Links between sediment reactivity, sediment oxygen demand, and the N isotope effect of benthic N loss: Model and field observations

MORITZ F. LEHMANN[1]* AND MOHAMMAD ALKHATIB[2]

[1] Universität Basel, Department for Environmental Science, Basel, Switzerland, moritz.lehmann@unibas.ch (* presenting author)

[2] GEOTOP, UQAM-GRIL, Département des Sciences Biologiques Montreal, Canada, alkhatib.mohammad@courrier.uqam.ca

Abstract

We report $^{15}N/^{14}N$ ratios of pore water nitrate and reduced dissolved nitrogen (RDN=DON+NH_4^+) in sediments from various marine environments, where microbial nitrate reduction has previously been identified as a significant sink for fixed nitrogen (N). In order to address the combined isotope effects of benthic N-cycle processes (ε_{sed}) on the water column nitrate pool and to assess the dependence of ε_{sed} on various environmental factors, we calculated the net fluxes of dissolved N across the sediment-water interface from simulated pore water profiles corresponding to denitrification under varying sedimentation regimes. The model simulations suggest that differences in sediment reactivity and sediment oxygen demand have a significant effect on the geometry of the oxic layer and the denitrification zone, and thus on the expression of the biological N-isotope effect of denitrification in the water column. Model predictions were confirmed by observational benthic isotope flux data from an estuarine environment characterized by gradients in organic matter (OM) reactivity, bottom water oxygen concentrations, as well as benthic respiration rates. In agreement with the model, observed values for ε_{sed} ranged between 1 and 6 ‰ and diffusion-limitation of nitrate to the depth of denitrification was identified as the main cause of the general under-expression of the biological fractionation (>20‰) at the sediment water interface. The pore water RDN pool in the sediments was enriched in ^{15}N relative to the water column so that the (OM reactivity-controlled) efflux of RDN to the water column acts to enhance ε_{sed} . ε_{sed} reflects the $\delta^{15}N$ of the N_2 lost from marine sediments and thus best describes the isotopic impact of N elimination on the oceanic fixed N pool. Our mean value for ε_{sed} (4.6‰) is larger than assumed by earlier work, questioning current ideas with regards to the state of balance of the modern N budget.

A multiproxy approach ($^{87}Sr/^{86}Sr$, $\delta^{44}Ca$, $\delta^{13}C_{DIC}$) for tracking seasonal changes in permafrost dynamics

GREGORY O. LEHN[1*], ANDREW D. JACOBSON[1] THOMAS A. DOUGLAS[2], JAMES W. MCCLELLAND[3], AMANDA J. BARKER[2], MATT S. KHOSH[3], CHRIS HOLMDEN[4]

Global change predictions indicate the warming will be greatest in the high latitudes, where permafrost soils have historically been a large carbon sink. As temperatures increase, the seasonally thawed active layer will extend downward into previously frozen soils, potentially releasing large quantities of greenhouse gases to the atmosphere, thus accelearting the pace of warming. In addition, dramatic changes in the hydrology and biogeochemistry of Arctic landscapes will result. A better understanding of the dynamics of permafrost thaw is needed to gauge the importance of feedbacks between Arctic warming and global climate change. Conventional methods for probing the depth of the active layer are labor intensive and may not address the spatial heterogeneity of Arctic soils. Alternatively, geochemical gradients in permafrost may be harnessed as spatially integrative, natural tracers of the downward movement of the active layer. This study evaluates $^{87}Sr/^{86}Sr$, $\delta^{44}Ca$, and $\delta^{13}C_{DIC}$ in stream water as potential tracers of seasonal variations in permafrost thaw.

Surface waters were collected from six watersheds on the North Slope of Alaska between May and October of 2009 and 2010, focusing on early spring thaw through late season freeze-up. All rivers drain continuous permafrost: three drain tussock tundra-dominated watersheds, and three drain bare bedrock catchments with minor tundra influences.

Large interstream variations in $^{87}Sr/^{86}Sr$ ratios imply heterogeneity in soil composition across watersheds. However, within individual watersheds, $^{87}Sr/^{86}Sr$ ratios vary with changes in discharge, including early season melt, base flow, and large rain events. During periods of high discharge, slightly elevated $^{87}Sr/^{86}Sr$ ratios indicate flushing of the shallow soil pool, which has a relatively low carbonate mineral content. $\delta^{44}Ca$ values in tundra streams decrease during the melt season while $\delta^{44}Ca$ values in bedrock streams increase. In tundra streams, low $\delta^{13}C_{DIC}$ values in the early season indicate silicate weathering. Higher mid- to late-season $\delta^{13}C_{DIC}$ values indicate carbonate weathering. Bedrock streams have nearly constant $\delta^{13}C_{DIC}$ values and high dissolved sulfate concentrations throughout the year, indicating the signficance of sulfuric acid carbonate weathering. In late fall of 2010, $\delta^{13}C_{DIC}$ values suggest a shift from sulfuric acid- to carbonic acid-dominated weathering, possibly due oxygen limitation during active layer freezing. Our initial findings illustrate how seasonal changes in mineral weathering have potential for tracking active layer dynamics.

Model of isotope distribution during water-rock interactions

LEMARCHAND D.[1*], DI CHIARA ROUPERT R.[1]

[1]LHyGeS-EOST, University of Strasbourg, Strasbourg, France, lemarcha@unistra.fr (* presenting author)

Soil particles evolve by contact with weathering agents supplied by meteoritic waters (mainly protons) or produced by the near activity of living organisms (protons, organic acids and ligands). The chemical budget of soil-forming reactions depends primary on the nature of the parent bedrock but also on the extent and rates of the weathering reactions. The mechanisms and controls of soil particles (trans)formation depend on multi-parametrized and non-linear reactions that are therefore difficult to characterize and even more to model on the basis of chemical composition alone.

In the present study, we developed a general model of isotopic evolution of bulk soil samples in response to progressing weathering reactions. It is based on mass and isotopic budgets and treats the bulk soil evolution as a simple gain-and-loss problem in which soil-forming reactions consist in mineral dissolution (loss) and secondary mineral precipitation (gain) including exchange of matter with the surrounding soil solution. Since dissolution and precipitation reactions have distinct effects on stable isotopic systems (like B, Ca, Li, Mg, Si, and many other metals of intermediate mass), then analyses of bulk soil samples give insights on the degree of soil evolution by comparison with a reference material that can be either the parent bedrock or a deeper soil layer. Adding analyses of the soil solution with knowledge of the water velocity provides additional information on the reaction rates as well as helps distinguishing reactions currently active from those active the past.

Because the water-rock interaction system may rapidly be under-determined, we developed a population-based stochastic search technique based on a modified Particle Swarm Optimization approach (PSO) to solve our system of differential equations. This has the advantage to provide sets of solutions without requiring the precise knowledge of model parameters like isotopic fractionation factors or the relative mass of parent material lost.

The model has been tested with B chemical and isotopic compositions in two soil profiles developed on granitic bedrock from the Strengbach watershed (Vosges Mountains, France) and showing different dissolution/precipitation dynamics. First numerical solutions are consistent with our hydrological and mineralogical knowledge of the two soils. They also clearly show varying intensity of soil-forming reactions with depth in line with the tree roots density or the soil horizons. These results encourage further work coupling isotopes with advanced numerical approaches for investigating water-rock interactions in multi-parametrized systems.

The role of Fe(III) (hydr)oxide structure in controlling the kinetics and products of biogenic sulfide oxidation in low sulfate media with *Desulfovibrio* sp.

CHRISTOPHER J. LENTINI[1*], SCOTT D. WANKEL[2], COLLEEN M. HANSEL[1,2]

[1]School of Engineering and Applied Sciences, Harvard University, Cambridge, MA, U.S.A.,

[2] Earth and Planatery Sciences, Harvard University, Cambridge, MA, U.S.A.,

(* presenting author; lentini@fas.harvard.edu)

Iron (hydr)oxides are a diverse groups of minerals which exist in a spectrum of crystallinities and subsequent bioavailabilities; ranging from ferrihydrite (poorly crystalline) to hematite (well crystalline). While the organisms responsible for the reduction of the poorly crystalline phase ferrihydrite have been well documented (*Geobacter* and *Shewanella*), these model dissimilatory iron-reducing microorganisms (DIRMs) show diminished abilities to reduce the more crystalline Fe(III) (hydr)oxide phases, goethite and hematite. In agreement with this, we have previously shown through enrichment experiments that these model DIRMs are enriched on goethite and hematite yet their presence does not correlate with reduction of these more crystalline phases. Instead, within Fe(III)-reducing enrichments supplemented with lactate, the reduction of goethite and hematite was detected in significant amounts (30–60%) and appeared to be a function of organisms associated with sulfate reduction, *Desulfovibrio putealis* and *Desulfovibrio vulgaris*. Media specific thermodynamic calculations along with enrichment data suggest that sulfate reduction may dominate and control Fe(III) reduction when more recalcitrant Fe(III) phases are provided as the terminal electron acceptor.

Interestingly, sulfate concentrations (200 μM) and subsequent sulfide oxidation alone could not account for the amount of Fe(III) reduction observed, without the cycling of sulfur. Consequently, the data suggest that either *Desulfovibrio* directly participates in the reduction of goethite and hematite or catalytic amounts of sulfur are being cycled multiple times.

In order to further elucidate the mechanisms of Fe(III) reduction by sulfate-reducing bacteria, pure culture Fe(III)-reducing experiments with *Desulfovibrio* species were conducted using three Fe(III) (hydr)oxides (ferrihydrite, goethite, hematite) and varying freshwater sulfate concentrations (0-800 μM). In order to track how intermediate Fe and S species varied as a function of Fe(III) (hydr)oxide type and S:Fe ratio, a variety of spectroscopic techniques were coupled with voltammetric microelectrodes. This aqueous data was combined with S and Fe EXAFS to further elucidate the products of sulfide oxidation and Fe(III) reduction. These findings will further illuminate how sulfate reduction kinetics in low-sulfate waters controls Fe(III) reduction of structurally diverse Fe(III) (hydr)oxides. In addition, the role that Fe(III) (hydr)oxide mineralogy and S:Fe ratios play in controlling the stoichiometry of different oxidized S species will be highlighted.

Did life turn the global weathering thermostat back up after turning it down?

TIMOTHY M. LENTON[1*]

[1]University of Exeter, Exeter, UK, t.m.lenton@exeter.ac.uk (*presenting author)

It is now widely accepted that plants (and their associated soil communities) amplify the weathering of silicate rocks, thus accelerating the drawdown of atmospheric CO_2 and ultimately leading to a lower stable state for CO_2 and global temperature. In metaphorical terms, land life has turned down the dial on the global weathering thermostat. Indeed it may have done so several times.

This is a neat way of explaining episodes of global cooling. Most notably, the rise of rooted vascular plants has been linked to the Late Devonian and Permo-Carboniferous glaciations. Recently, we suggested that the earlier rise of the first non-vascular plants could have been responsible for the Late Ordovician glaciations [1]. More speculatively, we have argued that lichen-like land colonisers could explain the episode of extreme glaciations in the Neoproterozoic [2]. Others extend the argument even further back in time [3].

But why were these cold episodes in Earth history transient ones? If the effects of life on weathering persisted each time, one would expect it to have remained cold. One can appeal to a steadily brightening Sun to warm things up again, but that is far too slow a process to explain the rather striking returns to warmer conditions. Often geological mechanisms are invoked to explain recovery from the cold. But it would be rather surprising if every time a biological innovation cooled the planet, some tens of millions of years later a change in geological forcing acted to warm it up again.

Here I suggest that biotic increases in weathering are naturally followed by biotic decreases in weathering. The key mechanism is a transition from weathering-fuelled phases of land colonisation to recycling-based ecosystems. Initially, new colonisers of the land must weather their rocky substrate to extract essential elements for growth, but as that substrate becomes exhausted and soils become established, ecosystems switch to internal recycling of essential elements. Also, by stabilising landscapes and suppressing erosion, vegetation and soils further suppress chemical weathering.

This could provide an intrinsic mechanism by which biotically-driven cooling of the planet would be followed by a relaxation back towards warmer conditions. In other words; perhaps after turning down the weathering thermostat, life turns it back up again.

Natural organobromine in terrestrial and marine environments

ALESSANDRA C. LERI[1*] AND SATISH C. B. MYNENI[2]

[1]Marymount Manhattan College, New York, NY, USA, aleri@mmm.edu (* presenting author)
[2]Princeton University, Princeton, NJ, USA, smyneni@princeton.edu

In natural systems, bromine (Br) is generally believed to exist in the form of inorganic bromide. The perception of bromide as unreactive in soils justifies its frequent use as a hydrological tracer. Similarly, the oceanographic classification of Br as a conservative element in the water column has persisted for decades. We have recently shown that stable organobromine of natural origin is ubiquitous in terrestrial [1] and marine [2] environments. Using a novel quantitative technique based on XRF and X-ray absorption spectroscopy, we quantified organobromine concentrations in estuarine and marine sediments. Organobromine occurs in correlation with organic carbon and varies with sediment depth (Fig. 1) due to biogeochemical cycling of Br.

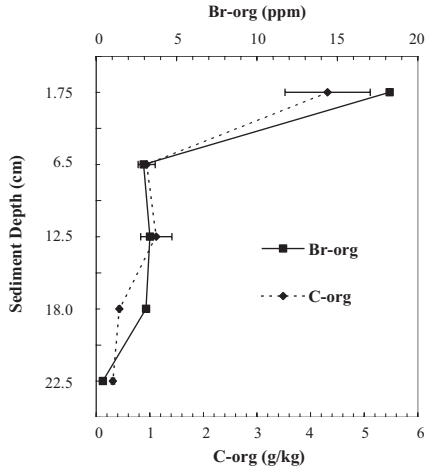

Figure 1: Organobromine and organic carbon concentrations with depth in estuarine sediments from Cape Cod, MA, USA.

X-ray spectromicroscopic images of sediment sections reveal a heterogeneous Br distribution, with associations between organobromine and metals such as iron and calcium. Organobromine also appears in particulate material from sediment traps deployed in the water column, suggesting that some fraction of sedimentary organobromine originates in overlying waters.

In the terrestrial environment, the Br in plant litter, organic-rich surface soils, and isolated humic substances is exclusively bonded to carbon. Terrestrial organobromine production is linked with plant litter decay and may be catalyzed by haloperoxidase-like enzymes in the soil environment.

These findings overturn the paradigmatic classification of Br as unreactive in the environment, shedding light on a biogeochemical cycle that may ultimately contribute to our understanding of the environmental fate of anthropogenic organobromine pollutants.

Redox and Ca/Mg/Fe ratios in clay formations

C. LEROUGE[1*], C. TOURNASSAT[1] AND E.C. GAUCHER[1]

[1]BRGM, Orléans, France, c.lerouge@brgm.fr (* presenting author)

Redox control and Ca/Fe/Mg ratios remain among sensitive factors to improve modelling of porewaters chemistry in geological clay barriers. The existing models consider pure phases at equilibrium with porewater [1, 2], however accurate observations show more complexe mineralogy. In that way two marine clay formations (Callovian-Oxfordian (COx) clay at Bure, France and Opalinus (OPA) clay at Mont Terri and Benken, Switzerland) were investigated to describe diagenetic minerals, the processes involved in their deposition and the effects of these processes on redox conditions and phase stabilities.

Mineralogical constraints in COx clay [3] and OPA clay

Diagenetic sequence defined in the three clay formations consists of: 1) dominant micritic calcite with minor dolomite, and pyrite resulting from bacterial reduction of dissolved marine sulphate; calcite and dolomite are characterized at this stage of low Fe/(Fe+Mg) ratios (<0.4);

2) calcite, Fe-rich dolomite/ankerite, siderite ($Ca_{0.1\text{-}0.3}$ $Fe_{0.5\text{-}0.7}$ $Mg_{0.2\text{-}0.4}$ CO_3) and glauconite. Calcite and siderite have Fe/(Fe+Mg) ratios higher than 0.5-0.6 in the both clay formations. At contrary Fe-rich dolomite shows heterogenous Fe/(Fe+Mg) ratios depending of the clay formation: ~ 0.1 in COx clay, ~ 0.35 in OPA Clay of Mont Terri and up to 0.7-0.8 in OPA clay of Benken;

3) galena, sphalerite, celestite, calcite veinlets.

Redox control

Redox is controlled by pyrite in the models [1, 2, 4]. When Sphalerite and galena are taking account in the COx porewater model, the three sulfides are not at equilibrium with porewater. Further investigations on the distribution of sphalerite and galena in the clay formation are needed to affine the chemical system (introduction of Zn and Pb or not) to control the redox.

Ca/Fe/Mg ratios in porewaters

The cation exchanger of clay rocks reflects the relative amounts of exchanged cations in porewater through exchange equilibrium reactions [3]. Porewater is also at equilibrium with some diagenetic minerals. In Pearson [1] (OPA Clay model) and Gaucher [2] (COx Clay model), porewaters are likely at equilibrium with calcite (for Ca), dolomite (for Mg), siderite (for Fe) and celestite (for Sr). The large chemical variations of carbonates and their distribution (present at the scale of the formation or only at some levels) must be taken account to improve the models. Further work is to precise the carbonate compositions at equilibrium with present-day porewaters, specifically of dolomite in COx, ankerite and siderite in OPA, and to calculate the solubility constants of the carbonate solid solutions for Ca/Mg/Fe ratio control. The Fe control by siderite in the COx model will be discussed, siderite being present at a level of the COx Clay.

This research has been financially supported by the ANDRA BRGM–scientific partnership, the University of Bern and by the Mont Terri Consortium.

Experimental constraints on Fe-isotope fractionation at the core-mantle boundary

CHARLES E. LESHER[1*], JAMES BRENAN[2], GRY H. BARFOD[1], AND JUSTIN GLESSNER[1]

[1]Dept Geology, University of California, Davis, USA, celesher@ucdavis.edu (* presenting author), ghbarfod@ucdavid.edu, jjglessner@ucdavid.edu

[2]Dept Geology, University of Toronto, Canada, j.brenan@utoronto.ca

Background

The core-mantle boundary (CMB) is the largest thermal boundary layer within the Earth with temperature differences estimated between 1000-1500 K over length scales of 10-100's km. This complex boundary layer, including reaction products between the outer core (molten Fe ± light elements) and the lowermost mantle (silicates), may be partially molten and bounded below by a stagnant layer (10-100's km thick) of buoyant molten iron alloy. The conductive geothermal across the CMB and uppermost portion of the outer core thus creates a setting wherein diffusive transport of components along a temperature gradient can occur. This process of thermal (Soret) diffusion can be an agent of isotopic fractionation. The sense, magnitude and rates of isotopic fractionation by Soret diffusion of core-forming melts are largely unknown.

Results and Conclusion

We report experimental results of Soret diffusion of pure Fe and Fe (Ni-S-C) alloy melts conducted at 2 GPa within a temperature gradient from 1750 and 2000°C. We show that the sense of fractionation is consistent with Chapman-Enskog theory based on classical mechanics predicting that lighter isotopes are preferentially enriched at the hot end, while heavy isotopes are enriched at the cold end of the temperature gradient [1]. At steady-state, $\Delta\delta^{56}Fe/^{54}Fe$ between the hot and cold ends of the temperature gradient are 6-8 ‰ - similar in magnitude to those reported for silicate melts [2-4]. Steady-state profiles are also linear in temperature at high temperatures – as also observed for silicate melts. Time studies show that the approach to the steady state occurs rapidly and governed by Fe self diffusion. Simple scaling suggests that significant fractionation of Fe isotopes can occur across a stagnant boundary layer at the top of the outer core transporting heavy Fe into the overlying mantle. Soret effects should not be dismissed as an agent of iron isotope fractionation in the vicinity of the CMB.

Clay minerals and geochemical indicators of past environments on Earth and Mars

RICHARD J. LÉVEILLÉ[1*], JENNIFER BENTZ[1,2]

[1] Canadian Space Agency, St-Hubert, QC, Canada, richard.leveille@asc-csa.gc.ca ([*] presenting author)

[2] University of Saskatchewan, Saskatoon, SK, Canada, S7N 5A8

Introduction and Background

Identifying and characterizing specific minerals present on Mars is critical to reconstructing past environmental conditions and geological processes, and is essential for accurately assessing past habitability. Various clay minerals have been identified in ancient rocks on Mars, including rocks at Gale Crater, and their presence suggests an early, active hydrologic system. The formation of these minerals would have required the presence of persistent liquid water over extended periods of time. However, the timing, duration, and extent of hydrologic activity and nature of mineral formation processes are poorly constrained. While Al- and Fe-Mg-phyllosilicates seem to be most common on Mars, Mg-rich phyllosilicates (e.g., serpentine, talc, saponite, Mg-smectite) have also been identified. Due to the greater solubility and mobility of Mg, compared to Fe and Al, Mg-clay minerals generally indicate sustained aqueous conditions (either long-term presence of liquid water or high water-to-rock ratios). On Earth, Mg-clay minerals form most commonly in circumneutral to alkaline conditions, either by direct precipitation (neoformation) or via transformation of precursor phases. In fact, pH is a major control on clay mineral precipitation and Mg-phyllosilicates will form mostly at a pH >8.0, with specific minerals often being indicative of narrow pH ranges. Hence, the presence of Mg-phyllosilicates on Mars may indicate areas of increased or extended liquid water activity, and/ (or) aqueous environments where circumneutral pH may have favored habitable conditions or the preservation of organics. However, Mg-clay minerals can also form at high temperatures in hydrothermal systems, such as deep-sea hydrothermal vents, or during low-grade metamorphism. Therefore, developing criteria to distinguish between low and high temperature Mg-clay formation is needed to assess past environmental conditions and habitability of Mars.

Results and Conclusion

We present the results of our characterization of analog natural and synthetic clay minerals using a Terra XRD instrument, a laboratory laser-induced breakdown spectroscopy (LIBS) instrument, a prototype multi-spectral microscope, and regular laboratory analytical facilities. We critically assess the likelihood of distinguishing clay minerals formed at low and high temperatures on Mars by combining mineralogical, elemental and isotopic information. In particular, we target elemental indicators of hydrothermal activity, such as Ti, Mn, and Ba within clay minerals, that can be readily detected by LIBS. This information will be invaluable for the Mars Science Laboratory mission, where an integrated mineralogical and geochemical approach using a suite of instruments will enable accurate mineral identification, geochemical analyses, and paleoenvironmental reconstructions on Mars.

Baseline characterization of surface water at the Coles Hill uranium deposit, Virginia

DENISE M. LEVITAN[1*], MADELINE E. SCHREIBER[1], ROBERT R. SEAL II[2], ROBERT J. BODNAR[1], AND JOSEPH G. AYLOR JR.[3]

[1]Department of Geosciences, Virginia Tech, Blacksburg, VA, USA, dlevitan@vt.edu (* presenting author)
[2]U.S. Geological Survey, Reston, VA, USA
[3]Virginia Uranium, Inc., Chatham, VA, USA

Increasing interest in uranium deposits in temperate locales such as Virginia requires a reassessment of existing characterization methods. The goal of a pre-operational baseline characterization is to provide data which will enable both the identification of potential environmental impacts during mining and the establishment of post-mining closure targets.

A baseline surface water characterization study has been conducted at the undeveloped Coles Hill uranium deposit in agricultural Pittsylvania County, southern Virginia, USA. The study area included locations in stream reaches and ponds both upgradient and downgradient of potential mining, milling, and storage sites within the footprint of the deposit, as well as sampling locations in surrounding watersheds outside the area of potential operations.

Twenty-two stream sites were sampled twice, in early spring during high flow and late summer during low flow. Water samples were analyzed for major and trace elements, dissolved organic carbon (DOC), O and H isotopes, and field parameters. Major and trace elements abundances and mineralogy of sediment samples were also determined. Water at a subset of nine sites was sampled monthly for the above constituents and for radioisotopes. Discharge was measured to calculate loading. Fourteen ponds were sampled quarterly for the same analytes.

Statistical tests were used to compare analyte concentrations in stream reaches upstream and downstream of the deposit to evaluate the effect of the undeveloped deposit on surface water quality. Geochemical data collected at the site will also be compared to publicly available data from elsewhere in the Appalachian Piedmont and other uranium deposits to test for anomalies at Coles Hill.

Surface waters in the vicinity of the deposit are circumneutral (pH 3.9–7.6) with low total dissolved solids (specific conductance 3–93 µS/cm). Radionuclides, including U, ^{226}Ra and ^{228}Ra, and Th species, gross alpha and beta radiation, and trace metals, including As, Ba, and Pb, are below EPA regulatory limits for drinking water.

Statistically significant differences in composition were observed among streams, in particular in small drainages flowing near the ore bodies relative to other streams studied. Compositions at individual sites vary over time but indicate no regular trend. Positive correlations between DOC and dissolved trace metals such as Fe, Al, U, Ba, and Pb suggest complexation of metals by organic ligands. Higher concentrations of total metals relative to dissolved reflect metal transport via suspended sediment.

Sedimentary evolution in the northern South China Sea since Oligocene and its responses to tectonics

LI ANCHUN[1*], HUANG JIE[1,2], JIANG HENGYI[1,2], WAN SHIMING[1]

[1]Key Laboratory of Marine Geology and Environment, Institute of Oceanology, Chinese Academy of Sciences, Qingdao 266071, China, acli@qdio.ac.cn (* presenting author)

Introduction

The South China Sea (SCS), one of the largest marginal sea of the West Pacific, has complex geological structure, unique development mode and has been controled by the Eurasian plate, Pacific plate and Australia - the Indian plate interaction since the late Mesozoic. Its formation underwent continental rifting, separation and seafloor spreading[1]. The tectonic evolution has a close relationship with peripheral geological units and can be recorded by sedimentary strata. This work is try to reconstruct sedimentary evolution of the SCS and its response to tectonics since Oligocene based on a multi-proxies including a monomineralic quartz oxygen isotope (δ^{18}O), grain-size of isolated terrigenous materials, terrigenous mineral accumulation rate of sediment samples from Ocean Drilling Program (ODP) Site 1148 in the northern SCS.

Results and Conclusion

The results show that the sedimentary evolution of the northern SCS Basin could be divided into five stages: period of initial expansion (34～28.5), period of intense tectonic activity (28.5～23), period of reduced tectonic activity (23～16.5), period of thermal subsidence (16.5～3.5) and period of Taiwan uplift (3.5 Ma to present). Terrigenous mineral composition and oxygen isotope values of quartz altered significantly between 28.5 Ma and 23 Ma during which provenance transition took place, corresponding to the most active period of the SCS since Oligocene. Sediments of the study area were mainly from southern source (presumptively from Palawan) during the early spreading period of the SCS. With the extensive spreading of the SCS, especially when the spreading axis of the SCS jumped to south during 25～23 Ma, Palawan continental block moved away from the study site, while northern sources did not set up as Tibetan Plateau uplift had not spread to Yunnan-Guizhou Plateau, so that, terrigenous mass accumu-lation rate was very low. Later owing to the rapid uplift of Qinghai-Tibet Plateau, rivers such as Pearl River developed gradually, so did the headward erosion, as a result, South Mainland of China turned to be the main source of ODP Site 1148, and in the meantime the northern SCS converted to distal deposition. While the hiatus of ODP Site 1148 in the late Oligocene resulted from the lack of terrigenous materials supply, sea level rise and relatively stronger currents during the source transformation. With uplift and development of Taiwan island, it turned to be the major sediment provenance of the study area since 3.5 Ma.

Changes in ocean redox chemistry during the Cryogenian are likely to have had a strong influence on the emergence of animals[1]. A detailed, multi-element (Fe-C-S-Mo) biogeochemical study was conducted for two outcrop sections reflecting different water depths for the ca. 663-654 Ma Datangpo Fm. The Datangpo was deposited between the two major Neoproterozoic glacial episodes (Sturtian and Marinoan) in the restricted Nanhua Basin, South China. Basinal restriction may have been a common feature throughout the world in association with widespread rifted margins during global sea-level lowstands, particularly during build-up of the Marinoan ice sheet. Our findings are consistent with a highly stratified basin in which water column chemistry was strongly controlled by Fe and other nutrient fluxes, low dissolved marine sulfate concentrations, varying inputs of marine organic carbon delivered via primary production, and changing sea-level. Sea level was the overarching control on much of the observed variation. A compilation of new and published S isotope data for the Datangpo Fm. suggests a ^{34}S-enriched deep marine sulfate pool generated, in part, during the Sturtian glaciation by bacterial sulfate reduction in combination with suppressed riverine sulfate inputs and restriction of the basin during a dramatic drop in sea level. This study highlights the importance of both global and local controls in determining the chemical conditions in Neoproterozoic basins.

Introduction

Oriented attachment (OA) of molecular clusters and nanoparticles in solution is now recognized as an important mechanism of crystal growth in many materials, yet the alignment process and attachment mechanism have not been established. Here we performed high-resolution TEM using a fluid cell to directly observe attachment of iron oxyhydroxide nanoparticles. Images were recorded with lattice fringe-resolution, enabling us to track particle orientations throughout the experiments.

Results and Conclusion

We find that the primary particles undergo continuous rotation and interaction until they find a perfect lattice match. A sudden "jump to contact" then occurs over < 1nm, followed by lateral atom-by-atom addition initiated at the contact point. Interface elimination proceeds at a rate consistent with the curvature-dependence of the Gibbs free energy. From the measured translational and rotational accelerations we calculate the magnitude of the inter-particle forces. The results show that highly-direction-specific interactions drive crystal growth via OA, and are likely the result of electrostatic forces.

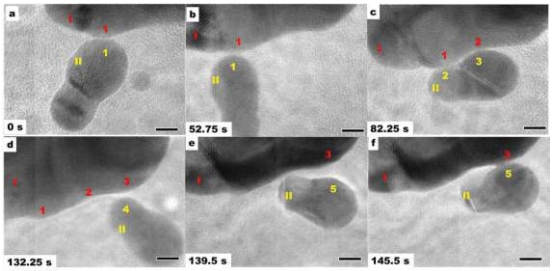

Figure 1: Typical dynamics of attachment process. Scale bar: 5 nm.

The findings of this study provide a dynamic view of the process of OA and answer the essential question of whether co-alignment occurs prior to attachment or comes about afterwards. In the case of freely diffusing nanoparticles, either near-perfect crystallographic orientation or a specific twin orientation that ensures interfacial coherence is required for attachment to occur. The results also shed light on the magnitude and nature of the forces that drive OA.

Strains of *Clostridium* sp. induce formation of carbonate minerals

FUCHUN LI, WENWEN GUO and JINPING WANG

College of Resources and Environmental Sciences, Nanjing Agricultural University, Nanjing 210095, China. fchli@njau.edu.cn

Large amounts of natural sediments and bacterial experiments have evidenced that microorganism in nature might be very important in formation of carbonate minerals. In order to study the mechanism of bacterially induced formation of carbonate minerals, a series of culture experiments using Lagoa Vermelha medium with 6:1 molar Mg/Ca ratio within 55 days at 28℃ and starting pH=7.5 was made under the mediation of two stains of *Clostridium* sp., which were isolated from the Nanjing suburb soil (named MH18 strain) and from the Qinghai Lake sediment in NW China (named SN-1 strain), respectively. At the same time, the aseptic experiments were carried out as control.

In the mediation experiments with strains, the morphologies of formed carbonate minerals were various, including club-shaped, dumbbell-like, spherical, rhombohedral and irregular. However, in the sterile experiments, only the rhombohedral minerals appeared. We propose that this morphological variation might be related with different nucleation sites and with different growth stages. At the initial stage, the microbe-generated organic acid with low molecular weight and extracellular polymer substance (EPS) could only affect the microenvironment surrounding the bacteria bodies. The carbonate crystals might be nucleated and grew on the cell surfaces of the bacteria, and the rod-like minerals with a morphology closely analogous to bacterial shape were formed. Afterwards, these “clubs” gradually developed to dumbbells, as well as spheres. However, in the EPS, the carbonate could be nucleated and grew with an irregular shape. Along with the longer reaction times, deamination of bacteria resulted in rising pH values of the whole medium. Consequently, carbonate super-saturation and homogeneous nucleation took place locally. Finally, the carbonate crystals were formed with a rhombohedral shape.

It is usually considered that the high-magnesium environment is favourable for formation of aragonite, but not for calcite. At the same time, the monohydrocalcite is a thermodynamically unstable mineral. Nevertheless, our study results showed that high-magnesian calcite and monohydrocalcite were dominant minerals in our experiments by using MH18 and SN-1 strains.

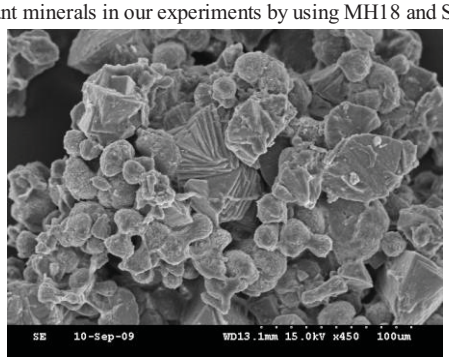

Figure 1 SEM images of carbonate minerals with different morphologies at the 55-th day by using SN-1 strain

Geochemical signatures of Tibetan dust

GAOJUN LI[1*]

[1]Department of Earth Sciences, Nanjing University, Nanjing 210093, China, ligaojun@nju.edu.cn (* presenting author)

Asian dust is one of the major components of global dust inventory. Provenance identification of Asian dust is helpful for understanding the paleo-environmental implications of the eolian deposits such as the loess on Chinese Loess Plateau, the pelagic sediments in North Pacific, and the dust in Greenland ice cores. Geochemical methods are effective ways to trace the provenance of eolian dust. Previous source tracing of Asian dust using geochemical methods mainly focus on the arid lands in North China and the neighboring Mongolia as the major potential source regions. However, recent studies indicate that Tibetan Plateau is probably an important source region of Asian dust. Tibetan dust, which only needs to be uplifted by 1-2 Km, could be carried into westerly jet and thus enable a long-distance transportation. The northern Tibetan Plateau, especially the arid lands in Qaidam Basin, is also probably an important source region of the loess on Chinese Loess Plateau. This study will systematically investigate the geochemical compositions of the surface materials on Tibetan Plateau, hoping to find out the geochemical signatures of Tibetan dust. Through comparing the geochemical compositions, this study will also confirm the possible contribution of Tibetan dust to the loess on Chinese loess, the pelagic sediments in North Pacific, and the dust in Greenland ice cores.

Brines and saline fracture waters in the terrestrial subsurface: A niche for the deep biosphere and unique analog for Mars

L. LI[1*], B. SHERWOOD LOLLAR[1], G. HOLLAND[2, 3], G.F. SLATER[4], C.J. BALLENTINE[3], G. LACRAMPE-COULOUME[1]

[1] University of Toronto, Toronto, Canada, longli@geology.utoronto.ca (* presenting author)
[2] Lancaster University, Lancaster, UK, g.holland@lancaster.ac.uk
[3] University of Manchester, UK, chris.ballentine@manchester.ac.uk
[4] McMaster University, Hamilton, Canada, gslater@mcmaster.ca

Saline waters and brines have been widely observed in deep fractures in the Precambrian igneous rocks of the Canadian Shield and South Africa. Recent molecular studies indicate that these deep brine waters contain low-abundance, low-diversity microbial ecosystems [1, 2] distinct from those found in the shallower, less saline fracture waters. This discovery has significantly expanded our understanding of life in the deep anaeorobic terrestrial environment and provided an important analog for studies of early life on Earth and for the search for life on Mars.

To understand the dependence of microbial ecosystems on water chemistry, we studied the brine waters from Timmins (Ontario), and Thompson (Manitoba) in the Canadian Shield. The fracture brine waters are dominant by Ca, Na, Cl with salinities of 150-290 g.TDS/L. Na-Cl-Br relationships exclude the possiblilty of brine sourced by freezing seawater during the Pleistocene glaciation as had been recently suggested [3]. The geochemistry of Na-Cl-Br favors a source related to evaporated seawater which may originate from the mid-Devonian or even earlier [4]. Oxygen and hydrogen isotope compositions of these brine waters lie well above the global meteoric water line, indicating significant oxygen and hydrogen isotope modification by fluid-rock interaction. Noble gas studies indicate 100s Ma to possibly Ga gas components in the fractures, suggesting little or no disturbance of these fractures over geological time scales and bulk water residence times on the order of millions of years – again supporting an a geologically ancient origin for these fluids.

Based on above observations, we propose that the fracture saline waters and brines in the deep terrestrial subsurface provide the best opportunity to host microbial ecosystems that have been separated from those on the surface for millions of years and sustained on the limited energy and nutrient sources produced by fluid-rock interaction. They demonstrate the potential for life to sustain its activity over geologic time in ancient low temperature tectonically quiescent rock fractures that serve as an important analog for the Martian subsurface.

(* presenting author)

Experiments and results

Junger Basin was located among the intersection of Kazakhstan, Tarim and Siberia plates during Palaeozoic. The research on the basin formation and the volcanos during this period were never stopped because of the complicated structural settings and great breakthough of gas exploration has gained in Carboniferous volcanos.

12 Volcanic rocks samples dating by SHRIMP and LA-ICPMS and elemental analysis, palynologic analysis were conducted in this essay. The results were follows. There were different eruption structural settings of volcano during carboniferous period in front of Kelamli Mountain. The duration of early stage was about from 354Ma to 330Ma. The range of dating detection is 350Ma~335Ma.Volcanos were arc. The samples points are in the arc areas in the figure of logτ-logσ. Elements Nb, Ta, Ti are parrent deficit and element Sr is abnormal in the figure of the distribution of elements cobweb. All of above were interrelation with the lagoon or tide of sedementary environment in this period. The duration of late stage was about from 320Ma to 295Ma. Volcanos were intraplate. The sample points are in the intraplate areas in the figure of logτ-logσ such as typical sample DX17. Elements Nb, Ta, Ti are little deficit and element Pb is abnormal in the figure of the distribution of elements cobweb. All of the above were interrelation with the occurrence of considerable granite aging from 314 Ma to 295Ma in the mountain around the basin in the same period. This indicates that geological setting was extended. During the period between 330Ma and 320Ma, volcanic activity stopped and a set of sedmentary rock deposited.

The evolution of the carboneferous system as follows. The early volcanic eruption stage indicated that Junger basin and its near areas were in a concourse geological setting. Kelamli Ocean began to dive and a lage scale of volcanos erupted during this period. During the 330Ma to 320Ma, Kelamli Ocean had dived into the plate of Yemaquan and had been died out since then. Accompany with this, a depression was formed in front of the mountain. During the late of the carboneferous, with the gelogical setting changing from concourse to extend, another large-scale of volcanic activity occurred again.

Conclusions

There were 3 evolution stages during carbonferous. From early to late stage, there were coexisting volcanos and sedments, maily sedments and volcanos respctively. In a all, there formed two sets of source rocks and two sets of reservoirs during carboniferous period.

A mixing model for crustal growth in Northeastern China as revealed by U-Pb age and Hf isotopes of detrital zircons from modern rivers

MING LI[1*], SHAN GAO[1], GINGLIANG GUO[1], KANG CHEN[1] AND XIANLEI GENG[1]

[1]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China, liming19820426@163.com (* presenting author)

Northeastern (NE) China consists of the eastern part of the Central Asian Orogenic Belt (CAOB), which is the most important site of juvenile crustal formation in the Phanerozoic. Detrital zircons from young sediments, or in modern river sediments, may record crustal material that has not been preserved or is no longer exposed. Here, we report U-Pb ages and Hf isotopes of 1381 detrital zircons in 13 sand samples from 5 modern rivers, which drain the most part of NE China, in order to characterize the crustal growth and evolution. These zircons give three magmatic age groups of 100-600 Ma, 1600-2000 Ma and 2300-2700 Ma. The third group from the Songhua river characterizes the North China craton. The first and second group zircons were derived from rivers that drain within CAOB, and display a large spread in Hf isotope two-stage model ages (T_{DM2}) between 400 and 3000 Ma but with a significant peak at 600-1600 Ma. They suggest that 98% of the crust for much of NE China formed 500 Ma ago. However, NE China has significant production of juvenile crust in the Paleozoic [1]. Clearly, the obtained Hf model ages are a mixing product. To estimate the true crust formation age, we simply assume the mixing source consists of the depleted mantle (juvenile crustal addition) and the regionally known oldest crust components, whose proportions can thus be calculated for each zircon from its U-Pb age and Hf isotope. The mixing model shows that proportions of the juvenile crustal component are about 50-90% in the 100-400 Ma age group, 40-70% in the ~500 Ma age group and below 50% in the 1600-2000 Ma age group. The corresponding crustal growth rates suggest that 20%, 47% and 98% of the present crustal volume were formed by 2700 Ma, 200 Ma and 100 Ma ago, respectively (Figure 1).

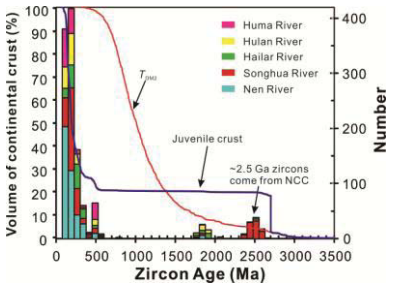

Figure 1: Histogram of concordant U-Pb ages and crust growth curves based on two-stage Hf crust formation ages and our mixing model for detrital zircons from rivers in NE China.

Geochronology and geochemistry of the Mesozoic volcanic rocks from the Hailar basin, NE China

SHUANG-QING LI, FUKUN CHEN, JIA-DE WU, YUE QI, QUN LONG

CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei, 230026, China

Mesozoic volcanic rocks and granitoids are widespread in northeastern China, which are interpreted as a large igneous province in eastern Asia and are distinguished by extensive Phanerozoic crustal growth as a part of the Central Asian Orogenic Belt. These Mesozoic volcanic and pyroclastic rocks are important reservoir rocks of petroleum in the basins distributed in NE China, e.g. the Songliao basin that has been a major oil and gas field in China. This study focuses on a successive volcanic rock series that are exposed along the northwestern bank of the Hulun Lake of the Hailar basin.

Two rock formations, the Shangkuli Formation and the Tamulangou Formation, contain volcanic rocks in the Hailar basin. Zircon U-Pb dating of six rhyolitic samples successively collected from the Shangkuli Formation in a profile along the western bank of the Hulun Lake yields ages of 137 Ma to 147 Ma, possibly implicating a long term of volcanic activities in this area. This magmatism is likely related to the closure of the Mongolia-Okhotsk Oceans in late Mesozoic. The volcanic rocks are characterized by low contents of MgO and compatible elements in spite of the variations in major element contents. Both the basic and acid volcanic rocks of the Tamulangou and the Shangkuli Formations are characterized by slightly depleted Nd isotopic composition with initial ε_{Nd} values of 0.63 to 2.67 and relatively low initial $^{87}Sr/^{86}Sr$ values of 0.7033 to 0.70548. Homogeneous Sr-Nd isotopic composition of different volcanic rocks in context of the spatial and temporal relationship indicate that they were derived from a similar mantle source and formed through different degrees of fractional crystallization of the primary melt(s). This study is supported by the Ministry of Science and Technology of China (grant No. 2009CB219305).

[3]University of California, Department of Chemistry & Department of Physics, Davis, USA, gagalli@ucdavis.edu

Abstract

The prediction of contribution to global radiative budget and future climate change by cirrus clouds requires computation of the formation rates, growth rates, shape evolution and size distribution of small ice particles. The formation of ice particles under various thermodynamic, dynamic, and chemical environments still remains very poorly understood. Here we report a large-scale numerical study of spontaneous ice nucleation from supercooled nano water droplets, with the size of droplets ranging from 6 nm to 12 nm at 230K. In this study, we combined forward flux sampling method [1] with molecular dynamics simulations, and employed a recently developed coarse-grained water model [2]. The large number of nucleation trajectories (500) sampled in this study allowed obtaining nucleation rates directly from molecular simulations and identifying ensembles of various crystal structures and morphology of the fully crystallized ice clusters. The calculated nucleation rates show strong size dependence below 10 nm: it increases from $1.97\pm0.92\times10^{8}$ $m^{-3}s^{-1}$ to $1.08\pm0.47\times10^{14}$ $m^{-3}s^{-1}$ as the size of water droplets increase from 6 nm to 9.5 nm. When the size of water droplets is beyond 10 nm, the calculated ice nucleation rates become indistinguishable from the calculated ice homogenous nucleation rates in bulk supercooled water at the same temperature [3]. The preferential location of the formation of ice embryos also shows variation with the size of water droplets, with a strong preference for the location identified within the subsurface (1~1.5 nm below the immediate surface) for larger water droplets (>7.6 nm). The fully crystallized ice clusters are found to be mixtures of both hexagonal ice (I_h) and cubic ice (I_c), and display a variety of structures and shapes. In consistent with previous study in bulk water [3], we also identified the five-fold twin boundary (FFTB) structure in ice cluster. A single FFTB per ice cluster yields a nearly decahedral shape of crystallized ice cluster. In addition, we have also identified a more complex and highly symmetrical defect structure that is composed of 12 FFTB merging and forming a 512 water cage at the center of the defect. Such defect structure results in a nearly icosahedral shape, which also displays nearly 5 fold rotational symmetry.

Evolution of Earth's early atmosphere is critical to understanding the geologic history of the Earth, yet the levels of oxygen in Earth's atmosphere in the Archean continue to be debated. The hematite-bearing 3.4 Ga Marble Bar Chert (MBC) at Marble Bar area of the Pilbara Craton, NW Australia, has been used to argue that Earth's early atmosphere contained significant amounts of oxygen [1]. We measured Fe and U-Th-Pb isotope composition of the MBC samples. Our results indicate that the Marble Bar Chert was deposited from a Fe-rich, but U-poor ocean. The δ^{56}Fe values of hematite in MBC range between 1.71‰ and 2.63‰, which are the most positive δ^{56}Fe dataset that has ever been reported from natural rocks (Figure 1). Given that hydrothermal sources of aqueous Fe^{2+} should have had a δ^{56}Fe value of around 0‰ [2], and that Fe isotope fractionation between hydrous ferric oxides and aqueous Fe^{2+} is ~3-4‰ [3][4], the high δ^{56}Fe values of hematite in MBC requires partial oxidation of aqueous Fe^{2+}. This suggests that the oxidant was extremely limited and the main body of ocean water was reduced and rich in Fe^{2+}. In addition, U concentrations of the MBC samples are over one order of magnitude lower than those of Phanerozoic cherts, indicating lower U content of Archean ocean water than modern ocean water. Moreover, U-Th-Pb isotope analysis shows that the MBC samples has actually undergone U addition during the Phanerozoic, which further attests to low U contents during deposition at 3.4 Ga. This indicates low O_2 levels in Archean atmosphere.

[3]State Key Laboratory of Organic Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China

Abstract

A total of 65 daily aerosol samples were collected in two open cruises covering the whole northern SCS in September 2005 and August 2007, respectively. The concentrations of Cr, Cu, Ni, Zn and Pb in particular matters (PM) of the northern SCS were comparable to the values measured in suburban and background sites of south China. Cu showed relatively high concentrations during the two sampling periods, suggesting the regional sources of Cu pollution in the Pearl River Delta (PRD) area, south China. The calculated enrichment factor (EF) values of Cu, Zn and Pb were generally greater than 10, indicating the strong influences of anthropogenic inputs. As shown by the backward air trajectory analysis, the high concentrations of trace metals in the air during the sampling periods were mainly related to the air mass passing over the neighboring cities or countries around the SCS. Elevated concentrations of Pb and Zn in the daytime of the 2007 summer criuse may indicate the effects of traffic emissions from the nearby cities around the SCS. The relatively high concentrations of trace metals during the northeastern monsoons in 2005 were probably attributed to local emissions and long range atmospheric transport of pollutants by the Asian monsoon.

Fluorescent nanoparticle tracers

YAN VIVIAN LI[1*], LAWRENCE M. CATHLES[2]

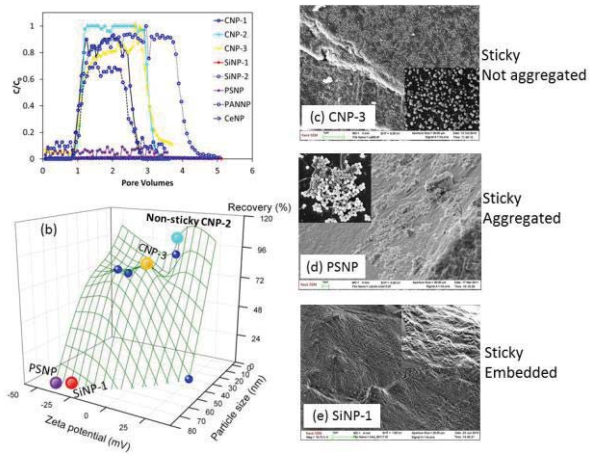
[1]The KAUST-CU Center of Energy and Sustainability, Cornell University, Ithaca, NY, USA, yl398@cornell.edu (* presenting author),

[2]Department of Earth and Atmospheric Science, Cornell University, Ithaca, NY, USA, lmc19@cornell.edu

Introduction

Tracers are perhaps the most direct and efficient way of determining subsurface fluid flow pathways. Particle tracers could arrive faster at a detection site because they would not diffuse, as would chemical tracers, from the fractures where flow occurs. Indeed their early arrival could measure the fraction of flow that occurs through the fractures. A requirement is that the particles not aggregate or stick to mineral surfaces. Here we describe our method for screening paticles for stickiness and present results for 8 nanoparticles that suggests small size and neutral charge keep particles from sticking.

We inject a slug of artifical brine that contains nanoparticles into a column filled with crushed calcium carbonate, and follow this slug with particle-free brine. The particle concentration in the effluent is measured by the fluorerscence of the nanoparticles, and the fraction recovered is determined by intgration over time. Results are shown in Figure 1 for 8 nanoparticles: small ethanolamine carbon dot (light blue, CNP-2), large ethanolamine carbon dot (CNP-3), small Jeffamine carbon dot (CNP-1), commercial silica (SiNP-1), silica coated with polyethylene glycol (SiNP-2), polystyrene commerical (PSNP), polyacrylonitril (PANNP), and a



Ce-fluoride (CeNP).

Figure 1. (a) NP concentration (in brine) as a function of injection pore volumes. (b) 3D-countour plot showing particle recovery as a function of particle size and zeta potential. (c-e) SEM images of the CNP-3, PSNP and SiNP-1 particles.

Results and Conclusion

The nanoparticles that showed the least stickiness is the small 3 ± 2 nm ethanolamine carbon dot (CNP-2 light blue on plots) which has zeta potential near zero.

Relationship between Leaf Phosphorus and Soil Phosphorus：A Case Study of Degraded Grassland in western Jilin Province, NE China

Y.F.LI[1*], S.WAN[1], D.Y.WANG[1], Q.FU[1], D.Y. GUO [1]AND Y. Y.YANG[1]

[1] College of Earth Sciences, Jilin University, Changchun 130061, China, yfli@jlu.edu.cn(* presenting author), Lasoukhan_09@yahoo.com, wang_dy@jlu.edu.cn, fly19881118@yahoo.com.cn, jluguodongyan@163.com, yyyang10@mails.jlu.edu.cn

Introduction

Plant growth should be expected to be limited by phosphorus (P) availability in most terrestrial ecosystems. The previous studies indicate that the leaf P concentrations of Chinese terrestrial plants should be considerably lower than the global average, resulting in a higher leaf N/P ratio. However, how does the content of soil total P and available P influence leaf P and N/P ratio? It has been one of the hotly-discussed issues in the ecological stoichiometry. However, the P stoichiometry in the leaves of Leymus chinensis and soil conditions from the Jiangjiadian grassland in Da'an city in western Jilin Province, NE China, provides insights for the above issue. Our objective is to determine how and to what extent soil total P and available P influence leaf P and N/P ratio in the study region.

Material, Method, Results and discussion

This paper reports the total P and available P contents of 25 surface soil samples and the leaf P contents of 25 Leymus chinensis samples.The results indicate that the content of leaf P ($1.3mg \cdot g^{-1}$) is lower than the global average content ($2.0mg \cdot g^{-1}$), however, the N/P ratio in Leymus chinensis leaf (15.26) is higher than the global average value (13.8). These findings are consistent with previous findings[1]. Moreover, the contents of soil total P and available P are $0.34mg \cdot g^{-1}$ and $5.25mg \cdot kg^{-1}$, respectively. The available P content of degraded grassland in western Jilin province is higher than Chinese soils ($3.83mg \cdot kg^{-1}$), United States soils ($3.41mg \cdot kg^{-1}$) and Australian soils ($2.17mg \cdot kg^{-1}$). But, available P is lower than the global soils ($7.65mg \cdot kg^{-1}$). In addition, Pearson correlations analyses done by SPSS software indicate that soil total P(r=0.345) and available P(r=0.25) do not exhibit evidently positive correlations with leaf P concentrations. The soil total P concentrations has no significant correlation with N/P ratio(r=-0.3). While the soil available P has significantly negative correlation with N/P ratio($r_{0.05}$=-0.416*). Taken together, it is suggested that the soil total P and available P can influence leaf P concentrations, but be not necessarily leading factor, because contents of soil total P and available P are not accurately reflect leaf P concentrations. Compared with leaf P concentrations, leaf N/P ratio is more related to soil P concentrations, especially to soil available P concentrations.

Conclusion

Therefore, we conclude that low leaf P and high N/P of Leymus chinensis are caused by low soil P content on one hand, on the other hand they are likely caused by other factors such as plant characteristics, climate, and external environment and so on.

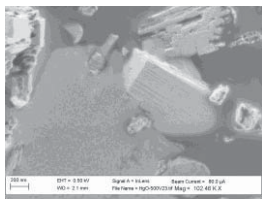
The fate of mercury at a contaminated site

DAVID WATSON, CARRIE MILLER, JANE HOWE, FENG HE, ERIC PIERCE, LIYUAN LIANG*

Oak Ridge National Laboratory, PO Box 2008 Oak Ridge, TN, 37831-6038, U.S.A., liangl@ornl.gov (*presenting author)

Soils contaminated with mercury present unique challenges for remediation due to the variety of chemical forms in which mercury occurs. Mercury, like many other heavy metals, cannot be degraded in the environment and its remediation must therefore involve either removal or immobilization. The characteristics of the mercury in sediment, i.e., Hg(0) beads with or without coatings of HgO and $Hg(OH)_2$, or oxidized Hg(II) that is attached to sediment minerals, or precipitated Hg as mercury sulfide (HgS), underpins the technologies that can be effective for clean up. When selecting mercury remediation technologies at a given contaminated site it is essential that the form of mercury—especially speciation—is well understood.

During the mercury use era at the Y-12 National Security Complex, Oak Ridge, Tennessee, large quantities of mercury were lost to the subsurface environment[1]. Spilled elemental mercury has undergone complex biogeochemical transformations under both saturated and unsaturated conditions. High-levels of mercury have recently been found in soil collected from a Hg use area (which housed a mercury retort furnace from 1957 until 1962[2]). Hg concentrations, determined by atomic absorption following core collection, sampling and soil digestion, ranged from 0.2 to 19000 ppm. Hg(0) was the dominant form in sediment samples where mercury beads were visually present[3]. Additionally micron-sized Hg(0) beads were also observed. Although the formation process is under investigation, the observed micron-sized beads may have formed in situ due to high vapor pressure and/or disintegrated from the original Hg(0) beads over the last 50 years in the subsurface. New SEM and XRD evidence shows that the coatings of the mercury beads are predominantly HgO, but that native clay minerals are also



present. These results are being incorporated into further laboratory tests focused on evaluating the fate and transport of mercury as well as the development of new remediation strategies.

A two-lithology model for melting and melt migration in an upwelling and chemically heteogeneous mantle

YAN LIANG[1]

[1]Department of Geological Sciences, Brown University, Providence, RI 02912, USA (yan_liang@brown.edu)

Several lines of evidence suggest that the melt generation and segreatation regions of the mantle are heterogeneous consisting of chemically and lithologically distinct domains of variable size and dimension. Partial melting of such heterogeneous mantle source regions give rise to a divers range of basaltic magmas erupted on the sea floor. Although the diversity and importance of mantle source heterogeneity have long been recognized, simple models for trace element fractionation during concurrent melting and melt migration in a lithologically heterogeneous mantle have not been fully developed. In this study we develop a two-lithology model for trace element fractionation during concurrent melting and melt migration in a vertically upwelling, chemically and lithologically heterogeneous mantle column. As a first model, we consider a special case in which strings of enriched lithology are regularly distributed in a depleted background or ambiment mantle. The enriched and depleted lithologies, referred to as channel and matrix, respectively, are treated as two overlapping continua each with a prescribed melting rate and starting composition. Part of the melt generated in the matrix is segregated into the channel along the upwelling column. Part of the channel melt is extracted into a melt-filled open network within the channel continuum at a prescribed depth. Analytical solutions for the abundances of a trace element in the matrix melt, channel melt, and open channel melt have been obtained. Essential features of the two-lithology model have been investigated through simple analysis and case studies. Using the two-lithology model as a module, we have also developed a "bundle of columns" model for melting and melt migration in a heterogeneous mantle over a broad upwelling region.

Applications of the two-lithology model to REE abundances in olivine-hosted melt inclusions in one hand sample from Mid-Atlantic Ridge and $^{87}Sr/^{86}Sr$, $^{143}Nd/^{144}Nd$, La/Sm ratios and REE abundances in basalts in near-ridge seamounts and axial valleys from East Pacific Rise demonstrate the importance of melting and melt migration-induced mixing in a two-component mantle and magma mixing at the top of the melting column in producing compositional diversities and variations observed in basalts erupted on the surface. Such mixing poses considerable challenges to deciphering the original mantle source composition and lithology based on compositions of basalts erupted on the surface.

Mineralogy and oxygen-isotope geochemistry of clays from the Te Mihi area, Wairakei Geothermal Field, New Zealand

RYAN B. LIBBEY[1*], FRED J. LONGSTAFFE[2], ROBERTA L. FLEMMING[2]

[1]McGill University, Montreal, Canada, ryan.libbey@mail.mcgill.ca (*presenting author)
[2]The University of Western Ontario, London, Canada

Abstract

Drill cuttings recovered from the Te Mihi area of the Wairakei Geothermal Field, New Zealand, have been analyzed to determine the mineralogical, morphological, and isotopic systematics of hydrothermal clays present in these samples. These data provide a tool for assessment of the paleo-hydrological conditions and temperature variations that have operated in the subsurface. Mixed-layer illite-dioctahedral smectite (I-S) and R0 chlorite-trioctahedral smectite phases are the principal clay minerals present. Mixed-layer I-S clays in well WK244 display a well-defined prograding sequence exhibiting R1 to R3 ordering and illite proportions grading from 50 to >90% over a 160 m depth interval. The interlayer proportion of illite in I-S correlates positively to measured downhole temperatures with a correlation coefficient (r) of 0.98. SEM photomicrographs demonstrate a change in clay morphology from micron-scale laths and hairy fibers to pseudo-hexagonal plates alongside this illitization sequence. Methylene blue estimates of swelling clay percentages show a strong inverse relation to %I of mixed-layer I-S with a correlation coefficient of -0.91, which further validates this method as a tool for delineating illitization sequences in active geothermal environments. The oxygen isotope compositions of I-S exhibit a continuous downhole depletion of ^{18}O, which tracks the corresponding gradation of subsurface temperatures prevailing at the time of clay formation. The oxygen isotopic compositions are used to calculate fluid compositions, under isotopic equilibrium assumptions, and assess thermal changes in the subsurface. Estimates of water/rock mass ratios calculated using the I-S oxygen isotope compositions display an inter-stratigraphic variability that correlates with known unit permeabilities. The isotopic methods applied in this study have proven useful for delineating reservoir evolution and detailed permeability characteristics in an active geothermal system.

A complex ecological role for submarine groundwater discharge in the formation of toxic *Pseudo-nitzschia* spp. blooms

JUSTIN D. LIEFER*, WILLIAM C. BURNETT[2], HUGH L. MACINTYRE[3]

[1] Dauphin Island Sea Lab, Dauphin Island, AL 36528 USA, jliefer@disl.org (* presenting author)
[2]Department of Earth, Ocean and Atmospheric Sciences, Florida State University, Tallahassee, FL 32306, USA, wburnett@fsu.edu
[3]Dalhousie University, Halifax, NS B3H 4J1 Canada, hugh.macintyre@dal.

Abstract

The potentially-toxic diatom *Pseudo-nitzschia* is common in th northern Gulf of Mexico (NGOM), including the coastal waters of Alabam The NGOM shoreline near Little Lagoon, AL, is a hot spot for blooms of *Pseudo-nitzschia* spp. and their population density is correlated with proxi for groundwater discharge[1]. Little Lagoon, AL (USA) is a shallow coasta lagoon that lacks riverine inputs but has persistent salinity gradients betwee the ends and the narrow pass connecting it to the Gulf of Mexico. Covarian between salinity and the groundwater tracer ^{222}Rn in Little Lagoon indicate that submarine groundwater discharge (SGD) is responsible for the salinity gradients and is likely the primary source of freshwater to the lagoon. Clus analysis based on temperature, salinity and two proxies of SGD revealed tw regimes with different drivers for nutrient concentrations and chlorophyll a samples characterized by high discharge, total nitrogen (TN) was negatively correlated with salinity and total phosphorus (TP) was correlated with temperature. In samples characterized by low discharge and higher temperatures, both TN and TP were highly correlated with temperature and inferred to originate from benthic efflux.

Monitoring within Little Lagoon from 2007 to 2010 showed tha phytoplankton community structure during periods of high aquifer discharg was distinct from other periods and tended to be dominated by diatoms and chlorophytes. *Pseudo-nitzschia* spp. abundances were also greatest during these periods and were correlated with increases in groundwater elevation. *Pseudo-nitzschia* spp. abundance had a negative relationship with measures nutrient availability and nutrients were relatively low during periods of high *Pseudo-nitzschia* spp. and high aquifer discharge. Other blooms of *Pseudo nitzschia* spp. in coastal Alabama were also associated with periods of high aquifer discharge and low nutrient availability. Dilution grazing experiment also indicated that the effects of SGD are likely to favor *Pseudo-nitzschia* spp. due to their high growth rates and susceptibility to grazing. We hypothesize that the link between SGD and *Pseudo-nitzschia* spp. blooms i not due simply to nutrient inputs, but rather that SGD is part of a disturbanc regime that favors fast-growing, heavily grazed diatoms like *Pseudo-nitzsc* spp.

[3]University of Bristol, School of Earth Sciences, Bristol, UK, h.buss@bristol.ac.uk
[4]U.S. Defense Threat Reduction Agency, Edgewood, MD, USA

Abstract

Using next generation sequencing and metagenomics analysis tools, bacteria community composition and structure were assessed in the context of chemical and mineralogical characteristics of a 9.2 m depth regolith profile developed on volcaniclastic material of the Fajardo formation in the Bisley watershed in Puerto Rico. We have hypothesized that Fe oxidation is important in weathering of intact bedrock to disaggregated regolith, and that chemolithoautotrophic microorganisms play a role in Fe cycling at depth.

The regolith forms along a gradient between conditions of low oxygen and higher pH at depth, to higher oxygen and lower pH at the surface. Secondary clay minerals and Fe oxides are present from the surface down to 8.3 m, while the weathered primary minerals chlorite and feldspar were detected from 8.3 m to the bedrock at 9.2 m. Both total cell counts and heterotrophic cell counts generally decreased from the surface to ~9 m, with variations in bacterial numbers correlating with variations in clay content. Cell numbers in iron-oxidizing media decreased with depth, but increased near the weathering front at 8.3 m depth. Increased concentrations of organic-bound iron at 8.3 m were observed as well.

Rarefaction curves generated at a 97% similarity value indicated that the regolith was representatively sampled for determining community richness. At all depths analyzed, 4 phyla were dominant – Proteobacteria, Acidobacteria, Planctomycetes, and Actinobacteria. Sub-phylum groups containing known iron-oxidizing microorganisms (e.g. subclass Acidimicrobidae) were found in the deepest samples, near the regolith-bedrock interface, consistent with the hypothesis that chemolithoautotrophic bacteria play an important role in weathering and element cycling in the deep regolith. Iron-reducing groups (e.g. *Geobacter* and *Anaeromyxobacter*) were detected as well. The data obtained from this study are consistent with the hypothesis of an iron-cycling community that in turn supports heterotrophs at depth. It is furthermore possible that this Fe-related ecosystem at depth contributes to disaggregation of bedrock to form noncohesive regolith.

Active filtration of phosphorus with hydrated oil-shale ash in constructed wetlands: geochemical modelling and phosphorus removal efficiency

MARTIN LIIRA[1]*, MARGIT KÕIV[2], RIHO MÕTLEP[1], CHRISTINA VOHLA[2], ÜLO MANDER[2], KALLE KIRSIMÄE[1]

[1] University of Tartu, Department of Geology, martin.liira@ut.ee (*presenting author)
[2]University of Tartu, Department of Geography, margit.koiv@ut.ee

Kerogenous Oil-shale used at Estonian thermal power plants is a solid fuel of low energetic value. More than 95% of power production in Estonia relies on the use of oil-shale and about 45-50% of oil-shale remains after combustion as calcareous ash. The ash is rich in free lime (CaO) and anhydrite (CaSO4), with an Al-Si glass-like phase and secondary Ca(Mg)-silicate minerals [1]. The ash is hydraulically transported to large open plateaus, and due to hydration reactions forms a variety of secondary Ca-minerals ettringite, portlandite, Ca-aluminates and calcite. More than 280 million tons of ash is deposited and these dumps are considered as point source of contamination which almost completely lacks any further use.

Recent studies [2] [3] have shown a large potential of Estonian oil-shale fly ash and the hydrated ash sediment as an alternative media for phosphorous (P) removal in constructed wetland systems via active filtration through the alkaline media. The active filtration technique uses the direct immobilization of phosphates into low soluble forms and extensive super-saturation of pore-water is required for the precipitation of stable Ca-phosphate phases.

We studied the phosphorus binding capacity of hydrated oil shale ash in onsite pilot-scale experiment (with subsurface flow filters) in Estonia, using pre-treated landfill leachate (median P 3.4 $mg \cdot L^{-1}$) for a total of 12 months. The results show efficient P removal (median removal of phosphates 99%) in filters. The P removal efficiency of the hydrated ash increases with increasing P loading, suggesting direct precipitation of Ca-phosphate phases.

A computer programme Geochemist's Workbench was employed to calculate the saturation-index (SI), according to the data obtained from the experiment, with respect to hydroxyapatite (HAP) and Ca-minerals in ash (e.g. ettringite, portlandite). The SI values for the different Ca- minerals were between -2 to -12, indicating dissolution of these minerals. and thus providing Ca^{2+} ions to the pore-water.Especially ettringite (with average SI= -6.5) is most important mineral providing Ca^{2+} ions for the precipitation of HAP. The SI values for HAP were more than 8 during all the experiment.

Precambrian palaeosol from Baltica – reconstructing the Neoproterozoic climate

SIRLE LIIVAMÄGI[1*], KALLE KIRSIMÄE[1], PEETER SOMELAR[1], JUHO KIRS[1]

[1]University of Tartu, Department of Geology
sirle.liivamagi@ut.ee (*presenting author)

Precambrian palaeosol profiles provide important and direct evidence for early weathering conditions reflecting the past climate (temperature, precipitation), atmospheric composition (pCO_2, pO_2) and (microbial)biota. In this contribution we study a well-preserved Neoproterozoic weathering crust that is widespread under the Ediacaran-Phanerozoic sedimentary cover at the southern margin of the Baltic Shield, Baltic Basin.

The palaeosol marks an unconformable contact of peneplained Palaeoproterozoic – Mesoproterozoic metamorphic-plutonic rocks and overlaying unmetamorphosed Ediacaran sandstones –claystones. Palaeosol profiles were developed on rapakivi granites, sillimanite-cordierite and biotite-amphibole gneisses, amphibolites in the northern part and pyroxene and amphibole gneisses in the southern part of the area. The maximum age of the palaeosol is estimated at 1.3-0.8 Ga by the age of major denudation in Fennoscandia and the minimum age is defined by the age of overlying Ediacaran terrigenous sediments estimated at 600 Ma, which suggest that the age of weathering falls into the period of final stage of atmosphere oxygenation during Cryogenian.

Palaeosol is accessed in more than 100 drillcores where the thickness of the alteration profiles varies from few meters to exceptional 152 m on fractured-faulted sections of alumo-gneiss parent rocks. Palaeosol is preserved unmetamorphosed, but probably slightly modified by diagenetic illitization.

Palaeosol profiles are characterized by well-developed alteration zones grading gradually from (lateritic?) kaolinitic zone (kaolinite content 30-40wt%) to smectite-illite/smectite and chlorite(illite)-smectite zones and into saprolite and fresh basement rocks. Chemical Index of Alteration (CIA, [1]) reaches values >90(95) in the uppermost parts of the alteration profiles. The Ti/Al ratios from parent rock into uppermost kaolinitized laterite are in most profiles constant at ~0.04-0.06 or 0.15-0.17 depending on host rock composition, suggesting *in situ* formation of profiles. Several profiles are characterized by Fe accumulation (Fe_2O_{3tot} are as high as 20%.) in the zone below strongly kaolinitized upper part of the palaeosol.

The quantitative weathering indicators suggest intense weathering in well drained landscapes under humid and warm conditions, with mean annual precipitation estimated at 1500-1800 mm/yr. This interpretation well agrees with palaeoposition of the Baltica continent at equator at the transition from Mesoproterozoic to Neoproterozoic [2], but there is no indication of global Snow Ball Earth glaciations that are believed to have occurred in the same period at about 710 and 635 Ma [3].

Electro-osmostic removal of PAHs: A journey from the lab to the field

ANA T. LIMA[1,2*], PHILIPPE VAN CAPPELLEN[1], J.P. GUSTAV LOCH[2]

[1] University of Waterloo, Waterloo, Canada, atlima@uwaterloo.ca
[2] Utrecht University, Utrecht, the Netherlands

Polycyclic aromatic hydrocarbons (PAH) are persistent and toxic contaminants of difficult removal from fine porous materials using conventional remediation techniques. Electro-osmosis is a potential remediation technique for the mobilization and cleanup of hydrocarbon contaminants [1-3]; it may be a promising and cost-effective technology for the removal of PAHs from clay-rich soil. By applying an electrical potential gradient, a flow of water, generally from the anode to cathode, is induced. Together with the movement of water, PAHs may be entrained towards the cathode as well. In order to demonstrate this process, we carried out studies with a custom made electro-osmosis cell (Figure 1), described elsewhere [4]. Clayey soil from Olst, the Netherlands, was used as it presents a unique study matrix: the site has been contaminated by asphalt industry for over 100 years. Using the experimental cell, up to 30% of PAHs were removed by electro-osmosis with the aid of Tween 80 [5].

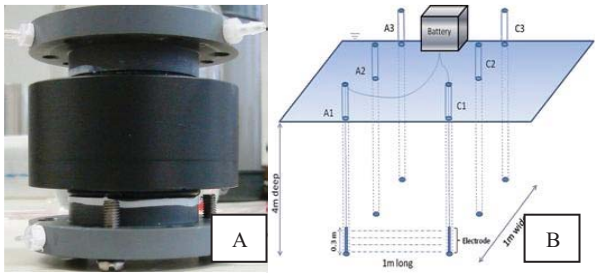

Figure 1: Picture of the electro-osmostic cell used for lab experiments (a) and design of the field experiment (b)

The Tween 80-assisted electro-osmotic clean-up was subsequently scaled up to the Olst field site (Figure 1). A release of PAHs from the soil was observed, with significant concentrations accumulating at the cathode after 90 days of continuous application of an electrical field [6]. However, most of the PAHs could not be remobilized. The percentages of PAHs that could be removed from the Olst soil, both in the laboratory and in the field, fall well below those reported for experiments with artificially spiked soils. This is likely due to the presence of PAHs in pure solid phase tar particles, from which release by dissolution is very slow. Aging effects with respect to sorption must also be taken into account when extrapolating laboratory tests to field conditions.

Abstract

Arsenic contamination in groundwater, natural or man-made, has become a major environmental concern worldwide, with adverse effects to human health[1]. The mobility, toxicity and bioavailability of arsenic in groundwater are known to strongly depend on its nature and speciation in source rocks. Also, when incorporated in the bulk rather than simply adsorbed on the surfaces, arsenic is less susceptible to secondary contamination. In this context, enormous efforts have been devoted to investigate arsenic uptake and speciation in minerals and synthetic materials[2]. Struvite, a common biomineral and increasingly important fertilizer recovered widely from sewage and waste water treatment plants, is known to accommodate a wide range of toxic metalloids, including arsenic. Experiments have been conducted to investigate the pH dependence of arsenic uptake in struvite. Microbeam synchrotron X-ray flurorescence (μ-SXRF) imaging shows heterogeneous distribution of arsenic in synthetic struvite. Arsenic K edge X-ray absorption near edge spectra (XANES) reveal that As in struvite occurs predominantly in the pentavalent oxidation state. Similarly, single-crystal electron paramagnetic resonance (EPR) spectra identified at least four varieties of paramagentic $(AsO_3)^{2-}$ centers derived from diamagentic $[^{V}AsO_4]^{3-}$ precursors at the $[PO_4]^{3-}$ positions, further supporting the presence of lattice-bound As^{5+} in struvite.

Time series of elemental carbon concentrations at Alert, Canada

COURTNEY BELDEN,[1] PHILIP K. HOPKE,[1] LIN LIN,[1*] SHELDON LANDSBERGER[2]

1. Institute for a Sustainable Environment, Clarkson University, Potsdam, NY, llin@clarkson.edu
2. Department of Mechanical Engineering, University of Texas at Austin

Introduction

There is significant interest in the concentration of elemental carbon in the Arctic ambient aerosol because of its potential climatic effect in reducing the albedo of the snow cap. Ambient particulate matter samples have been collected at Alert, Nanuvut, Canada (latitude 82.3" N, longitude 62.5" W) since 1980 by Environment Canada. In 1989, they began making hourly black carbon mearusrements using an aethalometer [1] and the time series of these data are presented in Figure 1.

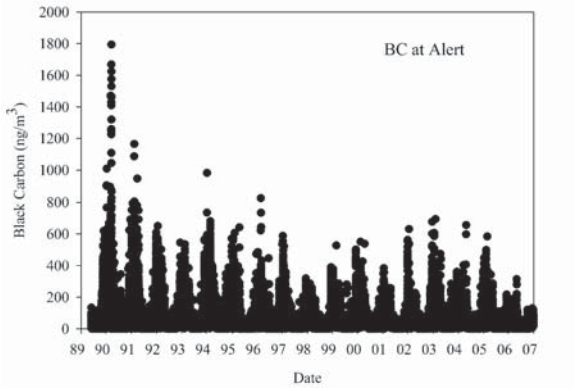

Figure 1. Environment Canada data for light absorbing carbon measured at Alert with an Aethalometer.

Methods

High volume samples have been collected on 20 x 25 cm Whatman 41 filters for 7 day periods. These filters were then cut into strips and we are analyzing one of these strips. The analysis follows the procedures developed by Husain et al.[2]. The filter material is dissolved in a concentrated $ZnCl_2$ solution. The elemental carbon particles are then collected on a baked quartz filter and the carbon determined using a Sunset carbon analyzer implementing the NIOSH protocol for organic and elemental carbon [3]).

Results and Conclusions

We will report the EC concentrations in almost 400 samples begiing with 1980 that we have analyzed. Thus, we will present the results in terms of the trends observed over the full 30 years spanned by these samples as well as fill in some of the gaps when the aethalometer was not functioning.

Archaeal and bacterial tetraether lipids in carbonate chimneys of the Lost City Hydrothermal Field

SARA A. LINCOLN[1*], ALEXANDER S. BRADLEY[2], SHARON A. NEWMAN[1] AND ROGER E. SUMMONS[1]

[1]Massachusetts Institute of Technology, Earth, Atmospheric and Planetary Sciences, Cambridge, MA 02139 USA slincoln@mit.edu ([*]presenting author)

[2]Washington University in St. Louis, Earth & Planetary Sciences, St. Louis, MO 63130 USA

The Lost City Hydrothermal Field is a peridotite-hosted hydrothermal system near the mid-Atlantic ridge [1] with a rich microbial ecosystem. Microbes inhabiting carbonate chimneys are sustained by reducing fluids that contan methane and H_2 derived from serpentinization reactions. Extensive tag sequencing of archaeal communities in Lost City revealed diversity to be low: biofilms composed almost exclusively of *Methanosarcinales* are common in active chimneys, inactive chimneys contain ANME-1, and a phylotype similar to Marine Group I *Crenarchaeota* was detected in the active chimneys with the hightest fluid temperatures. Less abundant phylotypes include groups similar to the order *Thermoplasmatales* and Marine Benthic Groups 1-2 [2].

Organic geochemical investigations provide a time-integrated record, offering insight complementary to nucleic acid-based studies. Previous work focusing on diether membrane lipids common to *Methanosarcinales* found evidence for methanogenesis and carbon limitation at Lost City [3]. Here, we present data on membrane-spanning glycerol dialkyl glycerol tetraether (GDGT) lipids from six active and five inactive chimneys. Although the distribution of individual GDGTs is similar across sites, concentrations are higher in inactive chimneys where biomarkers record the cumulative history of microbial history over years of active venting and dormancy.

We detected three GDGTs not commonly reported in marine systems: an H-shaped isoprenoidal GDGT found in thermophilic archaea isolated from hydrothermal systems and two branched, non-isoprenoidal GDGTs. Branched GDGTs, attributed to bacteria and abundant in many soils, have been used as a proxy for the input of terrestrial organic matter to marine sediments (BIT index, [4]). Their presence at Lost City, together with that of other GDGTs, suggests that input of hydrothermal sediments may complicate paleoproxies based on tetraether lipid distributions. Large, non-systematic variations in both the BIT index and the sea surface temperature proxy TEX_{86} [5] were observed in Lost City samples.

Finally, we discuss the likely archaeal and bacterial source organisms of GDGTs at Lost City.

Biogeochemistry of permeable reactive barriers for arsenic and selenium remediation

MATTHEW B.J. LINDSAY[1,2*], DAVID W. BLOWES[1], AND CAROL J. PTACEK[1]

[1]Earth and Environmental Sciences, University of Waterloo, Waterloo, ON, Canada, blowes@uwaterloo.ca, ptacek@uwaterloo.ca

[2]Present Address: Earth and Ocean Sciences, University of British Columbia, Vancouver, BC, Canada, mlindsay@eos.ubc.ca (*presenting author)

Introduction

Contamination of groundwater by arsenic (As) and selenium (Se) arises from the natural weathering of geologic materials, but can be exacerbated by mining activities. Column experiments were conducted to evaluate treatment of oxic groundwater containing As and Se using permeable reactive barriers (PRBs). Three columns were packed with varied mixtures of granular iron filings (GIF) from two separate suppliers (a and b), organic carbon (OC) and silica sand. An input solution containing 2 mg L^{-1} As(V) and 0.8 mg L^{-1} Se(VI) was passed through the 0.3 m long columns for 325 days.

ID	GIF-a	GIF-b	OC	Sand
C1	50			50
C2		50		50
C3	25		25	50

Table 1: Composition of columns given as volume percentages.

Water chemistry was monitored over time, and solid-phase samples were collected at the conclusion of the experiment. Reaction products were examined by field emission-scanning electron microscopy-energy dispersive spectroscopy (FE-SEM-EDS). Solid-phase As and Se speciation was investigated by X-ray absorption near edge structure (XANES) spectroscopy. Microbial ecology was assessed by tag encoded FLX amplicon pyrosequencing (TEFAP) of the bacterial 16S rRNA gene.

Results and Conclusions

Effective removal of As and Se was observed for all columns. Effluent concentrations of As and Se concentrations were generally < 2 μg L^{-1} for C1 and C2. Treatment improved over time for C3, with effluent As concentrations decreasing to < 2 μg L^{-1} after 120 days and Se concentrations remaining < 30 μg L^{-1} after this time. Examination by FE-SEM-EDS revealed the common presence of discrete As-bearing phases in C1 and C2. Results of XANES analysis indicate that As(V) and As(III) occurred in differing proportions within C1 and C2, whereas As predominantly exhibited a reduced oxidation state in C3. Solid-phase Se was consistently present in a reduced oxidation state in all columns. The microbial community within C3 exhibited the greatest phylogenetic and metabolic diversity. However, sulfate reducers were common to all columns, even in the absence of OC in C1 and C2. Results of this study demonstrate that As and Se removal by PRBs may result from various biogeochemical processes. Understanding these processes is critical for assessing long-term treatment performance and the potential stability of reaction products.

Crystal chemical constraints on element distribution in oxides

DONALD H. LINDSLEY,

Geosciences, Stony Brook University, Stony Brook, NY, USA

donald.lindsley@stonybrook.edu

Spinels

The oxide spinel structure, one of the first to be determined by x-ray diffraction, is based on a unit cell of 32 oxygens, which are (nearly) cubic-close-packed when viewed along the cube diagonals {1,2]. For stoichiometric spinels in the space group Fd3m, half the possible octahedral interstices (B) and one-quarter of the possible tetrahedral interstices (A) are occupied by cations, yielding the nominal formula AB_2O_4. Spinels may be normal or inverse, depending on whether the B cations are restricted to the octahedral sites or are split between the sites. The spinel structure is extraordinarily flexible; this stems from the fact that (1) the entire oxygen framework can expand *and* (2) the position of oxygens shared by tetrahedral and octahedral sites can shift along (111); the latter causes a puckering of the oxygen planes. This shift is measured by the **u** parameter, which ideally is 0.25, but can be either larger or smaller depending on the relative sizes of the tetrahedral and octahedral cations. The ideal spinel would contain cations having ionic radii of 0.0315 nm (tetrahedral) and 0.0575 nm (octahedral), but in fact at least 30 different caions, with valences ranging from +1 to +6 and ionic radii ranging from 0.026 to 0.103 nm, can form **major** components of spinels. As a great many trace elements have properties falling within these limits, the ability of spinels to host such elements is quite large.

Rhombohedral Oxides

The rhombohedral oxides, exemplified by hematite or corundum (A_2O_3) and ilmenite ABO_3, crystallize in space groups $R\bar{3}c$ and $R\bar{3}$ respectively. Oxygen forms planes parallel to (111) of the rhombohedral cell [(0001) of the equivalent hexagonal cell]; these planes are stacked in (nearly) hexagonal-close-packing, with 18 potential octahedral cation sites per 18 oxygens. Typically 2/3 of those sites are occupied by cations, most often as the couples 3^+-3^+ or 2^+-4^+ (as in hematite and ilmenite respectively). In hematite, oxygen layers alternate with cation layers, while in ilmenite the sequence of layers is O-Fe-O-Ti, thus leading to the lower symmetry. Again, however, at least 30 different cations with valences from +1 to +5, and ionic radii ranging from 0.039 to 0.095 nm (although the majority are 0.06-0.075) can form **major** components in the rhombohedral oxides. If the flexibility of the rhombohedral phases is not quite so great as that of spinels, their capacity to host many trace elements is still large.

Conclusions

In view of the great flexibility of the spinel and rhombohedral oxide structures, a more appropriate title for this abstract might well be "*Lack of* crystal chemical constraints..."

Constraints on the origins of adakites by using magnesium isotopes

MING-XING LING[1, 2*], FANG-ZHEN TENG[2], WEIDONG SUN[3]

[1]State Key Laboratory of Isotope Geochemistry, Guangzhou Institute of Geochemistry, CAS, Guangzhou 510640, P.R. China, mxling@gig.ac.cn (* presenting author)

[2]Isotope Laboratory, Department of Geosciences, University of Arkansas, Fayetteville, AR 72701, USA, fteng@uark.edu

[3]Key Laboratory of Mineralogy and Metallogeny, Guangzhou Institute of Geochemistry, CAS, Guangzhou 510640, P.R. China, weidongsun@gig.ac.cn

Adakite is a certain series of andesitic, dacitic and sodic rhyolitic rocks or their intrusive equivalents, with unique geochemical characteristics, e.g., $SiO_2 \geq 56$ wt%, $Al_2O_3 \geq 15$ wt%, Y≤18 ppm, Yb≤1.9 ppm and Sr≥400 ppm. It has attracted intensive attention because of its similar geochemical characteristics to Archaean tonalite-trodhjemite-granodiorite series (TTG) and its close association with many large porphyry copper-gold deposits. The genesis of adakites has been controversial, particularly on whether formed by partial melting of thickened/delaminated lower continental crust (LCC) or partial melting of subducting oceanic crust. A combination of major elements, trace elements and traditional isotopic systems was used to discrimate adakites formed by partial melting of subducting oceanic crust or LCC. However, traditional Sr-Nd-Pb isotopic composition can be easily altered by upper crust during magma ascent. By contrast, such processes cannot affect Mg isotopes significantly because the mantle has much higher Mg content than the crust. Magnesium isotopes may therefore shed light on the different origins of adakites.

In this study, Mg isotopic composition of a suite of adakites from three districts of central eastern China, the Lower Yangtze River belt (LYRB), the Dabie orogen and the Dexing porphyry deposits, were investigated to constrain their origins, e.g., slab melting or partial melting of thickened/delaminated LCC. The results indicate that adakites from the LYRB have relatively homogeneous mantle-like Mg isotopic composition, with δ^{26}Mg ranging from -0.366 ± 0.066 to -0.213 ± 0.078 (2SD). The adakites from the Dexing porphyry deposits have slightly scattered δ^{26}Mg from -0.340 ± 0.067 to -0.146 ± 0.068 (2SD), but with mantle-like average. By contrast, those from the Dabie orogen have heterogeneous Mg isotopic composition (δ^{26}Mg = -0.161 ± 0.065 to -0.059 ± 0.065, 2SD), slightly heavier than that of mantle (δ^{26}Mg = -0.25 ± 0.07). These distinct Mg isotopic compositions indicate different origins of these adakites, i.e., adakites form the LYRB and Dexing formed from slab melting whereas the adakites from the Dabie orogen presumably have contributions of the LCC components, consistent with previous studies [1,2]. Our studies suggest Mg isotopes may be a powerful tool for constraing the origins of adakites.

Radiotracer studies on the kinetics and equilibrium characteristics of adsorption of humic matter

HOLGER LIPPOLD[1*], JOHANNA LIPPMANN-PIPKE[1]

[1]Helmholtz-Zentrum Dresden-Rossendorf (HZDR), Institute of Resource Ecology, Germany, h.lippold@hzdr.de

Introduction

Humic substances are ubiquitous in near-surface natural waters, and they are known to act as carriers for organic and inorganic contaminants [1, 2]. In order to assess the impact of such humic-bound mobilization, transport models are developed (see [3] for a review). As a prerequisite, reaction rates for adsorption and desorption are commonly assumed to be high enough to ensure a steady local equilibrium under flow conditions. For humic matter as a polydisperse system of highly charged colloids, however, it is unclear whether a dynamic adsorption equilibrium (i.e., a permanent run of adsorption and desorption at equal rates) actually exists. Low recoveries in column experiments with geological materials suggest a limited reversibility.

Experimental

Using kaolinite as an adsorbent, the kinetics of adsorption and desorption were studied for a humic acid (Aldrich) and a fulvic acid (isolated from bog water). Their radiolabeling with ^{14}C (accomplished by azo coupling with [^{14}C]aniline) allowed sensitive detection and enabled tracer exchange experiments at surface saturation, providing direct insight into the dynamics of the adsorption equilibria for the first time. In these studies, a negligible amount of radiolabeled humic or fulvic acid was contacted with equilibrated systems of kaolinite and non-labeled humic material at different durations ranging from 6 hours to 4 weeks.

Results

The equilibrium state of adsorption was attained within few hours for the fulvic acid, whereas the process took considerably longer for the humic acid (~ 2 days), possibly as a consequence of competition effects within the polydisperse system [4]. In desorption experiments, initiated by diluting the supernatant, not any release was observed within a time frame of 4 weeks, neither for the humic acid nor for the fulvic acid. In view of transport modeling, this finding is rather disturbing since the basic assumptions do not hold if adsorption is irreversible. Our tracer exchange experiments, however, revealed that labeled humic material is adsorbed even though it is confronted with a saturated surface. Consequently, an exchange must take place, indicating a reversible process, albeit an exchange time of ~ 4 weeks was required for both materials until the adsorption equilibrium was quantitatively represented by the tracer. Apparently, the competitive situation in its presence is a stronger driving force for desorption than is a concentration gradient. Models for humic-bound transport are thus applicable under comparable conditions.

Glacial Atlantic Circulation - Insights from combined sedimentary ε_{Nd} and $^{231}Pa/^{230}Th$ records

JOERG LIPPOLD[1*], MARCUS GUTJAHR[2], FRANK WOMBACHER[3], EMANUEL CHRISTNER[1], MARCUS CHRISTL[4]

[1]University of Heidelberg, Institute of Environmental Physics, joerg.lippold@iup.uni-heidelberg.de (* presenting author)
[2]National Oceanography Centre, Earth and Ocean Sciences, Southampton, UK, m.gutjahr@soton.ac.uk
[3]University of Cologne, Institute of Geosciences
[4]ETH Zurich, Institute of Particle Physics

In contrast to the modern situation, several proxies point to a very different structure of water mass distribution in the Atlantic Ocean during the Last Glacial. However, there is still no consensus about variations of the circulation strength and timing or causation of such changes.

Seawater-derived ^{231}Pa, ^{230}Th, and neodymium isotopes, extracted from marine sediments, are promising inorganic proxies to reconstruct the past deep Ocean hydrography and water mass export. $^{231}Pa/^{230}Th$ yield information about the rate of overturning circulation, whereas ε_{Nd} derived from ferromanganese coatings carries a water mass provenance signal.

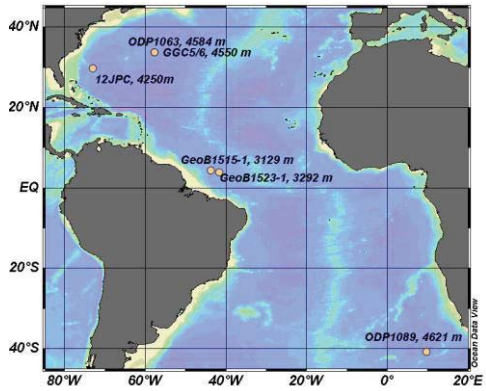

Fig.1: Locations of combined $^{231}Pa/^{230}Th$ and ε_{Nd} measurements.

First combined records of these tracers on the same sediment samples from the NW Atlantic (Bermuda Rise, ODP1063 and GGC5/6) vitally improved our knowledge about the timing of changes in past Ocean Circulation particularly with respect to centennial- to millennial-scale water column reorganisations [1,2]. We compare these earlier records to new North and South Atlantic core sites to better resolve basin-wide water column variations back to 30,000 years.

Our results show a general high level of concordance of both proxies. This is in agreement to former studies applying different circulation proxies [3,4,5], implying that both tracers indeed recorded invasion of Southern Source Water (high ε_{Nd}) during times of a weakened influence of North Atlantic Deep Water formation (high $^{231}Pa/^{230}Th$) in the Deep Atlantic Ocean.

Highly Siderophile and Chalcophile element systematics in Mid-Ocean Ridge Basalts

MORITZ LISSNER[1*], AMBRE LUGUET[1] AND STEPHAN KÖNIG [1,2]

[1] Steinmann Institut für Mineralogie, Universität Bonn, Germany moritz.lissner@uni-bonn.de, ambre.luguet@uni-bonn.de, stephan.koenig@uni-bonn.de (* presenting author)
[2] Institut für Geologie und Mineralogie, Universität zu Köln, Germany

Highly Siderophile Elements (HSE: Os, Ir, Ru, Pt, Pd, Re) as well as chalcophile elements (S, Se, Te) are potential key tracers of large-scale planetary processes such as core formation and late veneer addition. Therefore their signatures and concentrations in the primitive upper mantle (PUM) should be estimated based on our understanding of their behaviour and signatures in the mantle rocks and in partial melts at both the whole-rock and host-minerals' scales.

While a relatively large database is available for HSE, data for S, Se and Te are scarce for MORBs and peridotites. Recent preliminary investigations in depleted peridotites [1] support an incompatible behaviour of both Se and Te during mantle melting, with Te being more incompatible. This is in agreement with experimental data on sulfides [2] but is not supported by the few MORB data available, which show similar Te concentration range than peridotites [3, 4]. Additionally, an increase of Se/Te ratios for decreasing Te concentrations is observed for a suite of peridotites as well as within replicate analyses on a single sample [1], revealing the strong control of heterogeneously-distributed micrometric Te-rich phases on the Se-Te systematics in mantle residues. Strikingly, similar Se/Te fractionations are also observed in available MORB data [3].

We will present a comprehensive HSE and S-Se-Te dataset for a large suite of MORB samples, in order to provide, in the light of S and HSE, further constrains on the behaviour of Se and Te during partial mantle melting. This dataset will contribute to the characterisation of the coupled chalcophile-highly siderophile elements signatures in the terrestrial silicate reservoirs.

The isotopic mass balance of zinc in the oceans

S. H. LITTLE[1*], D. VANCE[1], D. M. SHERMAN[1], T. W. LYONS[2]

[1]Bristol Isotope Group, School of Earth Sciences, University of Bristol, Bristol, UK, s.little@bristol.ac.uk (*presenting author)
[2]Department of Earth Sciences, University of California, Riverside, USA, timothy.lyons@ucr.edu

Zinc isotopes represent a new tool that could track biological usage of trace metals in the ocean through time. Such an endeavour, however, must rest on a sound understanding of the biogeochemical cycling of zinc isotopes. Here we summarise this current understanding through analysis of the inputs and outputs of Zn to and from the modern ocean. The present Zn isotopic composition of the deep ocean is uniform, at ca. 0.5‰ for $\delta^{66/64}$Zn. This value is also an upper limit on the composition of the average whole ocean. Unlike some other transition metal isotopic systems studied so far, including Mo and Cu, this average value of δ^{66}Zn is similar to typical rock and detrital values (0.3‰) and to the principal sources of Zn to the oceans (including average global rivers = 0.33‰ [1], hydrothermal input = 0.24‰ [2], and dust ~0.2-0.4‰ [1,3]).

Both Mo and Cu isotopes are fractionated in seawater by preferential sorption of the light isotope onto Mn oxides in oxic settings. Ferromanganese crusts are isotopically light, and the imprint of their formation is stamped on the resulting heavy dissolved pool in seawater. Laboratory sorption experiments of Zn on δ-MnO_2 indicate that δ-MnO_2 also sorbs the light isotope of Zn, and an EXAFS study of three ferromanganese crusts indicates that Zn is associated with birnessite (δ-MnO_2) in these samples. This association with birnessite in nature, and the preferential uptake of the light isotope onto birnessite in experiments, are features that Zn shares with Cu and Mo. However, Zn isotope values from natural Fe-Mn crusts are uniformly heavier (at 0.7-1.2‰) than the deep ocean value. Either Zn is in a different crystal chemical environment on the oxide in experiment versus nature, or biology is, by an unknown mechanism, superimposed on Zn isotopes in crusts. In either case, the oxic sink for Zn, as sampled by Fe-Mn crusts, does not appear to significantly impact the average ocean isotopic composition. If anything, the isotope data for the inputs and for dissolved Zn in the deep ocean imply a total output that preferentially removes the light isotope. It is possible that the uptake of light isotopes into organic material [4] at least balances removal of the heavy isotope to Fe-Mn oxides.

The other key sink of redox sensitive elements is in anoxic settings, where, like Mo, Zn seems to undergo no isotopic fractionation on removal from seawater in to sediments. Data from the most Zn-enriched euxinic sediments of the Black Sea and Cariaco Basin give almost identical values to the deep ocean, of 0.5-0.6‰, whilst non-euxinic sediments from the margin of the Black Sea record the expected detrital value of 0.3‰. Hence the observed, small, difference between the input of Zn to the oceans and the average ocean isotopic composition is neatly replicated in these local anoxic-oxic settings.

[2]MARUM, University of Bremen, Germany.
uroehl@marum.de; twesterhold@marum.de

Introduction

The early Paleogene is generally accepted to have been a warm greenhouse world, with relatively high pCO_2 levels and little evidence for large-scale ice-sheets. However, ample geochemical and palaeontological evidence exists for both sustained and transient fluctuations in global climate during this time, which are often coupled to significant changes in the carbon-cycle [1, 2, 3, 4, 5, 6]. Controversially, some oxygen-isotope and sequence-stratigraphic evidence has been put forward to suggest that continental ice-volumes were large enough to drive significant changes in global eustatic sea-level during the early Paleogene [7, 8]. If ice-sheets capable of affecting global sea-level did exist, presumably on Antarctica, one would expect two things to be observed in early Paleogene marine geochemical records; 1. The presence of significant variance in eccentricity and obliquity periods in high-resolution benthic oxygen-isotope records, as is commonly observed in the icehouse world of the Oligocene–Neogene; and 2. A distinct residual seawater oxygen-isotope signal (i.e., $\Delta\delta^{18}O_{SW}$) once the temperature contribution to the benthic foraminifer $\delta^{18}O$ signal is extracted by applying the Mg/Ca or some other paleothermometer.

Results and conclusions

Here we present benthic foraminiferal $\delta^{18}O$ data from the South Atlantic (Site 1262, Walvis Ridge), which show orbitally-paced cyclic variations during the Late Paleocene and Early Eocene. Spectral analysis of these records reveals a strong eccentricity pacing throughout the entire ~6 Myr record, but no significant power in the obliquity band, suggesting global ice volumes were too low to influence $\delta^{18}O_{SW}$ beyond the background noise. Additionally, ongoing Mg/Ca analysis of benthic species at Site 1262 demonstrates that there were changes in deep-water temperature associated with eccentricity-paced carbon cycle fluctuations in the Late Paleocene, concurrent with changes in the oxygen-isotope record. Furthermore, these Mg/Ca records allow absolute temperatures to be estimated for the deep water of the South Atlantic during the Late Paleocene, which may help to establish a baseline for pre-PETM climate.

Zircon U-Pb ages and O-Nd isotopic composition of the Qinling Group in North Qinling, central China

BING-XIANG LIU, FUKUN CHEN, WEI WANG, YUE QI, QUN LONG, JIA-DE WU

CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei, 230026, China

The Qinling Group exposed in the North Qinling orogenic belt, central China, has been interpreted as the oldest basement rocks of Precambrian in age and it records crustal formation and evolution of the North Qinling orogenic belt. However, previous studies have demonstrated different formation ages such as Paleoproterozoic, Mesoproterozoic, and Neoproterozoic for the Qinling Group. In this study, we present U-Pb ages and O isotopic data of zircons obtained on the same analytical spot by the SIMS technique and Nd isotopic composition of whole-rocks from two different types of metamorphic rocks collected from the Qinling Group in the eastern part of the North Qinling orogenic belt. They are felsic gneiss and amphibolite in composition and both are major components of the Qinling Group.

Zircons of a biotite plagioclase gneiss show clear oscillatory zoning of magmatic origin but with complex core-rim structures shown in cathodoluminescence (CL) images. The cores of zircons mostly yield U-Pb ages of ca. 930 Ma, suggesting a Neoproterozoic formation age of the Qinling Group. The rims give U-Pb ages of about 500 Ma, recording an Early Paleozoic metamorphic event. Zircon grains have $\delta^{18}O$ values of 6.5 to 9.3‰ and whole-rocks yield low initial ε_{Nd} values of about -20, suggesting an origin of crustal material for magma(s) of the precursors. Zircons of amphibolite samples do not have clear oscillatory zoning and the residual cores are irregular shown in CL images. The SIMS dating yields U-Pb ages clustering in two peaks of 850 Ma and 510 Ma, also recording the Neoproterozoic formation age and the Early Paleozoic metamorphism. Zircons $\delta^{18}O$ values cluster around the mantle value with an average of 5.3 ±0.1‰, implying that the parental magma was derived from a mantle source. Initial ε_{Nd} values of whole-rocks range from -13.9 to -10.0, showing significant contribution of crustal material.

In combination with previous geochronological data and the results reported here, it is proposed that the Qinling Group formed in early Neoproterozoic. This rock group is obviously composed of variable rocks of different formation ages. The North Qinling block underwent metamorphism in Early Paleozoic related to the North Qingling orogenic event along the southern margin the North China Craton. This study is supported by the Ministry of Science and Technology of China (grant No. 2012CB416606).

Sr isotope study of Marinoan Cap carbonates from southwestern Mongolia

CHAO LIU[1], FRANCIS MACDONALD[2], ZHENGRONG WANG[1]

[1]Yale University, New Haven, CT, USA, chao.liu@yale.edu, zhengrong.wang@yale.edu

[2] Harvard University, Boston, MA, USA, fmacdon@fas.harvard.edu

The basal Ediacaran (Marinoan) Ol cap carbonate rests above the second of two glacigenic horizons in the Tsagaan Oloom Formation of southerwestern Mongolia [1]. This cap-carbonates is composed of a basal buff-colored micro-peloidal dolostone with tubestone cements, and an upper lime-mudstone with peudomorphosed aragonite crystal fans in between. In this work, we studied the Sr isotope compositions of the cap-carbonate to understand the origin of Sr isotope variability in basal Ediacaran cap carbonates globally.

Forty cap carbonate samples from Ol member, Tsagaan Oloom formation in Mongolia, were analyzed for $^{87}Sr/^{86}Sr$. An incremental leaching technique using 1N ammonium acetate and various concerntrations of acetic acid and hydrocloric acid was applied to extract Sr from different phases in the cap-carbonates (including surface adsorbed Sr, calcite, dolomite and clay minerals). The leacheates were then passed through chromatographic columns and pure Sr was analyzed using MC-ICP-MS (Neptune) at Yale university.

Our results show that the lowest $^{87}Sr/^{86}Sr$ values among all leacheates from each sample span 0.7089-0.7092, which is higher than both the overlying carbonate crystal fans and limestones (0.7082-0.7087), the least-altered samples from the Tayshir member below Khongoryn diamictite [1,2], and the lowest $^{87}Sr/^{86}Sr$ values previously reported in global basal Ediacaran carbonates (~0.7075) [3]. Very small $^{87}Sr/^{86}Sr$ variation has been observed throughout the 6-meter cap-dolomite section and leachates from the carbonate portion of each sample, suggesting these dolostones are quite uniform in chemical compositions, consistant with sub-per mil variation in $\delta^{18}O$ (-7.2 ± 0.8 ‰) and $\delta^{13}C$ (-1.2± 0.7‰) of these samples. The relatively high, but uniform $^{87}Sr/^{86}Sr$ ratios in the Ol cap dolostones could be explained by high-degree alteration or dolomitization process involving local waterbody with more radiogenic $^{87}Sr/^{86}Sr$, implying Sr isotope compositions in these dolostones might not be suitable for chemostratigraphic correlation.

Pore-scale Process Coupling and Apparent Surface Reaction Rates

CHONGXUAN LIU[1]*, CHANGYONG ZHANG[1], ZHI SHI[1], JIANYING SHANG[1], SEBASTIEN KERISIT[1], AND JOHN ZACHARA[1]

Introduction

Surface reactions such as metal oxide dissolution, reduction, and surface complexation occur in coupling with transport processes at the pore scale in subsurface sediments. The transport processes provide reactants and remove reaction products for continuous reactions, while reactions change concentration gradients and porous media properties that affect subsequent transport processes. This presentation discusses how the pore-scale process coupling affects the manifestation of surface reaction rates at the grain and Darcy scales. Uranium silicate dissolution, uranyl surface complexation, and hematite reductive dissolution by quinone-type reductants will be used as examples to demonstrate the coupled effects of reactions with transport processes on the apparent reaction rates.

Results and Discussion

Microscopic characterization revealed that geochemical reactions of interest often occur in intragranular domains in subsurface sediments such as in intragranular fractures, pores, or grain coating porous regions where reaction rates are affected by intragranular diffusion and intergranular diffusion and advection. Uranium silicate dissolution and uranyl surface complexation are two examples of such reactions that have been found to control contaminant release and transport in US Department of Energy (DOE) Hanford site [1, 2]. Experimental and modelling results at various scales consistently showed that the apparent rates of both uranium silicate dissolution and uranyl surface complexation reactions decreased with increasing scale from a single phase, to the grain scale, and to the Darcy scale. Pore-scale simulations in intragranular and flow domains revealed that the scale-dependence of the apparent reaction rates can be explained from the pore-scale coupling of the reactions with transport processes. A micromodel with complex pore-networks with pore surfaces coated with hematite are used to rigorously investigate the pore-scale coupling of reactions, diffusion, and advection and its effects on the apparent reaction rates. The surface-coated hematite in the micromodel was reduced by quinone-type reductants to mimic microbial reduction of iron oxides in the intragranular domains through a biogenic electron shuttling process. Local scale measurements within the micromodel and effluent monitoring, as well as pore-scale simulations, are collectively used to explore the coupling effect of reactions with the transport processes. The presentation will also discuss challenges to scale reaction rates at different scales and discuss effective approaches to the scale the reaction rates that can be used in reactive transport modelling at the continuum scale.

Age structure of lithospheric mantle beneath southeastern (SE) China

CHUAN-ZHOU LIU[1,*], FU-YUAN WU[1], JING SUN[1]

[1]Institute of Geology and Geophysics, Chinese Academy of Sciences, chzliu@mail.iggcas.ac.cn (* Presenting author)

Cenozoic basalts are widespread in southeastern China and commonly contain abundant deep-seated mantle xenoliths. In this study, we report the Re-Os isotope compositions of Cenozoic mantle xenoliths from two localities (Xinchang and Mingxi) to reveal the age structure of the lithospehric mantle beneath SE China. Twelve Xinchang mantle xenoliths have been analyzed, including two spinel lherzolites, seven spinel harzburgites and three garnet lherzolites. The relatively refractory spinel harzburgites contain 0.95-1.73% Al_2O_3, and 0.65-1.49% CaO. They have $^{187}Re/^{188}Os$ ratios ranging from 0.01 to 0.06 and $^{187}Os/^{188}Os$ ratios varying from 0.11999 to 0.12258, giving rehenium depletion ages (T_{RD}), relative to the primitive upper mantle, of 0.99-1.35 Ga and model ages (T_{MA}) of 1.09-1.48 Ga. In contrast, the fertile spinel- and garnet-lherzolites have higher Al_2O_3 contents (2.4-5.43%) and more radiogenic $^{187}Os/^{188}Os$ (0.12424-0.12801), which yield T_{RD} of 0.22-0.75 Ga.

The studied twenty-six Mingxi mantle xenoliths include eight spinel lherzolites, eight spinel harzburgites, nine garnet lherzolites and one garnet harzburgite. The spinel lherzolites have Al_2O_3 contents of 1.89-4.46%, whereas spinel harzburgites have lower Al_2O_3 contents (0.83-1.41%). The garnet lherzolites have Al_2O_3 contents of 1.41-3.59%, whereas the only garnet harzburgite contains 0.83% Al_2O_3. The spinel harzburgites display $^{187}Os/^{188}Os$ ratios ranging from 0.11685 to 0.12197, giving T_{RD} ages of 1.08-1.97 Ga. The $^{187}Os/^{188}Os$ ratios of the spinel lherzolites (0.11889-.13037) are more radiogenic than the spinel harzburgites, which yield T_{RD} ages ranging from 1.51 Ga to modern age. The garnet lherzolites have $^{187}Os/^{188}Os$ ratios of 0.12313-0.12733 and T_{RD} ages of 0.33-0.96 Ga. In contrast, the garnet harzburgite has a depleted $^{187}Os/^{188}Os$ ratio of 0.11737 and an old T_{RD} age of 1.72 Ga.

Our results show that spinel harzburgites from both localities have Proterozoic T_{RD} ages, which supports the existence of the Proterozoic mantle relics in the shallow depths beneath SE China. The garnet harzburgites and some garnet lherzolites from Mingxi also have unradiogenic $^{187}Os/^{188}Os$ ratios and ancient T_{RD} ages. This suggests that the ancient lithospheric mantle relic beenath Mingxi is thicker than that beneath Xinchang. In contrast, most spinel- and garnet-lherzolites from both localities have Os isotope compositions indistinguishable from the modern convecting upper mantle [1], representing the juvenile accretion of asthenospheric mantle in SE China. The juvenile mantle accretion in SE China could be accompanied with the lithospehric extension in this region since the Mesozoic [2].

Molecular Dynamics Calculation of the Calcite Zeta Potential in Brine

HONGYI LIU[1,2*] AND LAWRENCE M. CATHLES[2]

[1]The KAUST-Cornell Center for Energy and Sustainability, Cornell Unviersity, Ithaca, NY, U.S.A., hl373@cornell.edu (* presenting author) ,

Introduction

The surface charge on minerals in an aqueous enironment can affect rock strength, oil-particle adhesion, and other properties. The surface charge originates from defects in the minerals, but the charge that often counts is the electrostatic potential (zeta potential) at the distance from the mineral surface at the which the aqueous fluid becomes mobile. Here we use molecular dynamic (MD) methods to calculate the zeta potental adjacent to a calcite surface emersed in water of diffirent salinities.

Our forcefield for calcite is from a 2010 publication where MD methods successfully simulated the growth of calcium carbonate [1]. The brine solution is placed between a pair of planar numerical (1 0 4) calcite surfaces. We set the surface charge by removing Ca^{2+} or CO_3^{2-} ions from the top layer of the calcite crystal, and then calculate the electrostatic potential from the outer edge (symmetry boundary) of the calcite. The slipping plane is determined by inducing fluid flow with a gravity force and noting where the fluid movement starts. The electrostatic potential is shown as a function of distance from the calcite surface in Figure 1.

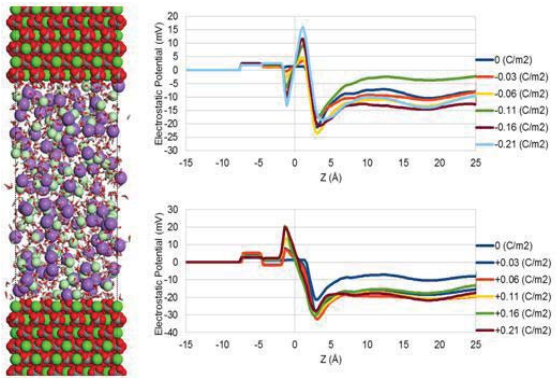

Figure 1: (a) The molecular calcite-brine sandwich (Ca: green, O: red, C: gray, Na: violet, Cl: aqua, and H_2O: red sticks). (b) The electrostatic potential of negatively charged surfaces and (c) postively charged surfaces. Z=0 marks the average VDW surface of the lower calcite layer.

Results and Conclusion

The vacancies where Ca^{2+} ions were removed are mostly ocuppied by sodium ions, while those where carbonate CO_3^{2-} ions were removed are occupied by Cl^- and Na^+ ions. The slipping plane lies about 5Å from the calcite surface (z=0 on plot). The plot shows that the sign of the zeta potential is negative whether the surface charge is positive or negative and ranges from -10 to -25 mV. If this holds true for other minerals it could help explain why the zeta potential of minerals tends to be negative.

21b. Soil and sediment remediation

Biochars (BCs), waste organic matter pyrolyzed under low temperature and oxygen conditions, have attracted great interest in environmental remediation processes [1]. However, few studies have focused on the characterization of BC prepared from a range of sources and their potential to release soluble components. In this study, eight groups of BCs produced from different materials at 300 °C and 600 °C, one group of charcoals (CL), and one group of activated carbon (AC) as a control were characterized for physical and chemical properties. Batch tests were conducted by adding BCs at a 1:75 mass ratio to river water (10 μg L^{-1} Hg). The experiments were sampled after two days to evaluate both the reduction of Hg and increase of soluble constituents in the river water. In the batch systems containing AC, CL and BCs pyrolyzed at 600 °C, concentrations of Hg were observed to decrease by >90%. In the systems containing the other BCs, concentrations of Hg decreased by 40-90%. The BCs with the highest Hg removals had relatively high specific surface areas, C and S contents, which likely contributed to Hg removal. Results obtained from FT-IR showed all BCs had hydroxyl, carboxylic and quinone functional groups, which also likely contributed to the Hg removal; the spectra of BCs prepared at 600 °C had fewer peaks compared to BCs pyrolyzed at 300 °C. Batch test results indicated that river water equilibrated with BCs prepared at 600 °C had higher pH and alkalinity and released more PO_4-P and NH_4-P than those prepared at 300 °C; however, BCs prepared at 300 °C released higher concentrations of dissolved organic carbon (DOC), short chain organic acids, NO_3^-, NO_2^-, and SO_4^{2-}, which were consistent with the FT-IR results. Biochars are promising reactive media to treat Hg contaminated waters and sediments; however, some BCs released DOC, sulfate, and organic acids, which could be utilized by methylating microbes to stimulate Hg methylation. Therefore further research needs to be performed to evaluate long term effect of the leached constituents from BCs amendments.

Results and Conclusion

Mercury concentration decreased by 40-99% in river water after two days of biochar amendment. Biochars pyrolyzed at different temperatures showed different chemical and physical properties.

Biochars are promising reactive media to treat Hg contaminated waters and sediments; however, further research still needs to be performed to evaluate long term effect of the leached constituents from BCs amendments.

Trace element of titanomagnetite in layered mafic-ultramafic intrusions: implications for oxide ore genesis

PINGPING LIU[1*], MEI-FU ZHOU[2] JIANFENG GAO[3], AND CHRISTINA YAN WANG[4]

[1] The University of Hong Kong, Earth Seicences, Hong Kong, China, liupp@hku.hk (* presenting author)

[4] Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, China,wang_yan@gig.ac.cn

Titanomagnetite has always been considered as a late crystallizing phase from basaltic magma. Precipitation of titanomagmetite is usually initiated after a lengthy period of fractionation of olivine and plagioclase, which has been proved to increase both the Fe content and the oxygen fugacity of the evolving magma [1]. However, early saturation of Fe-Ti oxides was proposed because of the occurrence of abundant Fe-Ti oxide inclusions in olivine and plagioclase [2]. In this study, we carefully examine the distribution, microtexture and chemical composition of Fe-Ti oxide minerals of Baima Fe-Ti oxide deposit in Emeishan Large Igneous Province, Southwest China. Titanomagnetite occurs as interstitial phase coexisting with a minimum amount of sulfides (Fig. 1a), or as droplet enclosed in olivine with/without other mineral assemblage (Fig. 1b, c). The major element compositions of titanomagnetite determined by electonic microprobe are highly variable, partially due to the extensive exsolution of ilmenite and spinel. Trace elements, including Ti, Zn, Cr, V, Mg, and Ni, are dertermined using in situ LA-ICP-MS. These datsets are compared with those of bulk compositions of oxide separates. From this study, the evolution stage of differentiation of titanomagnetite is revealed [3]. Combining with petrography of the oxide ores, the new dataset indicates that titanomagnetite formed from immiscible Fe-Ti-(P) melts in silicate magmas. From these immiscible melts, sulphur was saturated, resulting in the formation of sulfide blebs in oxide ores.

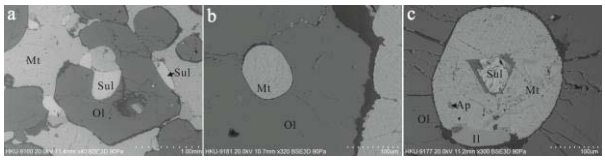

Figure 1: Titanomagnetite occurring as net-textured mass (a) or inclusions in olivine (b, c). Sul-sulfide, Mt-titanomagnetite, Ol-olivine, Ap-apatite, Il-ilmenite.

Theoretical calculations of equilibrium clumped isotope signatures beyond harmonic approximations

QI LIU, XINYA YIN AND YUN LIU*

State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, China, liuyun@vip.gyig.ac.cn (* corresponding author)

Clumped isotope geochemistry studies isotope distribution of isotopologues containing more than one rare isotope which could provide unique information such as formation temperatures of geological events. The measurement of clumped isotope signatures in laboratory needs calibration between observed isotopic data and formation temperatures in order to take account isotope fractionations in experimental procedures. One method of calibration is to measure the clumped isotope signatures of temperature-known materials to scale the temperature curve made of experimental data. Theoretical calculation using quantum chemistry methods could also become a powerful tool to study clumped isotope signatures. However, the precision required for clumped isotope calculation is very high. Theoretical treatments beyond harmonic approximations are therefore highly recommended.

In this study, theoretical treatments beyond the harmonic level by including several higher-order corrections to the Bigeleisen-Mayer equation are used to predict accurate Δ_i and Δ_{mass} results for ^{13}C-^{18}O and ^{13}C-^{2}H (or ^{13}C-D) clumps in carbonates and organic compounds. The details of these higher-order corrections can be found in [1]. Our preliminary results suggest significant improvement on the calculation of ^{13}C-D clumped isotope fractionations.

Study on the Effects between Soil Trace Elements and Apple-Pear Quality

Q.LIU[1*], D.Y.WANG[1], Y. Y.YANG[1], Y. SHANG[2] AND Q.FU[1]

[1] Jilin University, College of Earth Sciences, Changchun, China, 26246117@qq.com*, wang_dy@jlu.edu.cn, yangyuan52415241@163.com, fly19881118@yahoo.com.cn

[2] Land Surveying and Mapping Institute of Shandong Province, Jinan, China, rulyshang@yahoo.com.cn

Introduction

With a wide range of fertilizer applications in agriculture, soil trace elements are paid more and more attention in improving crop yields, especially in terms of the quality of agricultural products.

Material, Method, Results and Discussion

This study, for the first time, systematically analyzes and tests the 40 surface soil sample in the apple-pear growing areas of the total elements of Cu, Zn, B, Mo, Mn , the available elements and the corresponding quality indicators in the apple-pear samples of total sugars, total acid , soluble solids , water content and hardness in Yanbian area, Jilin (NE China). Correlation analyses are done by SPSS, calculated the correlation coefficient among the total elements of soil trace elements, the available elements and the quality indicators of the apple-pear respectively. The results show that the total sugar content of apple-pear and the total elements of soil trace elements Mn, Mo have extremely remarkable positive correlations, with the total elements of Cu, Zn exhibiting significant positive correlations, with the available Mn, Mo showing significant positive correlations. Total acid only have significantly negative correlations with the available Zn. Soluble solids, the total elements of Zn, Mn, Mo and the available Mo show extremely remarkable positive correlations, with the total elements of Cu, B having significant positive correlations. Water content and the total elements of Zn exhibit extremely remarkable negative correlations; the total elements of Cu, Mn and the available Mo show significant negative correlations. Hardness, the total elements of Mo and the available Mn, Mo indicate extremely significant negative correlations, with the total elements of Cu, Zn, Mn and the available Zn having significant negative correlations.

Conclusion

Taken together, the above analysis shows that the soil trace elements have the negative and the positive effects on the apple-pear and effects are remarkable. Therefore, it will make an important sense to combine the characteristics of the soil trace elements and fruit quality. The improving of the quality of agricultural products, reasonable landing using and scientific products program planning are of great significance.

Microscopic structures and acid chemistry of interfaces between phyllosilicates edges and water

Theme 18 Frontiers in Computational Geochemistry

Knowledge on phyllosilicates (2:1- and 1:1-type)–water interfaces is critical for both understanding natural processes and guiding development of advanced hybrid materials. Due to the layered structures, their surfaces can be grouped into basal surfaces and edge surfaces (i.e. broken surfaces). Compared to basal surfaces whose properties have been well realized, chemical properties of edge surfaces are much more subtle and therefore are impossible to reveal by experimenting or force field based simulations.

With FPMD (first principles molecular dynamics) and free-energy calculation techniques [1~3], we investigated the structures and acid chemistry of these complicated interfaces [4, 5]. According to systematic simulations, the following has been achieved. (1) Through investigating the leaving processes of coordinated waters of edge cations, interfacial hydration states are revealed and thus the topologies are pictured (see Fig. 1 for 2:1-type) (2) Interfacial acidic sites have been figured out with detailed analyses of H-bonding networks. (3) Acidity constants of those acidic sites are derived by free-energy calculations for proton transfer reactions.

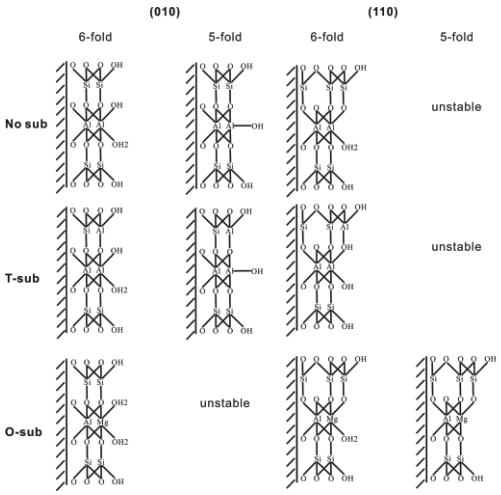

Figure 1: Topologies of edge surfaces of 2:1-type phyllosilicates.

FLUID ACTIVITY AND PARTIAL MELTING IN THE EVOLUTION OF UHP ROCK: EVDIENCES FROM ZIRCON U-PB AGE AND HF-O ISOTOPES

XIAOCHI LIU[1], YUANBAO WU[1*], AND JOHN M. HANCHAR[2]
[1]Faculty of Earth Sciences, China University of Geosciences, Wuhan, China, liuchicug@163.com; yuanbaowu@cug.edu.cn (* presenting author)
[2]Department of Earth Sciences, Memorial University of Newfoundland, St. Johns, Canada, jhanchar@mun.ca

In subduction- or collision-related metamorphism, fluid activity and partial melting occur at different stages and play key roles in many geological processes including metasomatism, crustal rheology, anatexis, resetting of isotopic clocks, transformation of mineral assemblages, and the creation and preservation of high-pressure (HP) and ultrahigh-pressure (UHP) rocks. The timing and features of fluid activity and partial melting, however, are quite difficult to constrain. In this study, in situ U–Pb geochronology, O and Hf isotopes in zircon have been done on a retrograde eclogite, a quartz vein and a leucosome vein enclosed in the eclogite and a country rock gneiss from the Xitieshan UHP terrane in the North Qaidam metamorphic belt, northwest China. Zircon from the quartz vein was dated at 438.0 ± 11 Ma and is consistent with the timing of peak UHP metamorphism in this region. This demonstrates that there was fluid activity during the peak UHP metamorphism. The homogeneous, bright in cathodoluminescence, zircon cores in the quartz vein contain O and Hf isotope compositions similar to the zircon in the eclogite, indicating that the zircon cores of quartz vein may be related to, or possibly derived from, the eclogite. In contrast, the oscillatory-zoned rims in the zircon crystals in the quartz vein have O and Hf isotope compositions consistent with the country rock gneiss sample. Most zircons from the leucosome vein have oscillatory zoning or wholly caliginous homogeneous in cathodoluminescence. The zircon U–Pb age of the leucosome vein is 419.6 ± 3.9 Ma, which can be regarded as the timing of extensive partial melting of the Xitieshan UHP rocks. The O and Hf isotope composition of the leucosome vein zircon is also consistent with the country rock gneiss. Therefore, the O and Hf isotopes in both the zircon rims of quartz vein and the zircons in leucosome vein are compatible with their origins from the surrounding felsic gneiss. The metamorphic zircon cores grew in the presence of fluids during the peak UHP metamorphism, whereas the younger zircon grew during partial melting of the surrounding gneiss during exhumation following granulite-facies metamorphism. This suggests that the fluid flow at the peak conditions might induce a low-degree of partial melting of the subducted slab and promote the initiation exhumation of the continental crust.

Tracing continental weathering using Li and Mg isotopes:

Insights from rivers draining the Columbia River Basalts

XIAO-MING LIU[1*], ROBERTA L. RUDNICK[1], WILLIAM F. MCDONOUGH[1], AND FANG-ZHEN TENG[2]
[1]University of Maryland, College Park, MD, USA, xliu1235@umd.edu (* presenting author), rudnick@umd.edu, & mcdonoug@umd.edu
[2]University of Askansas, Fayetteville, AR, USA, fzteng@uark.edu

Chemical weathering may have an important influence on continental crust evolution, as weathering of basalt removes Mg and can shift the crust composition towards more andesitic compositions, thus helping to solve the crustal composition paradox [e.g., 1]. We are exploring the use of soluble elements like lithium and magnesium, and their isotopes, to monitor chemical weathering of the continents. These elements are preferentially transfered to the rivers during weathering, coupled with large isotopic fractionations [e.g., 2], and therefore could be useful tracers of weathering processes. Here, we report chemical and isotopic analyses of small rivers and streams whose catchments lie entirely within the Columbia River Basalts in order to understand the processes associated with basalt weathering.

Soluble elements, such as Na, Mg and Ca are positively correlated with TDS (Total Dissolved Solids) in the rivers. The river water chemistry (e.g., Mg/Na vs. Ca/Na) reveals that more than 95% of the dissolved load comes from silicate weathering, consistent with the lithology of the catchments (basalt). There are large variations in the lithium isotopic composition of the river waters (δ^7Li varies from +9 to +30) and a negative correlation between δ^7Li and normalized Li concentration in the dissolved load, which likely marks the influence of two weathering regimes on river chemistry: incipient weathering (generating large isotopic fractionation, δ^7Li up to +30) vs. advanced weathering (with less significant isotopic fractionation, δ^7Li is around +10). This trend is opposite to that found in a previous study from rivers draining a multi-lithology basin [3]. Nonetheless, combined δ^7Li and normalized Li concentration may be a good tracer of weathering intensity. By contrast, the magnesium isotopic signature in river waters does not display an obvious difference between these two weathering regimes, which may due to the influence of additional factors, such as different isotopic fractionation associated with various secondary mineral formation, as well as biological activity on the Mg isotope signatures. Nonetheless, river waters have isotopically light δ^{26}Mg (varying from -0.8 to -0.2) relative to the basalts (-0.2 ± 0.1), consistent with equilibrium isotopic fractionation between water and regolith.

Characterization of EPS fractions before and after adsorption to goethite

X. LIU[1], K. EUSTERHUES*[1], J. THIEME[2], C. HÖSCHEN[3], CARSTEN W. MÜLLER[3], I. KÖGEL-KNABNER[3], K.U. TOTSCHE[1]

[1]Institut für Geowissenschaften, Friedrich-Schiller-Universität Jena, Germany (*correspondence: karin.eusterhues@uni-jena.de)
[2]NSLS-II, Brookhaven National Laboratory, Upton, NY, USA
[3]Lehrstuhl für Bodenkunde, Technische Universität München, Germany

Extracellular polymeric substances (EPS) are produced by many different microorganisms and are crucial for their initial attachment to solid surfaces. They consist of a mixture of polysaccharides, proteins, lipids and nucleic acids, i.e. of compounds, which are known to be easy degradable. In soils however, microbial-derived polysaccharides seem to be effectively stabilized against degradation when adsorbed to minerals. We therefore assume that EPS may be a long-term stable and significant component of organic coatings on soil minerals. This is of environmental concern as the coverage of mineral surfaces by EPS will completely change interface properties such as solubility, charge, and hydrophobicity.

We performed batch adsorption experiments using EPS extracted from liquid cultures of *Bacillus subtilis* and goethite. The pure EPS and the EPS covered goethites were characterized by atomic force microscopy (AFM), Fourier-transform infrared spectroscopy (FTIR), scanning transmission X-ray microscopy (STXM) and high-lateral-resolution secondary ion mass spectrometry (NanoSIMS). The original EPS was found to be spatially separated into three fractions which differ in their content of polysaccharides, proteins and aromatic groups. During reaction with goethite, we observed the formation of an additional fraction, rich in lipids and proteins, which is preferentially adsorbed. Polysaccharides, in contrast, remained in solution. NanoSIMS allowed to map the spatial distribution of C, P, N, and S. Phosporous was homogenously distributed throughout the whole EPS, whereas N was only found where EPS was in close association with goethite. Sulfur was enriched in some patches (~ 500 nm in diameter) of the goethite associated EPS.

We conclude, that mainly proteins and lipids, i.e., the EPS components which preferentially adsorb to goethite will be stabilized against biodegradation. Likewise, mainly these components, will change the surface properties and hence the reactivity of goethite.

Acidophilic Population Succession in Pilot Uranium Bioleaching Process

LIU YAJIE[1,2], LI JIANG[2], XU WEIYUN[2], D.B.JOHNSON[3], KEVIN HALLBERG[3], WANG XUEGANG[2], SUN ZHANSUE[2], LIU JINHUI[2], XU LINGLING[2], LIU JIANGSHE[1*]

Microorganisms community changes and develops with its environment. In uranium bioleaching, acidophilies especially some chemolithotrophic play an important role as well as some heterotrophic and mixtrophic acidophiles[1]. This paper investigated the acidophilic community successions by double layer solid plate and molecular methods such as t-RFLP, RFLP and Gene Clone Library methods.

Two different type minerals for bioleaching were set up as a 5000-ton heap and a 3-ton column, respectively. The main uranium mineral was pitchblende and the average uranium content was 0.021% and 0.290%, respectively. 9 mineral samples were taken from the bioleaching heap or column sites during the process of bioleaching, meanwhile, the chemical parameters such as pH value, Eh value, Ferric ion, total iron and uranium IV concentration of PLS before and after the samples were analysis. After 120 days and 116 days, the uranium extraction rate were reached to 55.92% and 90.20%, respectively. Results showed that the predominant bacteria of the 5000-ton heap were *At. thiooxidans, L. ferriphilum, Sulfobacillus thermotolerans*, *L. Ferrodiazotrophum*, *At. caldus* and *Acidocella sp.* and of the 3-ton column were *At. thiooxidans, L. ferriphilum, L. Ferrodiazotrophum*. It confirmed that *L. ferriphilum* always an active and predominant species in our laboratory and so did in the column, but not in the waste rock heap. It concluded that the bacterial population of the column bio-leaching was less influenced by the natural acidophilic bacteria, while in the 5000-ton heap, the bacteral population was highly influenced by the natural ones. More over, the population succession was evident with the temperature and bioprocessing.

MSS-sulfide melt partitioning of PGE and semi metal at controlled f_{o2}-f_{s2} conditions

YANAN LIU[1] AND JAMES BRENAN[1]

[1]University of Toronto, Geology
liu@geology.utoronto.ca (* presenting author)
j.brenan@utoronto.ca

Field evidence indicates that phases rich in the semi metals (As, Se, Sb, Te and Bi) may sequester significant amounts of Platinum Group Elements (PGE) relative to base metal sulfide at the magmatic stage [1,2]. To better understand the role of the semi metals on affecting PGE distribution within magmatic sulfides, a series of partitioning experiments have been conducted between Monosulfide Solid Solution (MSS) and sulfide melt at f_{o2}-f_{s2} close to natural conditions.

All the partitioning experiments were carried out in evacuated silica tubes, with Fe-Ni-Cu-S mixtures pre-melted and doped with approximately 80 ppm each of PGEs and semi metals. The oxygen fugacity was buffered by Fayalite-Magnetite-Quartz (FMQ), and the sulfur fugacity was calculated from the composition of the coexisting pyrrhotite. The correlation between sulfur fugacity and pyrrhotite composition [3] was independently calibrated at different sulfur buffers (Ru-RuS_2, Pt-PtS and Ir_2S_3-IrS_2), using a freshly synthesized FeS microprobe standard. The PGE partitioning experiments were conducted at 900 °C, 915 °C and 930 °C, while the semi metal doped runs at 915 °C, 900 °C and 885 °C. A comparison experiment was also conducted with all the PGE and semi meal dopants at 900 °C to test the effect of semi metals on PGE partitioning. The duration of experiments was 3-7 days.

Results indicate that the MSS/melt partition coefficient (D) of these semi metals are all less than one, with the relative order of compatibility: Se>As>Te>Sb≥Bi. There is a linear decrease in logD for the semi metals with their increasing covalent radius. These partition coefficients are not sensitive to variations in temperature, oxygen fugacity, or sulfur fugacity within the range of experimental conditions. Yet for any given semi metal element (except Se), the partition coefficient exhibits a weak dependence on the cation / anion ratio of the residual sulfide melt. D values for the PGEs remained unchanged by the addition of semi metals. These data imply that the crystallization of MSS can potentially lead to semi metal enriched residual liquid, resulting in the formation of immiscible semi metal rich melt or discrete semi metal rich Platinum Group Minerals (PGM). Thus the semi metal PGMs at Sudbury Ontario (tellurides and bismuthides being the most common ones, associated with late-stage low sulfur and haloes-bearing liquid around massive sulfide bodies [4]) could as well be produced by extreme fractionation of sulfide melt.

Water, water, everywhere on the Moon

YANG LIU[1*] AND LARRY A. TAYLOR[1]

[1]Planetary Geosciences Institute, Department of Earth & Planetary Sciences, University of Tennessee, Knoxville, TN 37996, USA. (yangl@utk.edu)

Different forms of "water" have been reported from surface of the Moon to igneous samples, as shown by many recent discoveries [1-10]. Reflectance IR identified OH (and possible HOH) on the upper-most lunar soil (top few mm) of 10-5000 ppmw H_2O [1-3]. An impact experiment on a permanently shadowed crater in lunar south pole observed 5.9 ±2.9 wt% H_2O ice in the impact site [4]. Using Secondary ion mass spectrometry, we have seen high amounts of H, regarded as OH, in volcanic glasses (<46 ppmw H_2O, [5]), apatite (<7000 ppmw H_2O, [6-8]), and melt inclusions (370-1410 ppmw H_2O, [10]). These studies of magmatic apatite and glasses suggest that the lunar mantle may contain OH comparable to that of Earth [5, 10]. These discoveries highlighted new questions about the formation and evolution of the Moon from surface to interior, and the total "water" budget on the Moon.

We are actively involved in the research of "water" on the Moon. Our most recent studies have focussed on a search of host phases of lunar "water" [11, 12]. We have discovered significant amounts of OH in lunar soils. The D/H isotope values suggest a depleted source (solar-wind) and an enriched source (likely meteorites or comets). These results provide direct evidence for meteorite inputs to lunar surface OH/H_2O. The observation of abundant solar-wind-like OH also supports models that suggest its migration as OH to ice in the permanently shadowed craters in lunar poles [13, 14]. Here, we will summarize our recent studies and its implications on the formation mechanisms of surface OH/H_2O on airless terrestrial bodies, and we will also attempt to quantify the total budget of the OH/H_2O, particularly on the surface of the Moon.

Passive treatment of perchlorate, nitrate, and sulfate in contaminated groundwater using zero valent iron and wood chips

YINGYING LIU *, CAROL J. PTACEK, DAVID W. BLOWES

University of Waterloo, Waterloo, Canada, yy4liu@uwaterloo.ca

21i. Groundwater Remediation

Perchlorate is widespread in the environment due to its use in rocket propellants, explosives, fireworks, and other applications. Its high mobility and ecotoxicity make treatment of perchlorate-contaminated water urgent [1]. Reactive media can be used to remove perchlorate in water in permeable reactive barriers and a variety of bioreactors [2]. In this study, a series of four column experiments was used to evaluate the effectiveness of reactive media for use in passive treatment systems for removal of perchlorate, nitrate, and sulfate from contaminated water associated with mining and blasting sites.

One column was packed with silica sand as a control, the other three columns were packed with granular zero valent iron (ZVI), wood chips (WC), a mixture of granular zero valent iron and wood chips, adjusted with 50 vol.% of silica sand. The experiments were operated in two stages; the flow rate was maintained at 0.5 pore volume (PV) day^{-1} in the first stage and at 0.1 PV day^{-1} in the second stage (after approximately 100 PV of flow in each column).

Results and Conclusion

Nitrate, sulfate, and perchlorate were effectively removed during the second stage of the experiment: nitrate (~10.8 mg L^{-1} NO_3-N) was almost completely removed to concentrations <0.02 mg L^{-1} NO_3-N in all columns; sulfate was removed with a variable removal of up to 70% of input sulfate (~24.5 mg L^{-1}) in Column WC; perchlorate (~857 µg L^{-1}) was effectively removed to concentrations <28 µg L^{-1} in Column WC and to concentrations <2 µg L^{-1} in Column ZVI+WC during the last 30 pore volumes in the second stage of the experiment.

The removal of nitrate and perchlorate followed first-order and zero-order kinetic equations, respectively. Nitrate and perchlorate were removed simultaneously within Columns WC and ZVI+WC, however, nitrate was removed much more rapidly than perchlorate. Nitrate inhibition of perchlorate removal was observed in Column WC at nitrate concentrations >2 mg L^{-1} NO_3-N. However, adding ZVI into WC effectively eliminated the inhibition of perchlorate removal by nitrate in Column ZVI+WC. Sulfate did not inhibit perchlorate removal in any of the columns in this study.

Triassic high-Mg adakitic andesites from Linxi, Inner Mongolia: Insights into the fate of the Paleo-Asian ocean crust and fossil slab-derived melt-peridotite interaction

YONGSHENG LIU*, XIAOHONG WANG, DONGBIN WANG, DETAO HE, KEQING ZONG, CHANGGUI GAO, ZHAOCHU HU

[1] State Key Laboratory of GPMR, China University of Geosciences, Wuhan 430074, China, yshliu@hotmail.com (* presenting author)

As the eastern Chinese extension of the central Asian orogenic belt, the Inner Mongolia-Daxinganling orogenic belt (IMDOB) has been regarded as a complex collage of island arcs, microcontinental blocks and fragments of oceanic crust that were amalgamated together during the Paleozoic closure of the eastern Chinese segment of the Paleo-Asian Ocean between the North China Craton and south Mongolia Block. The IMDOB is celebrated for its subduction-accretion tectonics and as being the world's most important juvenile crust production in Phanerozoic times.

Bulk element and isotopic compositions, single zircon U-Pb ages and trace element compositions of the Triassic high-Mg adakitic andesites (HMAs) from the Linxi area in the IMDOB were studied in this work to understand its petrogenesis and implications for Phanerozoic crustal growth. The Linxi HMAs are characterized by typical features of high-SiO_2 adakite with high Mg# and high Cr and Ni contents. Coarse clinopyroxene (cpx) phenocrysts with reverse zoning were found. These cpx phenocrysts have cores with lower Mg# and Ni contents, and higher incompatible element contents (e.g., Zr and La) compared to their mantles and rims. Bulk rock Sr-Nd isotopic compositions ($^{87}Sr/^{86}Sr_I$ = 0.70382 - 0.70396 and $\varepsilon_{Nd(t)}$ = 3.2 - 4.5) fall in the range of mid-ocean ridge basalt (MORB) and modern subduction-related adakites. Single zircon U-Pb dating by LA-ICP-MS suggests an eruption at ca. 238 Ma. Combined with the tectonic setting and Precambrian zircon age spectrum, these features suggest that the Linxin HMAs were derived from the subducted Paleo-Asian oceanic slab with sediments shed from the north China Craton and hybridized by peridotite in the mantle.

Trace element-age variations of zircons indicate that the oceanic crust was formed during Carboniferous-early Permian times, and then subducted during ca. 270 – 260 Ma. Melting of the subducted oceanic slab and hybridization by peridotite could have been initiated at ca. 250 Ma. It is suggested that the southern accretionary zone between the North China Craton and the Solonker suture in the IMDOB, where the Linxi HMAs are located, could have been consolidated by Carboniferous-Permian times. This implies that the Linxi HMAs could have been derived from partial melting of a fossil oceanic slab after the subduction, and subduction-related melting may have been delayed if the slab was subducted under an old, cold craton. Although we are unsure of the true extent of the fossil oceanic slab, the genesis of the Linxi HMAs is essentially a snapshot of the melting of a subducted slab lagging behind subduction, and melting of fossil oceanic slab could have played an important role in the Phanerozoic crustal growth in the IMDOB.

Equilibrium Mg and O isotope fractionations between silicates at high T and P: the test of a new calculation method

YUN LIU*, XIAOBIN CAO, XUEFANG LI, JIE YUAN

State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, China, liuyun@vip.gyig.ac.cn (* presenting author)

For the test of a cluster-model-based method which we developed for estimating isotopic fractionations of solids, Mg and O isotope fractionations between spinel, diopside, pyrope, omphacite and forsterite at different temperatures and pressures are investigated. There is a tremendous interest in developing a cluster-model-based method of isotope fractionation calculation for solids because most of the new techniques developed in modern quantum chemistry are for molecules which usually are represented by cluster models. Many local properties of solids (e.g., isotopic effect) can be calculated using much higher theoretical treatments if using cluster models. Another reason we developed this method is to remedy problems raised from a similar method used by Rustad and co-workers (e.g.,[1]), especially to enhance its implementation on isotope fractionation calculations between solids and aqueous species.

Recent studies (e.g., [2],[3],[4]) suggested the possibility of using equilibrium inter-mineral Mg isotope fractionations as a thermometer at mantle conditions. Here, we calculate equilibrium Mg and O isotope fractionation factors of geologically important silicate minerals by using our new method. Although our results of silicate minerals are generally close to those of Schauble (2011), our result of magnesite vs. Mg^{2+}(aq) ion is significantly different from his result. Our results are very close to existing Mg and O isotope experimental data, suggesting broad applications of this method in future.

Because an good isotope thermometer is required to exclude pressure effects, we checked the pressure effects of Mg and O isotopes of those silicate minerals mentioned up to 13GPa (i.e., roughly the upper mantle condition). Very small pressure effects are found within the lower pressure range (e.g. less than 4 GPa). However, slowly increasing pressure effects are found with the increase of pressure to 13GPa. We suggest to correct the pressure effects if the samples are from the lower part of the upper mantle.

Manganese (Mn) oxides are among the strongest mineral oxidants in the environment and impose significant influence on mobility and bioavailability of redox-active substances, such as arsenic, chromium, and pharmaceutical products, through oxidation processes. Oxidizing potentials of Mn oxides are determined by Mn valence states (II, III, IV). In this study, the effects of beam damage during Electron Energy-Loss Spectroscopy (EELS) measurement in the Transmission Electron Microscope have been investigated to determine the "safe dose" of electrons [1]. Time series analyses demonstrate that some Mn-oxide minerals experience a reduction of Mn valence during intense or prolonged electron beam exposure. We have determined the safe dose fluence (electrons/nm^2) for todorokite (10^6 e/nm^2), acid birnessite (10^5), triclinic birnessite (10^4), randomly-stacked birnessite (10^3) and δ-MnO_2 ($<10^3$) at 200 kV. The results show that precise measurements of the mean Mn valence can be acquired by EELS if proper care is taken. EELS anayses are shown to be as precise as chemical titration analyses, but with twelve orders of magnitude less volume (~5 attoliters, 10^{-18}).

The value of EELS analysis is demonstrated by two applications: 1) Analysis of run products from experiments reacting 1 mM dissolved Mn^{2+} with δ-MnO_2 in the presence of other cations (Na^+, Ca^{2+} Zn^{2+} and Ni^{2+},). These experiments, designed to determine reaction rates of the reduction of Mn(IV) in poorly-crystalline Mn-oxides by Mn^{2+}, produce mixtures of phases with variable mean valence. Unlike bulk chemical tiration or X-ray absorption spectroscopy, EELS, in concert with energy-dispersive X-ray analysis (EDS), can determine the individual phase valences and their mineral formulae (including other divalent cations). 2) Analysis of todorikite in a Mn-oxide crust from the Pacific ocean floor. This natural todorokite includes Fe(II,III) and other minor elements. EELS is capable of measuring the mean valence for both Mn and Fe, while simulaneously acquiring quantitative EDS analyses.

A modeling study of ecosystem carbon and nutrient cycling following oil sands mining

EMILY LLORET[1*], SYLVIE A. QUIDEAU[1], AND ROBERT GRANT[1]

[1]Department of Renewable Resources, University of Alberta, Edmonton, Canada, lloret@ualberta.ca (* presenting author)

Oil sands in northern Alberta provide a valuable resource for the national and international production of gas and petroleum. However after this resource is extracted, industries must restore disturbed landscapes to a productivity equivalent to that of natural landscapes. Carbon and nitrogen cycling play important roles in the restoration of this productivity. To examine these roles, we compared modelled vs. measured effects of three different depths of mixed peat-mineral soil covers on ecosystem productivity, soil quality and salinity in a disturbed landscape at the South Hills site of the Syncrude mine in northern Alberta. We then compared the productivities of these landscapes with that of a natural landscape to determine the depth of soil cover required to restore the productivity of a reclaimed landscape to that of a natural one. These results are preliminary pending more detailed measurements of site and soil properties.

Single cell genomics of uncultured subsurface archaea

[3]Max Plank Institute for Marine Microbiology, Bremen, Germany

Abstract

Microorganisms are dominant players in global biogeochemical cycling, and the marine subsurface contains many deeply-branching groups of archaea that have no cultured relatives.[1,2] Much of these archaea come from the Miscellaneous Crenarchaeotal Group (MCG) and the Marine Benthic Group D (MBG-D), which are globally distributed in anoxic environments. The phylogenetic identity of these archaea has only been established through genetic information in the 16S rRNA gene. Metabolic capacity, on the other hand, can be inferred by presence of functional genes that represent specific metabolic pathways. In order to link phylogenetic identity to metabolic capacity of these uncultured archaea, we sorted a single cell of each and sequenced the entire genome of each using a hybrid approach with 454 FLX and Illumina methods. We then compared this to abundance data in Aarhus Bay sediments to determine potential roles for these groups in marine non-seep sediments.

Out of the 56 single copy genes conserved in all cultured archaea, we found 14 and 29, MCG and MBG-D, respectively. A concatanation of these conserved genes provide support for an evolutionary grouping of the MCG within the mesophilic Crenarchaeota (or Thaumarchaeota) and the MBG-D within the Order Thermoplasmatales within the Euryarchaeota. MCG and MBG-D were found to comprise the bulk of the archaeal population, using qPCR as well as 454 FLX sequencing of archaeal 16S genes. The genomes of MCG and MBG-D contain nearly complete pathways for the tricarboxylic acid cycle, as well as transporters for externally-derived organic molecules. They both contain variations on pathways for amino acid degradation. These data support a heterotrophic lifestyle for uncultured archaea in the marine subsurface, as was predicted by bulk biomass isotopic ratios.[1] No evidence was found for commonly used inorganic terminal electron acceptors such as oxygen, sulfate, iron, or CO_2 (for methanogenesis). Therefore the physiology of MCG and MBG-D most likely diverges from those of their aerobic closest relatives.

High sensitivity laser ablation MC-ICP-MS

NICHOLAS S. LLOYD[1*], STEVE SHUTTLEWORTH[2], CLAUDIA BOUMAN[1], ANNE TRINQUIER[1], JOHN ROY[2] AND JOHANNES B. SCHWIETERS[1]

[1]Thermo Fisher Scientific, Bremen, Germany, nicholas.lloyd@thermofisher.com (* presenting author)
[2]Photon Machines, Redmond, USA, shutts@photon-machines.com

The Thermo Scientific NEPTUNE *Plus* MC-ICP-MS with Jet Interface option has previously been demonstrated to offer the highest ICP-MS analyte sensitivities for desolvated solutions [1] and for laser ablation [2]. A combination of nitrogen addition, special cones and a high capacity interface pump improved laser ablation Hf sensitivity by a factor of more than seven. The resulting sensitivity enabled highly precise and accurate $^{176}Hf/^{177}Hf$ isotope ratios to be measured from zircon 91500 using 25 µm diameter laser ablation spots, whereas typically 100 ppm 2σ external precision is only achieved using 50 µm diameter spots (with four times the ablated volume). It was noted that with increased sensitivity the Yb and Hf fractionation factors diverge further, highlighting the importance of independent measurement of the Yb fractionation factor used for the ^{176}Yb correction.

For these experiments a Photon Machines Analyte.G2 193 nm laser ablation system was operated with moderate fluence and repetition rate (6.22 J/cm^2 at 7 Hz). The short pulse width and short wavelength of this excimer laser ablation system is ideal for ablation of zircon mineral grains. The Analyte.G2 is equipped with a two-volume HELEX 2 cell for the fastest washout time. The combination of improved ICP-MS sensitivity and fast response laser ablation cell is critical for the emerging field of 'geochron, imaging' by LA-ICP-MS.

In this study we investigate the factors that influence external precision of $^{176}Hf/^{177}Hf$ isotope ratios from zircons, including the effects of nitrogen addition on analyte sensitivity and mass bias stability. We also describe a new multi-ion counting collector configuration that has been designed for the Thermo Scientific NEPTUNE *Plus*. This allows for increased flexibility of analysis, using combinations of ion counters and Faraday cups to accommodate the range of U-Pb isotope beam intensities expected from both young and old zircons.

Setting and Styles of Hydrothermal Mudstones near the Lemarchant volcanogenic massive sulfide deposit, Newfoundland Appalachians.

S. LODE ([1]*), S.J. PIERCEY[1], D. COPELAND[2], C. DEVIVE[2], B. SPARROW[2]

[1]Department of Earth Sciences, Memorial Univ., St. John's, Canada (*correspondence: slode@mun.ca)
[2]Paragon Minerals Corporation, 140 Water Street, Suite 605, St. John's, Canada

In some volcanogenic massive sulfide (VMS) deposits there is a close association of black shales and hydrothermal mudstones and massive sulfide mineralization, yet our understanding of the relationship of these muds to VMS deposit genesis and exploration is incomplete. The Lemarchant VMS deposit, Central Mobile Belt, Newfoundland Appalachians, Canada, is an excellent location to study the relationship of black shales/hydrothermal muds to VMS mineralization because there is an intimate relationship between precious-metal bearing Zn-Pb-Cu sulfides and hydrothermal sedimentary rocks. The Lemarchant VMS deposit is hosted by the late Cambrian Tally Pond volcanic belt and represents a bimodal felsic VMS deposit with a typical stratigraphic sequence consisting of rhyolite domes and/or breccias with a stockwork stringer zone, overlain by the massive sulfides, one or more barite bed(s), and capped by hydrothermal sediments/mudstones. Mafic volcanic flows, predominantly pillowed basalts, are deposited on top of this sequence and represent a new cycle of volcanic activity. Metalliferous mudstones represent a hiatus in this volcanic activity, where the deposition of hydrothermal matter dominates over the abiogenic pelagic background sedimentation. These hydrothermal sediments comprise brown to black graphite-rich mudstones and fine laminated shales, which can be intercalated by siliclastic and/or kidney-shaped chert layers as well as by fine layers of organic matter. The main sulfide phases are pyrite and pyrrhotite plus minor amounts of chalcopyrite, sphalerite, arsenopyrite and galena. Pyrite mostly occurs as diagenetic euhedral grains or as framboids, whereas pyrrhotite forms fine granulates or irregular shaped grains to massive grains that infill veins.

Preliminary lithogeochemical results illustrate that relative to upper crust normal shales, the hydrothermal sedimentary rocks have anomalous base and precious metals, volatile metals (e.g., Tl, Sb), high Fe/Al ratios, variable Ce/Ce*, Y/Ho ~27, and have Eu/Eu*≧1, indicative of deposition from reduced, hot hydrothermal fluids with only a minor detrital input. Ongoing research includes detailed mineralogical-petrographical studies of the sulfides, additional whole-rock lithogeochemical analyses, and sulfur isotope geochemistry. The research is aimed at understanding both the role that basin redox conditions has on the genesis of the Lemarchant deposit, discriminating the relative contributions of hydrothermal, detrital or hydrogenous (seawater-derived) materials in the genesis of the shales, distinguishing between hydrothermal, diagenetic and biological sulfur sources in the sediments, and utilizing the latter to create potential exploration vectors at Lemarchant and for other shale-associated VMS systems.

Trace element geochemistry of VMS-deprived and VMS-endowed 2720 Ma greenstone belts in the Wawa Subprovince, Superior Craton

R.W.D. LODGE[1*], H.L. GIBSON[2], AND G.M. STOTTT[3]

[1]Mineral Exploration Research Centre, Laurentian University, Sudbury, Ontario, Canada, rx_lodge@laurentian.ca (*presenting author), HGibson@laurentian.ca

[2]Ontario Geological Survey (ret.), Stott Geoconsulting Ltd., Sudbury, Ontario, Canada, stottgeoconsult@gmail.com

The northern margin of the Wawa subprovince of the Superior craton is marked by four relatively well studied greenstone belts that have vastly different endowments of economic volcanogenic massive sulphide (VMS) mineralization. These coeval greenstone belts (2720 Ma) are inferred to have formed within similar tectonic environments and to have experienced similar styles of volcanism, and therefore would be expected to have the same VMS-potential. Yet, significant exploration over the past century has yet to yield an economic VMS deposit in the Shebandowan and Vermilion greenstone belts (SGB, VGB, respectively). The smaller Winston Lake and Manitouwadge greenstone belts (WGB, MGB respectively) host the Geco (~50 Mt), Willroy (~4.5 Mt) and Winston Lake (~3.1 Mt) VMS deposits. This study aims to determine if the VMS metallogeny of barren versus endowed greenstone belts is related to different geodynamic settings or differences in the petrogenesis of their host volcanic successions.

VMS deposits are products of synvolcanic, high-temperature hydrothermal systems in extensional submarine geodynamic settings. Primitive mantle-normalized trace element contents of basalts have distinctive geochemical signatures depending on the geodynamic setting. Arc basalts have negative Nb, Ta, and Ti anomalies and LREE enrichment, whereas MORB have depleted to flat LREE patterns. Felsic-intermediate rocks commonly associated with VMS mineralization have flat REE patterns or slight LREE enrichment (FII–FIV rhyolites). Regional- and property-scale sampling and mapping in each greenstone belt have been completed to clarify the spatial distribution of these geochemical signatures in order to determine if there are differences in the geodynamic evolution and/or petrogenesis of VMS endowed versus barren 2720 Ma greenstone belts. Initial results suggest the dominance of FI felsic volcanics (Figure 1), arc-like mafic volcanics, and plume-fed ultramafic sequences hindered VMS-development in the SGB.

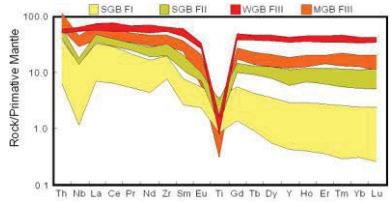

Figure 1: Trace element geochemistry of the Shebandowan (SGB), Winston Lake (WGB), and Manitouwadge greenstone belts (MGB).

Hydrothermal transport and deposition of high field strength elements (HFSE) attracts increasing attention as demand for these strategic metals rises. Data on the stability of aqueous complexes of geochemical twins, such as zirconium (ionic radius 590 pm) and hafnium (580 pm), can provide us with insights into the processes that concentrate these elements in HFSE deposits. Fluoride is an important ligand in such systems, greatly enhancing the solubility of HFSE. Fluorine-rich hydrothermal processes are also known to fractionate geochemical twins (including Zr/Hf) much more strongly than other geological processes.

Here we report experimentally determined Hf fluoride formation constants for 150, 200, and 250°C and saturated water pressure. The data were obtained using the method applied by Migdisov et al. [1] to determine Zr speciation in fluoride-bearing aqueous fluids. The pH and fluoride concentration range considered was 1.3 to 2.5 and 7e-4 to 2e-1, respectively.

Our experiments show that Hf is complexed exclusively as di-fluorohydroxy species under the conditions of our experiments. Zirconium forms either mono- or di-fluorohydroxy complexes under the same conditions, depending on fluoride activity [1]. This shows that Hf has a higher affinity for F than Zr. The di-fluorohydroxy complexes of Hf are more stable than those of Zr.

We conclude that the differential behavior of Zr and Hf in fluoride-bearing aqueous fluids is the reason for the high temperature fractionation of of these metals in hydrothermal HFSE deposits. In combination with other geochemical information, the data presented here allows us to better quantify the behaviour of Zr and Hf during HFSE ore-formation.

Temporal and Spacial Variation of Microbial Community Structures in Oil Sand Tailing Ponds

NADINE LOICK[1]*, ERNEST CHI FRU[2], CHRISTOPHER WEISENER[1]

[1]Great Lakes Environmental Institute for Research, University of Windsor, Windsor, Canada, nloick@uwindsor.ca*
[2]Swedish Museum of Natural History, Department of Palaeozoology, Stockholm, Sweden

Introduction

The process of extracting bitumen from oil sands produces large volumes of tailings that are deposited in large settling basins to become denser mature fine tailings; ultimately aiming at reclamation of the land by establishing viable envionmental systems such as wetlands or lakes.

Microorganisms enhance particulate matter sedimentation rates and the dewatering of tailings materials, releasing water for bitumen extraction. They are critical to biogeochemical elemental cycles and the degradation of toxic hydrocarbon contaminants coupled to greenhouse gas production in oil sands fine fluid tailings and influence remediation and land-reclamation efforts.

Results

Microbial community patterns were analysed using population ecology tools. A bioreactor study showed that after 300 days no significant differences existed between the microbial communities of the bioreactors and the fiel samples. This studdy suggests that bioreactor studies reflect field conditions. It also proposes a whole community succession pattern from bacterial dominance to a new assemblage predominated by archaea [1].

To reinforce these findings, a comparison between different sampling locations within the same tailings ponds was carried out and shows the degree of heterogeneity of the material; comparisons between ponds of different ages give an insight into the temporal changes in the microbial community composition during the settling of the material under field conditions.

Conclusions

These results will have implications for the stepwise development of microbial model systems for predictive management of field scale tailings basins. They will aid in the determination of times and locations within the pond where greenhouse gas (CH_4 and CO_2) production is likely to happen. This will assist in managing the ponds, as well as help remediation and land reclamation efforts.

Introduction

Starting in 2002, field-scale biostimulation experiments have been conducted in a uranium-contaminated, shallow alluvial aquifer located along the Colorado River in western Colorado. In parallel the naturally reduced zones in the aquifer have been examined. These experiments and observations have provided insight into the coupling of microbiological, biogeochemical, and hydrogeological processes controlling mobility of uranium in subsurface environments. Research at the U.S. Department of Energy's Integrated Field Research Challenge site (IFRC) at Rifle, Colorado, USA, initially focused on testing the concept that Fe-reducing bacteria such as *Geobacter sp.* could reduce soluble U(VI) to insoluble U(IV) during electron donor amendment (acetate) and that this could be used as a bioremediation strategy for uranium-contaminated aquifers.

Summary of Results

Initial experiments demonstrated a stimulation of microbial Fe(III) reduction *in situ* that correlated with an increase in Geobacter sp. within the subsurface microbial community and a decrease in soluble U(VI) concentration in the groundwater consistent with laboratory studies and the known physiological trait of *Geobacter sp.* to enzymatically reduce U(VI). After approximately 20-30 days, the dominant microbial process shifted from Fe(III) reduction to sulfate reduction and U(VI) concentrations increased. Subsequent experiments directly linked gene expression for metal reduction pathways in *Geobacter sp.* to decreases in U(VI) concentration. More recently it has been possible to sample and analyze both *in situ* proteomes and metagenomes during biostimulation, leading to a comprehensive understanding of both the metabolic potential of the biostimulated microbial community and its actively expressed metabolism.

Future Directions

Future research at the Rifle IFRC will focus on understanding the plume-scale behavior of uranium the context of the metabolic potential of the subsurface microbial community enabled by metagenomic sequencing. Initial results show assembly of nearly complete genomes for microbes present at ≥0.5% abundance is achievable. Coupled with proteomics, transcriptomics, and selected physiological studies, prediction of microbially-mediated uranium fate and transport should be possible for aquifers under conditions that include natural microbially-mediated reduction of uranium.

Magma chamber processes leading to the January 1835 eruption of Cosigüina volcano, Nicaragua

MARC-ANTOINE LONGPRÉ[1*], JOHN STIX[1], ANGÉLICA MUÑOZ[2], AND EVELING ESPINOZA[2]

[1]McGill University, Montréal, Canada
m-a.longpre@mcgill.ca (* presenting author)
[2]INETER, Managua, Nicaragua

Cosigüina volcano, in northwest Nicaragua, erupted violently in January 1835, producing pumice, scoria, and ash fall deposits, as well as pyroclastic flows for a total volume of ~6 km^3 [1]. Here, we present new geochemical data on bulk-rocks, matrix glasses, melt inclusions and minerals from the 1835 deposits, with the aim of shedding light on the magmatic processes that led to the eruption.

The deposits of the 1835 eruption are chemically zoned; a small volume of dacite pumice was erupted first, followed by silicic andesite scoria and andesite scoria, the latter representing by far the largest magmatic component. The dacite pumice is composed of microlite-free glass (65.6 wt.% SiO_2, 0.9 ± 1.6 (1σ) wt.% H_2O (by difference)), and scarce crystals of plagioclase (An_{50-65}, some with a An_{80} core), clinopyroxene (Mg#=64-68), orthopyroxene (Mg#=57-62), magnetite (14.6 wt.% TiO_2) and apatite that commonly occur as glomerocrysts. Rare melt inclusions are of dacitic composition and contain 4.0 ± 1.7 wt.% H_2O. In comparison, the andesite scoria comprises microlite-rich glass (62.1 wt.% SiO_2, 1.0 ± 0.8 wt.% H_2O), abundant crystals of plagioclase (An_{75-95}) and sparse clinopyroxene (Mg#=64-75), orthopyroxene (Mg#=59-72) and magnetite (8.4 wt.% TiO_2) generally occuring as individual crystals. Abundant melt inclusions trapped in An_{80} plagioclase are of andesitic composition and contain 3.3 ± 1.7 wt.% H_2O. Mineral-melt thermometry and hygrometry [2] suggest magmatic temperatures of 930°C and 1030°C and dissolved water contents of 4.5 wt. % and 3.3 wt. %, in agreement with H_2O-by-difference results, in the dacite and andesite magmas, respectively. Assuming water saturation, this translates into magma storage pressures of ~100-150 MPa. Parallel REE patterns for dacite and andesite show a negative Eu anomaly, particularly pronounced for the former. Yet, andesite bulk-rock Al_2O_3 contents depart from the glass and melt inclusion trend, implying that early extensive fractionation was followed by 15-30 % plagioclase addition in the andesite.

Together these observations suggest that the 1835 eruption was fed by a chemically and thermally zoned magma chamber and that the dacite and andesite magmas are closely related through crystal fractionation. However, the lack of plagioclase of intermediate compositions in the 1835 magmas requires efficient and 'sudden' separation (through e.g., gas-driven filter pressing [3]) of a dacitic melt, from which An_{50-65} plagioclase began crystallising. Accumulation of free gas at the top of the magma chamber may have led to the abrupt collapse of a foam layer, triggering the eruption and rapidly ejecting the dacite. Decompression associated with the eruption onset may have caused microlite growth in the andesite melt prior to its expulsion in the later stages of the eruption.

Bacterial Interactions with radionuclides in Bentonite Samples from Spanish Clays

MARGARITA LOPEZ FERNANDEZ[1*], ALBERTO MORENO GARCIA[1], JAIME LAZUEN ALCON[2], ANDREA GEISSLER[3], MOHAMED L. MERROUN[1]

[1]Department of Microbiology, University of Granada, Spain, margaritalopez@ugr.es (* presenting author), merroun@ugr.es
[2]CIC, University of Granada, Spain, jlazuen@ugr.es
[3]Institute of Ressource Ecology, HZDR, Dresden, Germany, a.geissler@hzdr.de

A reliable performance assessment of radioactive waste repository depends on a better knowledge on the interactions of radionuclides and natural microorganisms of geological formations (salts, granitic rocks and clays) used as host rock candidate for these disposal systems. Microbes are able to interact efficiently with actinides affecting their transport and mobility in the environment [1] .The main goals of the current work are: a) to characterize the bacterial diversity of two bentonite samples (BI and BII), recovered from Spanish clay deposits considered in this study as host rock candidate for geological disposal of radioactive wastes, and b) to investigate how these bacterial community will respond to uranium toxicity.

Results and conclusions

16S rRNA gene sequence analysis was used to explore the bacterial community structure of the two bentonite samples which indicated that the sample BI showed a higher diversity than the sample BII. Bacteroidetes (*Flavisolibacter* spp.), Alfaproteobacteria (*Rhodobacter* spp.), Cyanobacteria (*Phormidium* spp.) for example were identified in the sample BI. In contrast, the sample BII was dominated by Betaproteobacteria (*Ralstonia* spp.). Bacteria belonging to Actinobacteria (*Arthobacter* spp.), Gammaproteobacteria (*Stenotrophomonas* spp.), Firmicutes (*Bacillus* spp.), etc. were isolated by culture dependent methods from both samples and assayed for their tolerance to uranium. *Stenotrophomonas* spp. (strain BII-R6r) presented the highest level of U tolerance, being able to grow up to 8 mM of this radionuclide.

Flow cytometry studies (live/dead staining) indicated that the cellular viability of the U-exposed cells of the strain BII-R6r was not affected by this radionuclide (85% viable cells at 3 mM U) compared to that of *Bacillus simplex* (strain BII-S2) wich was U-sensitive showing 60% viable cells at only 1 mM U. In addition, results on the behaviour of the cells of *Stenotrophomonas* spp. BII-R6r in response to the oxidative stress, in term of membrane potential activation alterations and ROS production, caused by uranium will be discussed. Microscopic analysis indicated that uranium precipitation as uranium phosphate mineral phases (e.g. meta-autunite) was involved in the mechanisms of bacterial tolerance to this radionuclide.

This work was supported by the Grant CGL2009-09760 from the Spanish Ministry of Science and Innovation.

Platinum-group minerals in upper mantle peridotites : Implications for our understanding of whole-rock signatures of HSE.

LORAND, J.P.[1](*), LUGUET, A[2] AND ALARD, O.[3]

[1] LPGN, UMR-CNRS 6112, University of Nantes, Nantes, France,(jean-pierre.lorand@univ-nantes.fr)

[2] Steinmann Institute für Endogene process, Universität Bonn, Germany

[3] Geosciences Montpellier, UMR-CNRS, 5243, University of Montpellier II, Montpellier, France

Platinum-group elements (PGEs) have now been recognized to be highly sensitive geochemical tracers of Earth's mantle. However, compared to lithophile trace elements, PGEs occur as ultra-trace elements which may occasionally be present as major elements in discrete platinum-group minerals (PGMs) in addition to the base-metal sulfides (BMS). PGMs are not expected to be stable in the upper mantle because PGEs are highly soluble (at wt. % levels) in base metal sulfides (BMS), which control the largest part of the PGE budget in the uppermost mantle. However, micrometric PGMs (0.1 μm-3μm) have now been identified in a large panel of mantle-derived rocks (abyssal peridotites, orogenic peridotites, basalt-borne spinel peridotite xenoliths, cratonic peridotites) within both lherzolitic and harzburgitic compositions. These minerals may impact analytical precision (e.g. Os-Ir) and reproducibility of whole-rock analyses by generating nugget effects on some elements (e.g. Pt) and incomplete dissolution of some acid-resistant minerals (Os-Ir).

The PGMs so far recovered from the study of peridotites are invariably associated with BMS phases or derived from a BMS precursor indicating the key role of the BMS in the PGMs genesis. Decreasing temperature, decreasing activity of S or increasing semi-metal concentrations (Te, Bi, As, Sb…) are major factors triggering crystallization of PGMs. Adiabatic partial melting processes generate refractory PGMs (Pt-Ir-(Os) alloys Os-Ir-Ru alloys/ sulfides) by consuming all of the available BMS in the mantle residues. Refractory PGMs are long-lived minerals that may survive recycling and rejuvenation of residual peridotites while preserving Os isotopic signatures of Archean partial melting events. Reactions at decreasing melt–rock ratios (« mantle metasomatism ») as well as magmatic « refertilization » concentrate volatile semi-metals (Te, As, Bi…) which precipitate as high-temperature Pt-Pd-Te-Bi or Pt-As-S microphases intimately associated with Cu-Ni-rich sulfides. Transient fluid - rock interactions, subsolidus cooling, crustal contamination and serpentinization are also PGM-maker (PdSb, PdCuNi, Pt-Bi-Sb phases ; Pt-Fe-Ru alloys; Pd sulfides, native gold….). These non cogenetic HSE-rich minerals have thus important implications for our interpretation of the mantle HSE signatures and their use to constrain planetary processes.

Experimental insights into fluid-rock interactions in granite-hosted and CO_2-saturated geothermal systems

CAROLINE LO RÉ[1], JOHN P. KASZUBA[1, 2*], JOSEPH MOORE[3], AND BRIAN MCPHERSON[3]

[1]University of Wyoming, Department of Geology & Geophysics, Laramie, WY, USA, flore@uwyo.edu

[2]University of Wyoming, School of Energy Resources, Laramie, WY, USA, John.Kaszuba@uwyo.edu (* presenting author)

[3]University of Utah, Energy & Geoscience Institute, Salt Lake City, UT, USA, jmoore@egi.utah.edu, b.j.mcpherson@utah.edu

Hydrothermal experiments and geochemical modeling were conducted at 250°C and 25 to 45 MPa to evaluate geochemical and mineralogical relationships in a granite-hosted geothermal system. Experiments and geochemical models emulate geothermal conditions of typical granitic reservoirs and are based on the Roosevelt Hot Springs thermal area, Utah, USA. Additional experiments and modeling were also conducted to determine how these geothermal systems may respond to CO_2.

Hydrothermal experiments were conducted in rocker bombs and Au-Ti reaction cells (Dickson cells) using established methods. The granite consists of 75% ground (<45 um) and 25% chipped (0.1-0.7 cm) mineral separates, including sub-equal portions of quartz, perthitic K-feldspar (~25% wt% albite and 75% wt% K-feldspar), oligoclase (An_{23}), and 4 wt% Fe-rich biotite. The use of mineral chips allows post-experimental examination of textures, while use of powder enhances reactivity and kinetic rates. The synthetic brine ($I \cong 0.1$) contains ~ 0.1 molal Na and Cl and millimolal quantities of SiO_2, Al, Ca, Mg, K, SO_4, and HCO_3.

Five water+granite+/-epidote experiments reacted for ~28 days (water:rock ≅ 20:1). Two water+granite experiments and one water+granite+epidote experiment were subsequently injected with supercritical CO_2 and reacted for an additional 42 days. Excess CO_2 is injected to produce a separate supercritical fluid phase, ensuring aqueous CO_2 saturation for the duration of each experiment.

Prior to injection of CO_2 into water-granite experiments, relatively constant concentrations of aqueous Cl, Na, SO_4, and ΣCO_2, increasing aqueous SiO_2, K, and Al, and decreasing aqueous Mg are observed. Aqueous Ca concentrations initially increase and then decrease over time. Relatively constant concentrations of aqueous Cl, Na, and K are observed post-injection. Concentrations of aqueous Ca, SO_4, and Al decrease during the first 5 days after injection while concentrations of aqueous Mg and ΣCO_2 increase over the same period of time. Post-injection concentrations of aqueous SiO_2 gradually decrease over time.

Mg-Fe-rich illite and kaolinite precipitated in water+granite experiments whereas illite, kaolinite, and Fe-rich smectite precipitated in water+granite+CO_2 experiments. Decreasing aqueous Mg concentrations during the first 5 days of each experiment are consistent with illite formation. Increasing aqueous Mg concentrations during the first 2 days after injecting CO_2 may signal a shift in stability from illite to smectite. No carbonate minerals were observed as reaction products. These results are relevant to understanding processes in natural and enhanced geothermal systems.

Mass anomalous fractionations of sulfur isotopes in the Talvivaara Ni deposit, Finland - evidence for hydrothermal input

KIRSTI LOUKOLA-RUSKEENIEMI [1]*, SETH A.YOUNG[2], LISA M.PRATT[2], BO JOHANSON[1]

[1]Geological Survey of Finland, Espoo, Finland, kirsti.loukola-ruskeeniemi@gtk.fi (* presenting author)

[2]Indiana University, Department of Geological Sciences, Bloomington, Indiana, USA, seayoung@indiana.edu

Talvivaara black shale-hosted Ni deposit

The Talvivaara deposit contains 1 550 Mt of Ni-Cu-Co-Zn-Mn-U ore and was deposited in a stratified marine basin ca. 2 Ga ago. The deposit is characterized by high C_{org} and S concentrations with median values of 7.6% and 9.0%, respectively, and the occurrence of layers with Mn ≥ 0.8%. Pyrite, pyrrhotite, chalcopyrite, sphalerite, alabandite and pentlandite occur both as fine-grained disseminations and as coarser grains in quartz-sulfide veins.

The median $\delta^{34}S$ values of both pyrite and pyrrhotite are -3‰ in the Ni-rich black shales. In the black shales with Ni < 0.1% the $\delta^{34}S$ values are -4‰ in pyrite and -5‰ in pyrrhotite [1, 2]. Both thermochemical and biogenic sulfate reduction were important for the generation of reduced S as has been reported from the Sullivan Pb-Zn-Ag deposit in Canada [3] where $\delta^{34}S$ patterns resemble those at Talvivaara.

The black shales have undergone medium grade regional metamorphism but spheroidal pyrite with grain size < 0.01 mm and containing up to 0.7% Ni is still preserved in places.

Results

Sequentially extracted S fractions analyzed for 27 Talvivaara samples show mass anomalous $\Delta^{33}S$ values for spheroidal pyrite. For example, in one drill core sample (map sheet 3433, drill core 305, depth 150.89 m in the drill core), the values for spheroidal pyrite range between -2.27‰ to -7.73‰ for $\delta^{34}S$, -0.60 to -4.38‰ for $\delta^{33}S$ and 0.57 to -0.40‰ for $\Delta^{33}S$.

Values for recrystallized pyrite and pyrrhotite in the same sample range from -3.09 to -6.25‰ for $\delta^{34}S$, -1.57 to -3.20‰ for $\delta^{33}S$ and 0.01 to 0.05‰ for $\Delta^{33}S$.

Conclusions

Previous MIF sulfur anomalies have been reported for rocks older than 2.4 Ga. However, anomalous S isotope signatures may also result from reactions between organic matter and S-bearing aqueous solutions under hydrothermal conditions [4] which is the most likely case at Talvivaara. The uniform distribution of Ni in the extensive black shale unit indicates mixing between seawater and Ni-rich fluids.

The Great Artesian Basin (GAB) of Australia is one of the largest groundwater basins in the world and contains the largest storage of potable groundwater in the Australian continent. Because of its vast size and the potential for large regional flow systems to occur, the GAB has been considered an ideal basin to test emerging groundwater dating techniques such as Cl-36 and He-4. However both of these techniques are subjected to large degrees of uncertainty, as they require a detailed understanding of different sources and sinks of these two isotopes. Contrasting this Kr-81 is considered to be an ideal tracer as it contains only one source, the atmosphere with no or at most minimal sub surface production. Our study area is focused on the western margin of the GAB between the Finke River system in the Northern Territory and the iconic Dalhousie springs in South Australia. This represents the direction of groundwater flow from recharge to discharge through the Dalhousie spring complex. For the first time we have provided a comprehensive suite of analyse not only of Cl-36, He-4, C-14, Ar-39, stable isotopes of the water molecule and noble gases but also, Kr-85 and Kr-81. Our preliminary results indicate a spectrum of "tracer groundwater ages" ranging from modern as indicated by C-14 and Ar-39 up to hundreds of thousands of years as indicated by Kr-81, Cl-36 and He-4. We suggest that this groundwater flow transect may represent an ideal type section for understanding different isotope systematic in order to obtain a greater knowledge of regional groundwater flow.

Tracking Proterozoic Biospheric Evolution and Marine Redox Structure using Lipid Biomarkers

GORDON D. LOVE[1*], AMY E. KELLY[1], CHAO LI[1,2], MEGAN ROHRSSEN [1]

[1] Department of Earth Sciences, University of California, Riverside, CA 92521, USA, glove@ucr.edu (*presenting author), Amy.A.Kelly@shell.com, mrohr001@ucr.edu

[2] State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Wuhan 430074, China, chaoli@cug.edu.cn

Molecular geochemical analyses of Proterozoic rocks and oils that have experienced a reasonably mild thermal history generally reveal a wide diversity of hydrocarbon compounds. Robust biomarker information can be recovered from many Proterozoic rocks given due attention to potential contamination and thermal preservation issues, and novel evolutionary insights include the earliest record of ecologically significant Cryogenian-age animal biomass from distinctive C_{30} steranes from demosponges [1].

Despite speculation to the contrary [2], evidence for abundant anoxygenic photosynthetic bacterial primary production in mid-Proterozoic pelagic marine settings is not supported by fossil carotenoid biomarker evidence in most thermally immature sedimentary rocks and oils from China and Australia. Only in certain organic sedimentary facies of the 1.64 Ga Barney Creek Formation deposited in the northern depocenter of the Glyde Sub-basin [3], particularly for intervals influenced by dolomotic turbidite flows [4] bringing photosynthetic benthic mats from the shelf, are aromatic carotenoid markers for Chlorobiaceae and Chromatiaceae (green and purple S bacteria) detected in abundance. The biomarker assemblages associated with unusual organofacies reported from the Barney Creek Fm. in the Glyde Sub-basin has seemingly given a misleading picture of mid-Proterozoic ocean redox structure and the general mode of pelagic bacterial production, although poorly constrained groups of bacteria appear to be the dominant source organisms.

Nature Abhors a Vacuum: Geothermal gases at Yellowstone

LOWENSTERN J.B.[1*], EVANS, W.C.[1], BERGFELD, D.B.[1]

[1]U.S. Geological Survey, Menlo Park, CA, USA, jlwnstrn@usgs.gov (* presenting author)

Though off limits to geothermal development, Yellowstone remains the world's most prominent single source of geothermal heat, with many high-temperature aquifers underlying thousands of square km of alpine terrain. Our studies of gas and water compositions provide many lessons for the assessment of geothermal resources and the source of heat, solutes, and gases in long-lived hydrothermal systems in the shallow continental crust. We highlight three below.

Don't mix apples, oranges, and helium: Components in geothermal fluids originate from separate sources. Based on stable isotopes of H_2O, researchers recognized early on that >90% of the thermal water in Yellowstone comes from meteoric recharge. Yet most thermal waters have $^3He/^4He \geq 7R_A$, implying ~50% mantle He. Methane, a trace gas in meteoric waters and most magmatic gases is produced by thermogenesis of crustal sediments, and emerges in greatest abundance in the east side of the park. Additional CH_4 is generated through in situ equilibration of C-H-O gases. Each gas or isotope provides a different perspective on the source of heat, gas and water to a geothermal fluid.

All good things come to those who wait: An important insight from recent studies of gas composition and CO_2 flux at Yellowstone is that radiogenic He is emitted in quantities far too great to be accounted for by steady state ingrowth through radioactive decay. At the Heart Lake Geyser Basin, we measured thermal water discharge and the diffuse and fumarolic CO_2 flux. He isotopic ratios demand that 90-95% of the He is generated in the crust, yet discharge of 21 mmol L^{-1} of dissolved CO_2, and the CO_2/He ratio of the gases requires that 4.6 x 10^{-4} mol s^{-1} of He are released from this small thermal area (~1% of the thermal water discharge at Yellowstone). A He flux of this magnitude would require steady-state ingrowth of U-rich crust (7 ppm U and Th/U = 3.5) equivalent to the entire area of Yellowstone National Park down to 8 km depth. This astonishing calculation implies: i) igneous heat liberates ^4He produced by millions (and in some cases billions) of years of radioactive decay and He storage, and ii) the fluid flow and crustal degassing is ultimately short-lived on a geologic timescale, generating remarkable bursts of crustal gas.

A leopard cannot change its spots: The $CO_2/^3He$ ratio of Yellowstone gases is consistent throughout the park, with values between 10^9 and 10^{10} and shows no correlation with either gas chemistry or isotopes. The constant ratio of these gases and the similarity to mantle values demonstrates that the crustal component of CO_2 is < 50% of total CO_2 and that crustal and mantle CO_2 are well-mixed at depth. Moreover, thermodynamic models for CO_2 fugacities in calcite-bearing geothermal systems predict 2-3 orders of magnitude variation in CO_2 pressure over the 100-300°C range of geothermal temperatures. Clearly, deep magmatic and metamorphic degassing flood the geothermal system with CO_2. Low temperature solution-mineral equilibria provide little control on the $CO_2/^3He$ ratio of emitted gases.

Formation mechanisms of carbonate concretions of the Monterey Formation: Analyses of clumped isotopes, iron, sulfur and carbon

SEAN J. LOYD[1]*, WILLIAM M. BERELSON[2], TIMOTHY W. LYONS[3], DOUGLAS E. HAMMOND[2], ARADHNA K. TRIPATI[1], JOHN M. EILER[4], AND FRANK A. CORSETTI[2]

[1]Univ. Calif., Los Angeles, Los Angeles, USA, seanloyd@ess.ucla.edu (* presenting author)
[2]Univ. So. Calif., Los Angeles, USA
[3]Univ. Calif., Riverside, Riverside, USA
[4]Calif. Inst. Tech., Pasadena, USA

Carbonate concretions can form as a result of organic matter degradation within sediments. However, the ability to determine specific processes and formation temperatures of particular concretions has remained elusive. Here, we employ concentrations of carbonate-associated sulfate (CAS), $\delta^{34}S_{CAS}$ and clumped isotopes (along with more traditional approaches) to characterize the nature of concretion authigenesis within the Miocene Monterey Formation.

Integrated analyses reveal that at least three specific diagenetic reaction pathways can be tied to concretion formation. One calcitic concretion from the Phosphatic Shale Member at Naples Beach yields $\delta^{34}S_{CAS}$ values near Miocene seawater sulfate (~ +22‰ VCDT), abundant CAS (ca. 1000 ppm), depleted $\delta^{13}C_{carb}$ (~ –11‰ VPDB), very low concentrations of Fe (ca. 700 ppm) and Mn (ca. 15 ppm) and clumped isotope temperatures of ~18°C—characteristics most consistent with shallow formation in association with microbially mediated, organic matter degradation by nitrate, iron-oxides and/or minor sulfate reduction. Cemented concretionary layers of the Phosphatic Shale Member at Shell Beach display elevated $\delta^{34}S_{CAS}$ (up to ~ +37‰), CAS concentrations of ~600 ppm, mildly depleted $\delta^{13}C_{carb}$ (~ –6‰), moderate amounts of Mn (ca. 250 ppm), relatively low Fe (ca. 1,700 ppm) and clumped isotope temperatures of ~27-35°C, indicative of somewhat deeper formation in sediments dominated by sulfate reduction. Finally, concretions within a siliceous host at Montaña de Oro and Naples Beach show minimal CAS concentrations, positive $\delta^{13}C$ values (up to +16‰), the highest concentrations of Fe (ca. 11,300 ppm) and Mn (ca. 440 ppm) and clumped isotope temperatures of ~28-35°C, consistent with formation in sediments experiencing methanogenesis in a highly reducing environment. This study highlights the promise in combining CAS and clumped isotope analyses with more traditional techniques to more precisely characterize subsurface biospheric processes and particularly how they relate to Fe-S-C cycling in ancient sediments.

Two contrasting Sn- and W-bearing granites in the Nanling Range, South China: evidence from Hf isotopes

JIANJUN LU, RUCHENG WANG, DONGSHENG MA, WEIFENG CHEN, LEI XIE AND RONGQING ZHANG

State Key Laboratory for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Nanjing, 210093, China (lujj@nju.edu.cn)

The Nanling Range where many granite-related lager-superlarge rare-element deposits occur, is the most important area in terms of W-Sn deposits in the world. The Middle-Late Jurassic period (170-140Ma) is the most important metallogenic time for W and Sn in this area. The most granites associated with W-Sn deposits formed during this time can be divided into two groups: the W- and Sn-bearing granites. These two kinds of granites have different petrochemical and trace element geochemical features [1]. The W-bearing granites comprising biotite granites, two-mica granites and muscovite granites are peraluminous and belong to S-type, whereas the Sn-bearing granites consisting of hornblende-bearing biotite granites and biotite granites and containing little muscovite are metaluminous and belong to A-type [2].

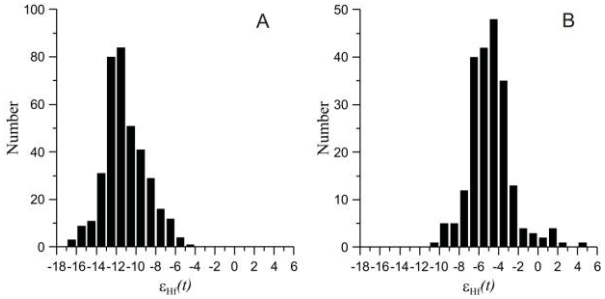

Figure 1: Histograms of zircon Hf isotopic compositions for the W-bearing (A) and Sn-bearing (B) granites

We have investigated the Hf isotope compositions of zircons in both the W- and Sn-bearing granites. The εHf(t) values of the zircons in the W-bearing granites vary from -8 to -14, with a peak value of -12; whereas the εHf(t) values of the zircons in the Sn-bearing granites range from -2 to -8, with a peak value of -5. The hafnium isotope compositions for these two kinds of ore-bearing granites in the Nanling Range indicate that the W-bearing granites were dominantly derived from the continental crustal materials; whereas the Sn-bearing granites were mainly generated by the crust-mantle mixed sources.

^{81}Kr-dating is now available

Z.-T. LU,[1,2*] W. JIANG,[1] A. SHARMA,[1,2] K. BAILEY,[1] P. MUELLER,[1] T.P. O'CONNOR,[1] S.-M. HU,[3] R. PURTSCHERT,[4] N.C. STURCHIO[5]

[3]University of Science and Technology of China, Hefei, China
[4]University of Bern, Bern, Switzerland
[5]University of Illinois at Chicago, Chicago, USA

Due to its simple production and transport processes in the terrestrial environment, the long-lived noble-gas isotope ^{81}Kr is the ideal tracer for old water and ice in the age range of 10^5-10^6 years, a range beyond the reach of ^{14}C. ^{81}Kr-dating, a concept pursued over the past four decades by numerous laboratories employing a variety of techniques, is now available for the first time to the earth science community at large. This is made possible by the development of ATTA-3, an efficient and selective atom counter based on the Atom Trap Trace Analysis method and capable of measuring both ^{81}Kr/Kr and ^{85}Kr/Kr ratios of environmental samples in the range of 10^{-14}-10^{-10}. The instrument was calibrated with 12 samples whose ^{85}Kr/Kr ratios were independently measured using Low Level Decay Counting, including six samples that were measured in a blind arrangement. Compared to the previously reported ATTA-2 instrument, the counting rates of ATTA-3 are higher by two orders of magnitude and the required sample size lower by one order of magnitude. For ^{81}Kr-dating in the age range of 200 – 1,500 kyr, the required sample size is 5 – 10 micro-L STP of krypton gas, which can be extracted from approximately 100 – 200 kg of water or 40 – 80 kg of ice. Moreover, a laser-induced quenching scheme was developed to enable measurements of both the rare ^{81,85}Kr and the abundant ^{83}Kr, whose isotopic abundances differ by 11 orders of magnitude. This scheme allows ATTA-3 to directly determine ^{81}Kr/Kr and ^{85}Kr/Kr ratios without other supplemental measurements. Combining the significant reduction in sample size with several advances in the measurement procedure, ATTA-3 represents the state-of-the-art instrument for routine analysis of these rare noble gas tracers for a wide range of earth science applications.

More information regarding ATTA-3 is posted at http://www.phy.anl.gov/mep/atta/. This work is supported by the U.S. DOE, Office of Nuclear Physics, under contract DE-AC02-06CH11357; and by NSF, Division of Earth Sciences, under Award No. EAR-0651161.

Climate controls the fluctuations of fish mercury levels in Québec lakes

MARC LUCOTTE[1]*, SERGE PAQUET[1], AND MATTHIEU MOINGT[1]

[1]GEOTOP, UQAM, Montréal, Canada
lucotte.marc_michel@uqam.ca
paquet.serge@uqam.ca, matthieumoingt@yahoo.fr

Data mining

The compilation of data bases of Québec Ministry of Environment, Hydro-Québec, COMERN strategic network as well as Environment Canada's CARA research program allowed us to reconstruct the history of total mercury levels (Hg) over the 1979-2011 period in two predatory fish species most consumed in mid-northern Québec (Canada): northern pike (*Esox lucius*) and walleye (*Sander vitreus*). We present results for a series of 82 large lakes frequently fished by sport fishers. In order to compare different years and lakes among each other, we calculated fish flesh Hg levels at standardized lengths using von Bertalanffy growth models. We also used fish growth rates data whenever available. We run our statistical analysis considering 20 GIS variables (lake order, watershed slopes, drainage density, mining sites, vegetation cover, geological substratum) and 15 climatic variables (monthly precipitations, temperatures, and sulfate deposition).

Trends in mercury levels in walleye and pike over the last three decades

Climatic factors such as annual mean temperatures and winter precipitations could explain 60% of the variations of walleye Hg levels. In turn, these climatic variables appeared to strongly control walleye growth rates. In addition, logging activities equivalent to at least 20% of the watershed surface every 10 years could explain 15% of the variations of waleye Hg levels. The influence of mining activities in lakes watershed appeared to be masked by the dominant climatic conditions and eventual logging activities. In fact, walleyes caught in lakes heavily impacted by mining activities such as Chibougamau and Matagami lakes presented some of the lowest Hg levels at standardized length. 35% of the variations of pike Hg levels could be explained by the nature of the watershed, rather steep slopes having a positive influence on the bioaccumulation of the heavy metal in that fish species. Mining activities in the watershed also explained 15% of the variations of pike Hg levels. Watershed characteristics (10 to 20% slopes and higher fraction of the watershed covered by mixed forest) was in turn linked to fish growth rates, which by itself explained 45% of the variations of pike Hg levels.

Climate conditions control fish mercury levels

Hg levels in walleyes and to some extent in pikes in large lakes of mid-northern Québec have been significantly increasing from the 1980's to the 1990's due to colder and dryer conditions prevailing at that time and sharply decreasing since then mainly because of average temperatures rises, in turn stimulating fish growth rates. The effect of measured decreased acid rain deposition could not be detected with our data set. In the absence of monitoring stations of wet and dry atmospheric Hg deposition in the region, the effects of decreased Hg atmospheric emissions at the continental scale could not be evidenced either.

The geochemistry of aqueous fluids and hydrous melts in subduction zones

STEFANIE LUGINBUEHL[1*], PETER ULMER[1] AND THOMAS PETTKE[2]

[1]Dept. Earth Sciences, ETHZ, 8092 Zurich, Switzerland, (*correspondence: stefanie.luginbuehl@erdw.ethz.ch)
[2]University of Bern, Institute of Geological Sciences, 3012 Bern, Switzerland

Aqueous fluids and silicate melts released from dehydrating slabs play a crucial role in mass transfer in subduction zones. Therefore, it is important to quantify the nature and composition of these mobile phases in order to understand elemental transport from the slab to the mantle wedge and the consequences for arc magmatism. We performed experiments at 2-3 GPa and temperatures between 700 and 1100°C on a K-free, H_2O-saturated and trace element-doped basaltic composition representing altered, oceanic lithosphere. This pressure-temperature range corresponds to a depth in subduction zones where hydrous phases, most prominently epidote group minerals and amphibole, are stable and constitute hosts for a number of trace elements like REE, HFSE, some LILE as well as U and Th.

Due to experimental and analytical difficulties in measuring the composition of fluids and melts directly and quantitatively, a "freezing stage" [1] is employed to determine compositions of frozen liquids and fluids by Laser ablation-ICP-MS. By applying this method, the loss of any potential precipitates and unquenchable solutes upon preparation for subsequent analyses is prevented. The employment of diamond traps in the experiments allows mobile phases to be collected in the trap and being analysed by this procedure. Coexisting eclogitic residual mineral assemblages are likewise measured by EMPA and LA-ICP-MS in order to obtain partition coefficients between fluids/melts and solid residual phases.

Preliminary results show hydrous phase assemblages with amphibole and epidote stable at lower temperatures (700 and 800°C), that are replaced by dominantly anhydrous phase assemblages with clinopyroxene and garnet coexisting with trondhjemitic melt at higher temperatures. Rutile is present as accessory mineral at all temperatures. H_2O contents of the liquid phase indicate an aqueous fluid being stable at 700°C and hydrous melts coexisting with eclogite above 800°C. Partition coefficients between hydrous mobile phases and the solid residue indicate garnet controlling Heavy REE at higher temperatures while Light REE, as well as Th and Sr, show strong compatibilities and suggest epidote group minerals controlling these elements below 800°C.

Recycled material in MORB sources: Os isotopes and HSE in the fossil Galapagos Rise lavas

AMBRE LUGUET[1*], KARSTEN HAASE[2] AND MARCEL REGELOUS[2]

[1]Steinmann Institut, Universität Bonn, Germany (* presenting author), (ambre.luguet@uni-bonn.de)
[2]Geozentrum Nord-Bayern, Universität Erlangen-Nürnberg, Germany (karsten.haase@geol.uni-erlangen.de, regelous@geol.uni-erlangen.de)

There is now growing evidence from trace elements and lithophile-element based isotopes (e.g. Sr, Nd, Pb) that enriched lithologies (e.g. pyroxenites) are significant contributors to the heterogeneous signatures of the Earth's mantle and a major source component in enriched basaltic melts such as the E-MORBs or OIB [1, 2].

Owing to the opposite geochemical behaviour of Re and Os during partial melting, the Re-Os isotopic system may be most sensitive to trace recycling and thus provide further insights into the mantle heterogeneity and its origin. We have analysed N-MORBs and E-MORBs from the fossil Galapagos Rise for $^{187}Os/^{188}Os$ ratios and highly siderophile elements (HSE). The distinct signatures in trace elements and Sr-Nd-Pb isotopic systems between these N- and E-MORBs have been attributed to variable contributions of a pyroxenitic source component due to variable mantle melting degrees and the ceasing of the spreading [3].

Both E- and N-MORBs show the overall positive-sloped HSE patterns, typical of partial melts. However, the E-MORBs are generally richer in Os, Ir, Ru Pt and Pd but contain less Re than the N-MORBs. E-MORBS contain 3.5 to 38 ppt Os and 117-230 ppt Re (Re/Os=6-33) while the N-MORBs have <1-4.5 ppt Os and 230-1190 ppt Re (Re/Os=115-690). N-MORBs have slightly radiogenic to radiogenic initial $^{187}Os/^{188}Os$ ratios (0.19-0.74) while the E-MORBs have extremely radiogenic initial $^{187}Os/^{188}Os$ ratios (0.90-0.99). Strikingly, the Galapagos Rise MORBs define a positive trend between Os concentrations and initial $^{187}Os/^{188}Os$ ratios, opposite to what is usually observed in OIB [4]. This trend suggests that the extremely radiogenic signatures of the E-MORBs may be a primary feature revealing a MORB source reservoir with a long-term Re-enrichment (i.e. high Re/Os).

Whole-rock pyroxenites and eclogites as well as their sulfides and platinum group minerals are likely candidates as source materials since they can develop similarly radiogenic signatures especially if residing in the mantle for a few billion years [5].

Permeability change from CO_2 injection: Experimental considerations

ANDREW J. LUHMANN[1*], BENJAMIN M. TUTOLO[1], XIANG-ZHAO KONG[1], KANG DING[1], MARTIN O. SAAR[1], WILLIAM E. SEYFRIED, JR.[1]

[1]University of Minnesota, Department of Earth Sciences, Minneapolis, USA, luhm0031@umn.edu (*presenting author)

Abstract

Geologic carbon sequestration experiments were conducted using a hydrothermal flow system. The flow system design enables a continuous record of permeability and periodic fluid chemistry sampling during experiments at elevated temperatures and pressures. Initial experiments were conducted with deionized water saturated with CO_2 at room temperature and arkose sediment from the Eau Claire Formation. Outlet pore pressure was 11MPa and confinement pressure was 20MPa throughout the experiments, and temperature of the core was incrementally increased from room temperature to 150ºC. Some temperature step increases were followed by relatively quick changes in permeability, such that measured permeability decreased by 3-4 orders of magnitude during a given experiment. Scanning electron microscopy (SEM) revealed clay mineral formation on potassium feldspar grains (Fig. 1). While some geochemical changes did occur, the relative role of different potential permeability-reducing mechanisms is not constrained by these initial experiments. Potential mechanisms include geochemical changes as well as physical redistribution of grains and CO_2 exsolution. Ongoing experiments are being conducted to isolate the roles of these different mechanisms. Experiments with pure St. Peter quartz sand and fluid supersaturated with CO_2 isolate the effect of CO_2 exsolution, and experiments with solid arkose cores and fluid undersaturated with CO_2 constrain geochemical controls on permeability changes.

Chemical speciation of sediment phosphorus and iron suggesting burial of iron-bound phosphorus in the northern Baltic Sea

KAARINA LUKKARI[1*], SANNA KUJANSUU[2], AND HANNA KAASALAINEN[3]

[1]Marine Research Centre/Finnish Environment Institute, Helsinki, Finland, kaarina.lukkari@ymparisto.fi *

[2]University of Helsinki, Finland, sanna.kujansuu@helsinki.fi

[3]University of Iceland, Reykjavik, Iceland, hannakaa@hi.is

Introduction

Biogeochemistry of phosphorus (P) is of special interest in the eutrophied Baltic Sea. Large areas of the sea-floor, especially in the central basin and in the Gulf of Finland, suffer from hypoxia, which affects P cycling and its burial [1]. Formation of authigenic carbonate fluorapatite, which is an important sink for reactive P in many marine sediments [2], is not significant in the Baltic. Instead, P is buried mostly as organic P [3]. However, in some estuary sediments, P is buried also in iron (Fe) bound form [4].

The Gulf of Bothnia is separated from the main basin by a sill and it has better oxygen conditions than the Baltic Proper. The Gulf receives high riverine input of organic and inorganic material. In order to assess whether part of P may become buried in the Fe-bound form in this Fe-rich basin, we collected samples at two oxic sites in the Gulf of Bothnia and, for comparison, from one anoxic site in the northern Baltic Proper. We made sequential extractions to assess the different forms of sediment P and Fe [5,6] and analysed nutrients and metals from the pore waters and the solid phases.

Results and Conclusions

P and Fe species in the two oxic sediments in the Gulf of Bothnia differed from those in the anoxic sediment in the Baltic Proper. At the anoxic site, sediment P was dominated by organic and detrital apatite-P and it was poor in P bound to hydrated oxides of Fe. This suggests that this redox-dependent form of P was lost during anoxia. Accordingly, reducible Fe oxides were relatively low, and Fe-speciation suggested that Fe was associated with sulphide, carbonate, and silicate phases. This was in agreement with the low dissolved Fe concentrations and the presence of hydrogen sulphide in the pore water. At certain sediment depths in the oxic Gulf of Bothnia, Fe-bound P formed more than 50% of total P concentration. Fe-speciation showed high concentrations of easily reducible and reducible Fe oxides at these same sample depths. Pore water data indicated reduction of Fe oxides and consequent release of dissolved Fe to the pore water below the 5 cm depth at both sites. However, relatively high concentrations of Fe-bound P was found down to 15-20 cm depth suggesting that part of it can be buried. Presence of benthic fauna may partly explain this finding.

Deep Pacific ventilation ages during the last deglaciation: Evaluating the influence of diffusive mixing and source region reservoir age

DAVID C. LUND[1*]

[1]University of Michigan, Earth and Environmental Sciences, Ann Arbor, MI, USA, dclund@umich.edu (*presenting author)

The rise in atmospheric carbon dioxide during the last deglaciation may have been driven by the release of carbon sequestered in the deep ocean. If this was the case, it would imply that deep Pacific ventilation ages should have A) been greater than today during the LGM and B) decreased during the deglaciation. Yet recent results based on the projection age method suggest Pacific ventilation ages during the LGM were similar to today and increased during the deglaciation, opposite the expected pattern [1]. Because the projection age method does not account for tracer diffusion [2] it can potentially yield spurious results and therefore requires validation with alternative techniques.

Here we determine ventilation ages using the transit-time distribution (TTD) method that explicitly accounts for diffusive mixing in the ocean interior [3]. To estimate TTD ages, we assumed an initial TTD width of 600 years, an equilibration-time distribution (ETD) mean of 900 years, and an ETD width of 1600 years. The ETD mean is equivalent to the average surface water reservoir age for the deep water formation region in the Southern Ocean [3]. We used five separate Monte Carlo chains with prior mean TTD values of 1000, 1500, 2000, 2500, and 3000 years. In each case, the chains were run 2000 times to ensure they had converged on a common ventilation age.

Both the TTD and projection age methods imply the ventilation age of the deep Pacific increased by ~1000 years during Heinrich Stadial 1 (H1) and ~500 years during the Younger Dryas (YD). Thus, explicitly accounting for mixing has little impact on the key features of the deep Pacific ventilation history. The similar results are due in part to the projection age error analysis in [1] that fully accounts for the uncertainty in calendar ages and benthic $\Delta^{14}C$ estimates. The resulting projection age distributions are similar to the transit time distributions produced by diffusive mixing in the TTD method.

Our ventilation age results imply that either: 1) the ventilation rate of the deep Pacific decreased during the deglaciation, 2) the surface water reservoir age in the Southern Ocean increased, or 3) there was an influx of ^{14}C-depleted carbon from another source into the deep Pacific. The first scenario would likely increase the residence time of deep water in the Pacific basin and promote oceanic sequestration of respired carbon. Although we cannot rule out this possibility, it seems unlikely given that atmospheric CO_2 increased during both H1 and the YD [4]. Alternatively, an increase in surface water reservoir age in the deep water formation region may have driven the ventilation age signal, but the timing of the required increase is inconsistent with upwelling proxies from the Southern Ocean [5]. Results from a simple geochemical box also show that a 2x increase in Southern Ocean mixing yields negligible changes in deep Pacific $\Delta^{14}C$. Turning off North Atlantic Deep Water formation reduces the quantity of ^{14}C-enriched carbon entering the deep Atlantic but increases the flux of atmospheric ^{14}C into the surface ocean in general, resulting in little net change in Pacific $\Delta^{14}C$. The lack of an obvious oceanographic mechanism implies that input of old carbon from another reservoir may have responsible for the deglacial ventilation age anomalies in the deep Pacific.

Non-traditional isotope ratios in the Sonju Lake layered mafic intrusion: insight into magma differentiation

CRAIG C. LUNDSTROM

[1]Dept. of Geology, University of Illinois at Urbana–Champaign, Urbana, IL USA (lundstro@uiuc.edu)

The Sonju Lake Intrusion (SLI) is a 1200 m thick layered mafic intrusion that directly underlies the equal volume Finland Granite (FG). These intrusions, part of the Proterozoic Keweenaw rift, provide a puzzle to standard models of igneous petrogenesis: examination of mineral modes, mineral compositions and even incompatible trace element ratios grade systematically between the two bodies as if the two intrusions were genetically related while U-Pb ages overlap. Yet, simple volume relationships argue against any fractional crystallization-like process linking the intrusions.

Despite expectations of minimal fractionation in igneous rocks, non-traditional isotope ratios show signficant variations with differentiation index in many igneous suites. Thus, examination of non-traditional systems may provide insight into the differentiation process and the SLI-FG genetic relationship. The sample set analyzed here provides a complete top to bottom transect; 10 samples come from the bottom of the SLI (the SNA drill core reaches the bottom contact); 8 come from the AC-1 drill core through the Finland Granite (these show the granite to be heterogeneous, possibly reflecting sill accumulation); another 20 field-collected samples span the SLI and SLI-FG contact zone. Results of MC-ICPMS analysis show clear distinction in $^{87}Sr/^{86}Sr$ testifying to the FG and SLI coming from different sources. $\delta^{56}Fe$ changes with stratigraphic height. The basal SNA drill core samples average -0.01 but have values as low as -0.2. The middle SLI samples average around the mean mafic earth but show systematic oscillations. The FG samples vary in $\delta^{56}Fe$ with heaviest values (0.35) in the most silicic samples.

The correlation of non-traditional isotope ratios with differentiation could reflect: 1) effects of fractional crystallization; 2) effects of fluid loss; 3) crustal contamination processes; 4) a temperature gradient effect. With regard to #1, the peak in Fe-Ti oxides in the SLI shows no relationship to the variations in $\delta^{56}Fe$; as magnetite tends to enrich in heavy Fe isotopes, the lack of correlation does not support control by FC. Although heavy $\delta^{56}Fe$ occurs in silicic FG samples (which have more radiogenic $^{87}Sr/^{86}Sr$), the relationship between Sr and Fe isotopes within each intrusion argues against crustal contamination (#2). Loss of a fluid (#3) is more difficult to assess but appears inconsistent because FG samples which are most fluid rich have the highest $\delta^{56}Fe$. A model of thermal migration zone refining shows that SLI modes and compositional trends are reproduced by a top down sill injection process; differentiation of a uniform composition basalt occurs by temperature gradient based diffusion-reaction above the sill [2]. The $\delta^{56}Fe$ pattern observed is generally consistent with the "S" shaped pattern with depth predicted by #4. If so, the FG could reflect a ripening effect of a basaltic sill system (the SLI) cooking an already existing rhyolite flow or dome into the Finland Granophyre.

The origin of Earth's water: Local or remote source?

JONATHAN I. LUNINE*

[1]Department of Astronomy, Cornell University, Ithaca NY, USA. jlunine@astro.cornell.edu (*)

Two Planets are Better than One

The classical idea that comets supplied the Earth's oceans [1] ran into trouble when dynamical models showed that no more than 10% of Earth's crustal water could have come from comets [2]. Since the final stage of the assembly of the Earth almost certainly involved collisions among lunar- to Mars-sized embryos, it is reasonable to imagine [2] that embryos from what is now the asteroid belt provided most of Earth's water. Our scenario works from a dynamical point of view, but probably adds too much carbonaceous chondritic material to Earth to satisfy geochemical constraints [3]. An alternative is that water was adsorbed or chemisorbed into grains locally where the Earth formed, a view championed by Mike Drake [4].

A potential test of local versus remote sources of Earth's water comes from examining Mars. Because of its small size Mars could not have gained water through the addition of large embryos—it is one of them—and so under the remote source hypothesis, a much larger fraction of Martian water must be cometary than is the case for the Earth [5]. *If* the cometary D/H is significantly higher than Earth's (SMOW) and that of Martian water, the local-source hypothesis is supported. Meteoritic evidence [6] suggests a slightly elevated D/H for early Martian water relative to SMOW, but D/H in comets varies from 1-2 times SMOW [7], so the jury is still out.

The Grand Tack Maneuver Outflanks the Geochemists

Walsh et al [8] showed that if Jupiter formed before Saturn, its interaction with the disk moved it inward to as close as 1.5 AU; the subsequent formation and entry into resonance of Saturn cause both planets to then move outward. This "Grand Tack" introduced outer solar system planetesimals into the inner solar system with a high collision probability, from which the Earth could have acquired much of its water [9] without excessive accretion of carbonaceous chondritic material. Of course, the composition of these colder bodies is not known, but being plausibly more water-rich than any known chondrite, their geochemical signature on the Earth may have been muted relative to those in our "classic" scenario.

At Odds with my Boss on Science, but Collegially So

It is said that one should never lend money to a close friend nor get into a scientific disagreement with one's Department Head. I've only done the latter. Mike Drake was my senior colleague at Arizona for 27 years and my Department Head for 18 of those. Although we disagreed on how the Earth acquired its water, it never affected our personal or professional relationship. No Department Head could have been more supportive of my professional development than Mike was. He was truly a statesman of science.

Sr-Nd isotope fractionation against water depth: a case study of Datong gauge station of Yangtze River

CHAO LUO [1*], HONGBO ZHENG [1] WEIHUA WU [1] AND PING WANG [1]

[1] Institute of Surficial Geochemistry, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China. chaoluo.niki@gmail.com (* presenting author)

This study reports Sr-Nd isotopic compositions as well as grain size distribution of suspended sediment collected from different water depths at Datong gauge station of Yangtze River during the raining season of year 2010, in order to investigate the influence of hydrological sorting during transportation on Sr-Nd. Samples were collected biweekly from surface, middle and bottome of river depth during June 12th, 2010 to Augest 29th , 2010.

Our results show that, $^{87}Sr/^{86}Sr$ decreases from surface to bottom, ranging from 0.730332 to 0.720857. $\varepsilon_{Nd}(0)$ ranges from -14.75 to -10.09, with surface sediments having the most negative values. In Yangtze River, $\varepsilon_{Nd}(0)$ decrease from the upper reaches to the lower reaches while $^{87}Sr/^{86}Sr$ increased. [1]

Hence, Sr-Nd isotopic compositions of suspended sediments in large rivers are heterogeneous from surface to bottom. In our findings, the isotope composition of suspended sediment collected from the middle of river channel can best represent the mean isotopic composition of suspended sediment transported by river. Stratification of Sr-Nd isotope may be caused by varied contributions of sources to different depths. At least in the Yangtze River, contribution from the upper reaches is larger in the bottom sediment than in the surface sediment.

Although Sr-Nd isotope is a well acknowledged tool in provenance study, our current results indicate that it is necessary to take the grain size and sampling location into consideration.

EVALUATION OF UNCERTAINTY BUDGETS OF Pb AND U DETERMINATIONS IN GLASSES AND ZIRCON AT HIGH SPATIAL RESOLUTION

Yan Luo Chris McFarlane

Department of Earth Sciences, The University of New Brunswick, Box 4400, 2 Bailey Drive, Fredericton, NB, Canada, E3B 5A3
yanluo@unb.ca*; crmm@unb.ca

Laser ablation inductively coupled plasma-mass spectrometry (LA-ICP-MS) has been widely used for element and isotope analyses in geological study. Recent research has highlighted that matrix induced laser fractionations between commonly used external reference materials (NIST61x SRMs), natural silicate reference materials (USGS glasses) and zircon are significant at high spatial resolution.[1] Question raised here is if such fractionation effect is the significant uncertainty source to combined uncertainty for the whole trace element analytical procedure. Luo et al (2007)[2] has addressed the uncertainty budget of Co, La and Th trace analysis using LA-ICP-MS. The results indicated that Poisson counting statistics prevailed for the uncertainty budget when the signal was relatively low. However, elements which have significant fractionation effect - such as Pb and U - at higher spatial resolution have not been addressed. Therefore, the objective of this study is to evaluate the uncertainty budget of Pb and U determination and assess the effect of elemental fractionation to their combined uncertainties. Experiment was conducted at 193nm excimer LA-ICP-MS lab at Department of Earth Science, University of New Brunswick. Spot sizes from 45 to 13 micron were chosen for evaluation. Calibration was performed using NIST610 with internal standardization using Ca or Si. NIST 612, NIST 614, USGS glasses and Zircon 91500 were treated as unknowns. Elemental fractionation and the matrix effect arising from 193 nm excimer laser ablation ICP-MS were evaluated in detail in this uncertainty budget study.

The influence of deep water circulation on the distribution of ^{231}Pa and ^{230}Th in the water column and sediments of the Pacific Ocean.

YIMING LUO*, ROGER FRANCOIS AND SUSAN E. ALLEN

Department of Earth and Ocean Sciences, University of British Columbia, 6339 Stores Road, Vancouver, BC, Canada V6T1Z4

SESSION 12b:
"Pa and Th distributions in the ocean: controlling mechanisms"

The Atlantic Meridional Overturning Circulation (AMOC) is increasingly recognized as paramount to controlling the broad distribution pattern of sediment ^{231}Pa/^{230}Th in the Atlantic Ocean [1,2]. In contrast, for the Pacific, "boundary scavenging", i.e. the enhanced removal of ^{231}Pa in high particle flux, opal dominated regions, is generally considered as the dominant factor [3,4,5].

We have revisited this apparent dichotomy by developing a two-dimentional Pacific scavenging model to investigate the possible influence of the Pacific Meridional Overturning Circulation (PMOC) on the distribution of sediment ^{231}Pa/^{230}Th. The circulation strength and geometry in the model are based on published field observations [6] and the scavenging parameters are chosen to reproduce the broad features of dissolved ^{231}Pa and ^{230}Th profiles measured in the Pacific Ocean. Boundary scavenging is taken into account by adding a removal term derived from a two-box model following [7]. The sediment ^{231}Pa/^{230}Th generated in the model between 30°N and 30°S is then compared to the existing database.

The results show that both boundary scavenging and overturning circulation play an equally important role in determining the distribution of ^{231}Pa/^{230}Th in Pacific sediments. The former by increasing ^{231}Pa/^{230}Th in zones of enhanced scavenging and the latter by producing distinct vertical and horizontal ^{231}Pa/^{230}Th gradients. As anticipated, the boundary scavenging effect is more prominent in the eastern equatorial Pacific but the influence of circulation in this region can still be recognized in the data. In areas of lower scavenging intensity, measured sediment ^{231}Pa/^{230}Th varies with water depth in accordance with model predictions, suggesting that PMOC strength and geometry are the main controlling factors. This finding suggests that past changes in the strength and geometry of the PMOC could be derived from the distribution of ^{231}Pa/^{230}Th in the low productivity regions of the Pacific.

MGMTP Software to obtain tritium concentration in precipitation

YUE LUO[1*], YANHONG ZHANG[1], SHUJUN YE [1] AND JICHUN WU[1]

[1] Department of Hydrosciences, Nanjing University, Nanjing, China kuaikuaikaikai@126.com

Tritium, as one of various environmental tracers, has been broadly applied in hydrogeology. However, observations of tritium concentration in precipitation are generally scarce. The utilization of tritium concentration is strongly limited by our knowledge of the natural distribution of tritium in precipitation over both space and time. The modified global model of tritium in precipitation (MGMTP) was developed by Zhang et al. (2011) [1]. For the purpose of making MGMTP model easy to use, the MGMTP software, a MATLAB Software Package, was developed to obtain the annual mean tritium concentration in precipitation in the area from 80°S to 80°N over the period from year 1960 to 2005. The MGMTP model was developed by improvement of Doney model [2] based on the method of factor analysis. The annual mean tritium concentration in precipitation $c_p(t)$ at any place in the MGMTP model is established by the equation:

$$c_p(t) = b + f_1\hat{c}_p(t,1) + f_2\hat{c}_p(t,2) + \varepsilon_a(t) \quad (1)$$

Where $\varepsilon_a(t)$ is the error term; $\hat{c}_p(t,1)$ and $\hat{c}_p(t,2)$ are the two reference curves (factor scores), which is determined by factor analysis using tritium data from International Atomic Energy Agency(IAEA) covering all the stations from 50°S to 70°N over period from 1960 to 2005. The coefficients f_1 and f_2 are unique for each station and are similar to the factor loadings; b represents the mean of the vector. Parameters of b, f_1 and f_2 are calculated from the least-squares solution for each selected station. The global maps of model factor coefficients f1, f2 and b are generated using a kriging interpolation method. The Software Package includes a MAT-file and a M-file. It was originally inspired by a MATLAB toolbox. The values of five parameters in MGMTP model have been stored in the MAT-file. User could easily update MAT-file if new observation data is available, because MATLAB offers functions of factor analysis and regression analysis. The role of the M-file is to solve equation (1). User can get tritium concentration with the input of specific latitude, longitude and time. The Software Package's Syntax is c = feval (Latitude, longitude, time).

Abstract

GWL had the pleasure to meet Bjørn Sundby at a Black Sea conference in Gotebørg, Sweden in 1986 hosted by David Dyrssen. After that George and Bjørn communicated on a regular basis and when our Delaware group developed solid state (micro)electrodes that could measure O_2, H_2S, Fe(II) and Mn(II), it was obvious that we should join forces on studying sediment biogeochemisry. In this talk, I will show our collaborative work in the St. Lawrence estuary and Portuguese salt marshes. This includes detailed work on Mn chemistry with the O, Fe and N cycles leading to new insights on soluble Mn(III) chemistry, and interesting Pb chemistry as the redox state of the sediment changes. The collaboration has been frutiful beyond our wildest imagination, and has led to much fun and the development of a great friendship for us as well as our students and colleagues.

THE ORIGIN OF SULFUR ISOTOPE MASS-INDEPENDENT FRACTIONATION IN ARCHEAN ROCKS

JAMES LYONS[1*], DOUGLAS BLACKIE[2], GLENN STARK[3], JULIET PICKERING[4]

[1]Dept. Earth & Space Sciences, UCLA, Los Angeles, USA, jimlyons@ucla.edu (* presenting author)
[2]Physics Dept., Imperial College, London, UK, douglas.blackie01@imperial.ac.uk
[3]Physics Dept., Wellesley College, Wellesley, USA, gstark@wellesley.edu
[4]Physics Dept., Imperial College, London, UK, j.pickering@imperial.ac.uk

Introduction

The discovery of unusual sulfur isotope fractionation in Archean and Paleoproterozoic rocks has promised to yield insights into the rise of O_2 and the nature of the sulfur cycle on ancient Earth [1], but interpretation has been hampered by the lack of a clear mechanism for the sulfur isotope signature. Proposed mechanisms include SO_2 photolysis [1-4], mass-independent fractionation (MIF) during atmospheric S_3 (thiozone) formation, and thermal sulfate reduction in sediments [5]. Studies focusing only on SO_2 photolysis, including measurements of isotopic cross sections [6], have yielded results differing greatly from theory [4], and have resulted in improbable interpretations [7].

Results

Here we report high-resolution ultraviolet cross section measurements of the sulfur isotopologues of SO_2 made with the UV FTS at Imperial College. This instrument has a dual-beam configuraton, allowing the D_2 lamp intensity to be monitored simultaneously with the gas absorption, effectively removing the lamp as a noise source. We measured cross sections at 1 cm^{-1} spectral resolution for $^{32}SO_2$, $^{33}SO_2$ and $^{34}SO_2$. Incorporating these cross sections into a simple atmospheric photochemical model, with a solar UV flux, yields sulfur MIF signatures for optically thin abundances of SO_2 due to small differences in the integrated cross sections. The $\Delta^{33}S$ values for SO and S produced by photolysis of SO_2 and SO, respectively, are positive in the 190-220 range, in contrast to the results of lower resolution cross section measurements of [6]. We therefore do not need to invoke an additional absorber to modify the sign of the MIF signature, as was done using OCS in [7]. We find that additional MIF by self-shielding by $^{32}SO_2$ places an upper limit on SO_2 of about 1 ppb. Our results imply that SO_2 photolysis alone is responsible for most of the Archean sulfur MIF record, and that sulfur MIF is a good proxy for the rise of O_2 in the earliest Paleoproterozoic. Work on $^{36}SO_2$ is in progress.

[4] Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy
[5] Scripps Oceanographic Institute, San Diego, USA
[6] Dept. Petrology, Vrije, Universiteit Amsterdam, Netherlands

Arc magmas typically display chemical and petrographic characteristics indicative of crustal input. Crustal contamination can take place either in the mantle source region or as magma traverses the crust (e.g. [1]). While source contamination is generally considered the dominant process (e.g. [2, 3, 4]), crustal contamination in high level magma chambers has also been recognised at volcanic arcs (e.g. [5, 6]). In light of this, we aim to test the extent of upper crustal versus source contamination along the Java segment of the Sunda arc, which, because of its variable upper crustal structure, is ideal for the task.

We present a detailed geochemical study of 7 volcanoes along a traverse from Anak-Krakatau in the Sunda strait through Java (Gede, Slamet, Merapi, Kelut, Kawah-Ijen) and Bali (Batur). Using rock and mineral elemental geochemistry and radiogenic (Sr, Nd and Pb) and, stable (O) isotopes, we show a correspondence between changes in composition of the upper crust and the apparent degree of upper crustal contamination. There is an increase in $^{87}Sr/^{86}Sr$ and $\delta^{18}O$, and a decrease in $^{143}Nd/^{144}Nd$ from Krakatau towards Merapi, indicating substantial input from the thick quasi-continental basement beneath East and Central Java. Volcanoes to the east of Merapi, and the Progo-Muria fault zone, where the upper crust is thinner and increasingly oceanic in nature have lower $^{87}Sr/^{86}Sr$ and $\delta^{18}O$, and higher $^{143}Nd/^{144}Nd$ indicating a stronger influence of the mantle source [7]. Our new data represent a systematic and high-resolution arc-wide sampling effort that allows us to distinguish the effects of the upper crust on the compositional spectrum of individual volcanic systems along the Sunda arc.

Multi-scale modeling of transverse reactive mixing in a coastal aquifer

H. M. NICK[1,3*], A. RAOOF[1], M. THULLNER[1,2], P.A.G. REGNIER[3]

[1]Faculty of Geosciences, Utrecht University, Utrecht, The Netherlands (*correspondence: h.m.nick@uu.nl, a.raoof@uu.nl)
[2]Department of Environmental Microbiology, UFZ – Helmholtz Centre for Environmental Research, Leipzig, Germany (martin.thullner@ufz.de)
[3]Department of Earth and Environmental Sciences, Université Libre de Bruxelles, Brussels, Belgium (pregnier@ulb.ac.be)

The transverse mixing between freshwater and seawater in coastal aquifers is a key process controlling the chemistry of submarine groundwater discharge (SGD). The quantification of such mixing and its effects on the fate of reactive chemical compounds in coastal waters are still the subject of debate. We developed reactive transport model approaches to study the mechanisms responsible for controlling reactive mixing processes in coastal aquifers. These models employ hybrid numerical methods for solving flow and transport [1,2], and benefit from utilizing the biogeochemical reaction network simulator (BRNS) [3].

Critical to advancing our understanding is the study of the interplay between reaction and flow. We particularly investigated the impact of dispersion, heterogeneity induced velocity variations and biogeochemical reactivities on reactive transport for density driven flow scenarios representing seawater-groundwater-interface in coastal aquifers. Our numerical observation showed e.g., that for highly reactive dissolved organic carbon (DOC) degradation processes are limited by the porous media properties controlling dispersion, whereas for relatively less reactive DOC degradation is controlled by reaction kinetics.

In general, we found three reactive flow regimes: reaction controlled, reaction-dispersion controlled and dispersion controlled transport. This is supported by further simulations utilizing pore-scale models to investigate these regimes at the smaller scale. Our results suggest that the chemical reactivity as well as dispersivity are important parameters governing the biogeochemical dynamics of SGD. Hence, an adequate representenation of these processes in the macro-scale models is essential.

Mantle Evolution from Plate Subduction to Post-orogenic Extension: Evidence from Permo-Triassic Mafic Dike Swarms in Northern Tibet Plateau

CHANGQIAN MA[1,2*], JINYANG ZHANG[2], FUHAO XIONG[2], BIN LIU[2], JIAN HUANG[2] AND BAIHUA WANG[2]

[1] State Key Lab. of Geological Processes and Mineral Resources, Wuhan, China, cqma@cug.edu.cn (* presenting author)

[2] China University of Geosciences,Wuhan,China

Five large mafic dike swarms have been discovered within the ~270 km-long Xiangride-Golmud segment of the East Kunlun belt, Northern Tibet Plateau, which are named, from east to west, the Balong, Binggou, Xiaomiao, Bairiqili and Nanshankou dyke swarms. The number of dikes in a given swarm can vary from 10 to 42, and the width of individual dikes ranges from 0.1 to 5 m. Most of the dikes trend N-S. The widest dikes are clearly banded with coarser textures and more phenocrysts in the middle portions than in the margins. Most of the dikes are porphyritic diabase with the coarser-grained varieties grading into diorites. All of the mafic dikes are composed chiefly of clinopyroxene, plagioclase and amphibole.

Based on the field relationships, hornblende Ar-Ar and zircon U-Pb dating we consider that the dike swams were formed in three episodes; Early Permian, late Permian and Triassic to Late Triassic. The Xiaomiao (277 Ma) and Binggou (225 Ma) mafic dikes are calc-alkaline in composition with low ∑REE (＜100 ppm) and relatively flat, chondrite-normalized REE patterns with no Eu anomalies. These rocks also have low Ni, Cr and V but are enriched in Rb, K, Pb and P, and depleted in Nb and Ta. In contrast, the Balong dike swarms (253 Ma) have high ∑REE (~100 to >150 ppm） and are enriched in HREE, with higher trace element contents than the other dikes. The Xiaomiao and Binggou dike swarms have similar Sr-Nd isotopic characteristics with ISr = 0.707-0.711 and εNd(t) ranges from -3.4 to 3.9, whereas the Bairiqili (251 Ma) and Balong dikes have somewhat more enriched and variable compositions, with ISr = 0.709-0.719 and εNd(t) ranging from -7.8 to -3.6. The geochemical similarities of the Permin –Triassic East Kunlun, South Qiangtang and north Himalaya dike swarms and basalts indicate that the north boundary of Gondwana reached the East Kunlun block at that time.

Further study of these dike swarms should lead to a better understanding of the influence of subducted slabs on the mantle source and subduction mechanics during the evolutionary stage between the Paleo-Tethyan oceanic plate subduction and post-orogenic extension.

Heterogeneous mantle sources of the alkaline-tholeiitic intraplate basalts from the Aleppo Plateau, NW Syria

[4]Department of Geosciences, National Taiwan University, Taiwan

Mantle-derived magmas are characterised by considerable chemical and isotopic variability that is difficult to reconcile with partial melting of a peridotite mantle alone. This reflects the presence of heterogeneities in the mantle, originated from, for instance, recycled oceanic crust or metasomatised lithosphere [1, 2, 3]. Identification of such heterogeneities and thus the mineralogy of the mantle source becomes more ambiguous because both crustal contamination and crystal fractionation may mask important source characteristics.

We present age, chemical and isotopic data to constrain the source and the chemical evolution of the continental alkaline-tholeiitic intraplate magmas from the Aleppo Plateau and vicinity, NW Syria. With the aid of new $^{40}Ar/^{39}Ar$ ages, two phases of volcanism have been recognised in the Miocene, ~19-18 Ma (Phase 1) and ~13.5-12 Ma (Phase 2), in the studied area. The chemical and isotopic compositions [$^{87}Sr/^{86}Sr$ = 0.7036-0.7051, $^{143}Nd/^{144}Nd$ = 0.51269-0.51287 and $(^{187}Os/^{188}Os)_t$ = 0.151-0.453] of the lavas reflect the unequivocal influence of crustal assimilation and fractional crystallisation. However, it is interpreted that the two phases of volcanism likely sampled a mineralogically heterogeneous source, as reflected by their compositional variations seen in the most-primitive, least contaminated magmas. Such variations are: (1) relatively high Si, low Ti and trace-element contents in the Phase 1 lavas, consistent with partial melting of a largely peridotitic mantle source; (2) relatively low Si, high Ti, Fe, Ca, P, alkalis, and L-MREE/HREE, plus sub-chondritic Th-(U)/Nb, Pb/Ce and Zr/Sm in the Phase 2 lavas, approaching compositions of experimental melts of amphibole-rich metasomatic veins [3]. Thus, it is inferred that the Syrian lithosphere had been pervasively metasomatised and contained veins of amphibole-rich cumulates shortly before volcanism, and that the changing compositions of the Phase 1 to Phase 2 lavas (increasing Si-undersaturation) reflected an increasing contribution from the metasomatic vein-derived melts.

Using Uranium Isotopes to Determine Salinity Sources in Rio Grande Waters

LIN MA[1*], ANNA SZYNKIEWICZ[1], DAVID BORROK[1], AND JENNIFER C. MCINTOSH[2]

[1]Department of Geological Sciences, University of Texas at El Paso, El Paso, TX 79968, USA, lma@utep.edu (* presenting author), aaszynkiewicz@utep.edu, dborrok@utep.edu

[2]Department of Hydrology and Water Resources, University of Arizona, Tucson, AZ 85721, USA, mcintosh@hwr.arizona.edu

Abstract

The Rio Grande flows from Southern Colorado through New Mexico and West Texas down to the Gulf of Mexico. It serves as an important water supply for agricutural and municipal needs. In Rio Grande waters, total dissolved solids (TDS) increase from ~40 mg/L at the headwaters to 500-1500 mg/L at El Paso, Texas. The elevated TDS values in downstream water cause various problems such as reduction in crop productivity and deterioration of soil quality due to salt loading. A number of natural and anthropogenic factors may lead to increased salinity, so the exact sources and their relative contributions to the salt load remain unclear. U isotopes (e.g., ^{234}U and ^{238}U) fractionate naturally when released from rocks to waters during chemical weathering processes at Earth's surface. It has been suggested that the degree of U isotope fractionation depends largely on local lithology and climate conditions, which affect chemical weathering and U release rates. U isotopes in natural waters thus have great potential to serve as natural tracers for chemical weathering processes, which in turn can help to determine the origins of dissolved solids (i.e., salts) and their history.

Here, we measured the U concentrations and isotope ratios for water samples collected along a ~ 1000 km stretch of Rio Grande (from the headwaters in Colorado to El Paso, Texas), as well as from streams and springs in the Jemez Mountains, a small drainage basin that recharges to Rio Grande in northern New Mexico. The comparison of these two case studies reveals different evolution histories for U in surface waters. In the Jemez Mountain region where human impacts are minimal, U isotope ratios in surface waters are largely controlled by rhyolite weathering, and both U concentrations (0.01-0.19 ppb) and ($^{234}U/^{238}U$) activity ratios (1.5-3.0) vary systematically with elevation (2600-2900 m). Here, solutes in streams largely represent mixing of two sources: young surface water (e.g., several months old) with low U concentrations and high ($^{234}U/^{238}U$) ratios and relatively old shallow groundwater that has higher U concentrations and lower ($^{234}U/^{238}U$) ratios. Similar ranges of U concentrations and ($^{234}U/^{238}U$) ratios are observed for the headwater regions of the Rio Grande. U concentrations in the Rio Grande increase significantly downstream (0.12 to 5.97 ppb) and correlate well with Ca^{2+}, Mg^{2+}, and HCO_3^- ions, revealing a control of carbonate dissolution/precipitation on river water chemistry. This is probaly due to a change of lithology. In addition, both ($^{234}U/^{238}U$) ratios (1.6-2.1) and U concentrations in the Rio Grande waters show strong seasonal patterns, reflecting the human impacts on river chemistry, such as the regulation of river flows by reservoirs and dams, agricultural irrigation return flows, and pumping of cold/geothermal aquifer waters.

Petrogenesis of the Aolunhua igneous complex, eastern Central Asian Orogenic Belt: Geochemical, and Sr–Nd–Hf isotopic constraints

XINGHUA MA[1*], BIN CHEN[1,2], AND ZHIQIANG WANG[1]

[1]Key Laboratory of Orogenic Belts and Crustal Evolution, Peking University, Beijing 100871, China, maxh@pku.edu.cn (* presenting author)

[2]Institute of Geology and Exploration Engineering, Xinjiang University, Urumchi 830046, China, binchen@pku.edu.cn

A large-scale Early Cretaceous magmatic-metallogenic belt (known as the Xar moron belt) has recently been recognized in the eastern Central Asian Orogenic Belt (CAOB), but the process and mechanism for the formation of this belt are controversial. Here we report geochemical and Sr–Nd–Hf isotopic data for the Aolunhua igneous complex (genetically related to a porphyry-type Mo deposit), to reveal its petrogenesis, source nature, and implications for the Mesozoic tectonic evolution of eastern CAOB.

The complex consists of a batholith (monzogranite-porphyry) and late-stage bimodal dyke swarms (quartz-porphyry and diorite dykes). Geochemically, the monzogranite-porphyry exhibits features of arc rocks such as conspicuous Nb, Ta negative anomalies and LILE enrichment (e.g., Sr and Ba). It has low I_{sr}, positive $\varepsilon_{Nd}(t)$ values of +0.5 to +1.4 and $\varepsilon_{Hf}(t)$ values of +3.5 to +9.8. These features, together with young inherited zircons (< 360 Ma) from the source region, suggest a juvenile basement dominated by the late Paleozoic island-arc series. The mafic enclaves hosted in the monzogranite-porphyry are characterized by containing H_2O-bearing minerals (e.g., Hb and Bi) and more calcic plagioclases, variable elements compositions, high $Mg^{\#}$, enrichment of Sr and LREE, and radiogenic Nd-Hf isotopic compositions ($\varepsilon_{Nd}(t)$ = +0.7 to +1.6 and $\varepsilon_{Hf}(t)$ = +3.3 to +10.9), indicating that they originated from a subduction-modified mantle, followed by a significant fractionation of ferromagnesian phases such as pyroxene and hornblende. Petrological and geochemical evidences including hornblende-rimmed quartz ocelli, pervasive acicular apatites in mafic enclaves, compositional disequilibrium in plagioclases and high $Mg^{\#}$ features of the host rocks, demonstrate that mixing between mantle magma and crustal melts have played an important role in the formation of monzogranite-porphyry. The quartz-porphyry dykes show high SiO_2 concentrations, low $Mg^{\#}$, conspicuous negative Eu anomalies and relatively flat REE patterns. The contemporaneous diorite dykes, however, show geochemical and isotopic characteristics similar to the mafic enclaves. The two kinds of dykes probably have been originated from melting of lower crust and mantle source, respectively, in a late stage when the monzogranite-porphyry batholiths was solidified.

In summary, the Aolunhua igneous complex formed due to the reactivation of the juvenile CAOB in the Early Cretaceous when the Paleo-Pacific oceanic slab subducted beneath eastern China, and triggered the upwelling of asthenosphere, which resulted in lithospheric thinning and extensive magmatism in the eastern CAOB.

Investigations into temporal and spatial variations in atmospheric helium isotopes

J.C. MABRY[1*], B. MARTY[1], P. BURNARD[1]

[1]CRPG-CNRS, 54501 Nancy, France (*correspondence: jmabry@crpg.cnrs-nancy.fr)

This work describes the development of a method to measure atmospheric helium isotopes at a very high precision (0.2% or better). The primary motivation is to look for potential temporal or spatial variations in the helium isotopic composition of the atmosphere. Since crustal helium has a large excess of ^{4}He relative to atmospheric helium, recent anthropogenic activities such as fossil fuel exploitation may give rise to a change in the atmospheric composition [1, 2]. However, previous measurements have put an upper limit on this near current measurement abilities [3, 4]. There are significant analytical challenges to improving the precision of atmospheric helium measurments as helium is only present in trace quantities in the air (5.24 ppm) and there are are many of orders of magnitude difference in the abundance of the two isotopes ($^3He/^4He_{air} = 1.38 \times 10^{-6}$).

To improve our ability to measure helium isotopes precisely, we have constructed an automated extraction line which can rapidly switch between measuring aliquots of sample with standards. For each measurement we purify a relatively large amount of gas (~20 cm^3) so that we can make many repeat analyses of the same sample gas. A major component of our method features an adjustable bellows on the sample aliquot volume that enables us to adjust the size of a sample aliquot to precisely match the standard, eliminating biases arising from nonlinear pressure effects in the mass spectrometer.

Prior to analysis we remove the neon (and any other gases remaining after purification) with a cryo trap. This lowers the pressure in the mass spectrometer and makes it easier to be sure that the standard and sample aliquots are the same size. There is an additional cryo trap on the mass spectrometer volume to maintain low background levels. Adding the cryo trap reduced the statistical errors of repeated standard analysis within one day from 0.5% to 0.3% (2σ). Meanwhile the absolute scatter of measurements over several days fell from ~5% before the addition of the cryo trap to better than 0.5%. We believe much of this remaining scatter can be attributed to an instability discovered in the high voltage power supply of the source.

All of the previous measurements were made on a GV Instruments Helix split flight tube multi-collector mass spectrometer, which was specifically designed for helium isotope measurements. Future measurements will be made on a new version of the same machine built by Thermo Scientific and recently installed in our lab (January 2012). The new machine has already demonstrated approximately three times higher sensitivity as well as better electronic stability. First results with the new machine will be presented at the conference.

Metagenome-enabled investigation of microbial sulfur precipitation in a carbonate aquifer

JENNIFER L. MACALADY[1*], DANIEL S. JONES[1], IRENE SCHAPERDOTH[1], CLARA CHAN[2] AND KEVIN CABANISS[2]

[1]Penn State University, Geosciences Dept., University Park, PA, USA (*presenting author, jlm80@psu.edu)

[2]Univ of Delaware, Earth, Ocean & Environment, Newark, DE, USA

Microbial coupling between carbon and sulfur elemental cycles in iron-poor, carbonate-rich environments results in the dissolution of carbonate minerals, precipitation of gypsum, and/or the precipiation and dissolution of elemental S. In particular, the incomplete oxidation of sulfide to elemental S strongly affects the availability of H2S and H2SO4, acids which contribute to limestone dissolution. The sulfidic Frasassi caves provide a superb model environment for understanding biotic and abiotic controls on the balance of these processes, which affect porosity development and fluid flow in sedimentary aquifers and the diagenesis of marine carbonates.

In the Frasassi system, four types of sulfide-oxidizing biofilm communities develop in separate niches defined by dissolved sulfide:oxygen ratios and hydrodynamic shear [1]. Elemental analyses suggest that S precipitates most rapidly in locations where turbulent mixing brings sulfidic water in contact with cave air, resulting in biofilms that are 40-80% sulfur by mass. Major populations in the biofilms include members of widely-dispersed and uncultivated sulfur-oxidizing clades, including Gammaproteobacteria related to "Thiobacillus baregensis" (Tbar) and Sulfurovumales-group Epsilonproteobacteria. Based on FISH population counts with genus and group-specific probes, Sulfurovumales are successful only when the sulfide:oxygen ratio exceeds 150. In contrast, Tbar populations are not correlated with concentrations of sulfide, oxygen, or the dissolved sulfide:oxygen ratio.

To further investigate the geochemical and ecological factors that favor the growth of Tbar and Sulfurovumales populations, and implications for sulfur precipitation and limestone dissolution, we investigated the metabolic capabilities of the sulfur-precipitating biofilms using enrichment culturing and metagenomics. Initial enrichment culturing efforts suggest that Tbar and Sulfurovumales populations are autotrophic or mixotrophic, and that batch (rather than flow-through) culturing methods favor the growth of Tbar over Sulfurovumales. Four metagenomes derived from biofilms naturally enriched in Tbar and Sulfurovumales populations are currently in production, and will provide genetic clues necessary to enhance enrichment culturing efforts and constrain the metabolic potential of these ecologically successful groups, including pathways for partial or complete S oxidation, S reduction, C and N fixation, heterotrophy, and biofilm formation.

Isotopic and mineralogical properties of surface sediment from the circum Arctic

JENNY MACCALI[1*], CLAUDE HILLAIRE-MARCEL[1]

[1]GEOTOP-UQAM, Montréal, Canada, jenny.maccali@gmail.com (* presenting author)

Radiogenic isotopes (RI) have been used to trace sediment origin in various ocean basins [1, 2, 3, 4, 5, 6]. This method is particularly useful in sites where ire-rafting deposition (IRD) represents an important sediment transport mechanism, as illustrated recently by RI-analyses in cored sediments from Fram Strait [7], the main sea-ice exit pathway from the Arctic Ocean towards the North Atlantic. Mineral-lattice bound Pb-, Sr- and Nd- isotopes (i.e., linked to detrital sediment supplies) from this sedimentary sequence displayed two distinct temporal trends since the Last glacial Maximum [7]. In this study, three main detrital supply areas were defined, based on literature data, respectively, the Canadian and Russian margins, and northern Greenland. Broad sea-ice paleocirculation patterns were then proposed based on the Fram Strait RI-record. In order to refine sea-ice paleo-circulation reconstructions, we have undertaken a more detailed survey of potential circum-Arctic sediment sources, using surface-sediment samples from the Canadian Arctic Archipelago, the Beaufort Shelf, Bering Strait, the Chukchi Sea, the East Siberian, Laptev, Kara and Barents seas. Nd- and Sr- isotope data now define more detailed isotopic domains with, for instance, low epsilon Nd values corresponding to North American cratons, and high epsilon Nd values linked to Pacific inputs through Bering Strait. These domains are compared with relevent mineralogical information (e.g. iron-oxides) from Darby [8]. This 'RI-mapping' data set should improve quantitative estimates of IRD sources and mixing in sedimentary records from the Arctic, thus of the dynamics of surrounding continental ice-margins during the Quaternary.

In Situ Determination of Sulfide Oxidation Rates in the Green Sulfur Bacterium *Chlorobaculum tepidum*

Daniel J. MacDonald[1*], Alyssa Findlay[1], Kevin Shuman[1], Daniel Hess[1], Thomas E. Hanson[1], and George W. Luther[1]

[1]College of Earth, Ocean, and Environment, University of Delaware, Lewes, DE 19958
*uri@udel.edu

Sulfur cycling in many environments is regulated by microbial activity. As the most reduced form of sulfur, H_2S, is toxic to many aerobic organisms; however, *Chlorobaculum tepidum* uses sulfide as an electron donor during photosynthesis. Microbial sulfide oxidation is a major sulfide removal mechanism, yet the relevant microbial oxidation rates are relatively unknown. In a recent study biological sulfide oxidation rates were determined to exceed abiotic oxidation rates by several orders of magnitude[1]. Voltammetric data will be presented that examines the rate of sulfide loss due to microbial uptake and oxidation over a variety of physical and biochemical parameters, such as the effects of light intensity, biomass concentration and total sulfide concentration. Speciation of sulfide oxidation products, such as elemental sulfur and polysulfides, and the rates at which these products form, will be presented. Initial data show that these organisms follow Michaelis-Menten kinetics with an approximate apparent saturation rate of 100 μM sulfide.

Natural-abundance stable carbon isotopes of small-subunit ribosomal RNA (SSU rRNA): first results from Guaymas Basin (Mexico)

BARBARA J. MACGREGOR*, HOWARD MENDLOVITZ, DANIEL ALBERT, AND ANDREAS P. TESKE

University of North Carolina, Dept. of Marine Sciences
*bmacgreg@unc.edu, mendlovitz@unc.edu, dan_albert@unc.edu, teske@email.unc.edu

Introduction

Small-subunit ribosomal RNA (SSU rRNA) is a phylogenetically informative molecule found in all cells. Being poorly preserved in most environments, it is a useful marker for active microbial populations. At Guaymas Basin, hydrothermal fluids interact with abundant sedimentary organic carbon to produce natural gas and petroleum. Where this reaches the sediment surface, it can support dense patches of seafloor life, including *Beggiatoa* mats. We report here on the stable carbon isotopic composition of SSU rRNA from a *Beggiatoa* mat transect, a cold background site, and a warm site with high oil concentration. Our initial hypotheses were that rRNA isotopic composition would be strongly influenced by methane supply, and that archaeal rRNA might be lighter than bacterial due to contributions from methanogens and anaerobic methane oxidizers.

Results and Conclusion

The central part of the mat overlay the steepest temperature gradient, and was visually dominated by orange *Beggiatoa*. This was fringed by white *Beggiatoa* mat and bare, but still warm, sediment. Methane concentrations were saturating beneath the mat and at the oily site, lower beneath bare sediment, and below detection at the background site.

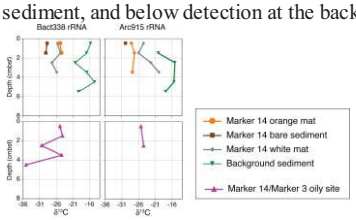

Figure 1. Stable carbon isotope composition of rRNA captured by magnetic bead capture hybridization [1].

We used biotin-labeled oligonucleotides to capture Bacterial and Archaeal SSU rRNA for isotopic determination (Fig. 1). Background-site rRNA was isotopically heaviest, and bacterial RNA from below 2 cm at the oily site was lightest, consistent with control by methane. Within the mat, however, rRNA from the bare periphery was lightest. There was no consistent isotopic difference between the probes, although RNA recoveries were too low for capture at depths where methanogens and methane oxidizers are expected.

Our prediction that rRNA isotopes would correlate directly with methane supply was clearly oversimplified. Future work will include the isotopic characterization of other potential carbon substrates. We are also investigating Gulf of Mexico sediments, where methane is significantly more ^{13}C-depleted than at Guaymas Basin.

Surface complexation modeling of Na^+ and Rb^+ adsorption by rutile to 250°C

MICHAEL L. MACHESKY[1]*, MILAN PŘEDOTA[2], MOIRA K. RIDLEY[3], AND DAVID J. WESOLOWSKI[4]

[1]Univ. of Illinois, Illinois State Water Survey, Champaign IL, USA, machesky@illinois.edu (* presenting author)
[2]Univ. South Bohemia, České Budějovice, Czech Republic, predota@prf.jcu.cz
[3]Texas Tech Univ., Dept. of Geosciences, Lubbock, TX, USA, moira.ridley@ttu.edu
[4]Oak Ridge National Laboratory, Oak Ridge, TN, USA, dqw@ornl.gov

Surface complexation models (SCMs) provide the means to rationalize and extend (to uncharacterized conditions) cation adsorption data, and increasing use is being made of molecular level experimental and/or modeling results to constrain SCM parameter space. One rather surprising finding of this molecular-level information is that monovalent alkali metal cations can bind in inner-sphere fashion to oxides such as rutile. Given the very common use of alkali metal salts as background electrolyte media for adsorption experiments, it therefore becomes necessary to incorporate inner-sphere adsorption of alkali metal cations into SCMs to best represent molecular-level reality.

Ridley et al [1] demonstrated that the CD-MUSIC model of Hiemstra, van Riemsdijk and co-workers can successfully accommodate inner-sphere binding of Na^+, K^+, and Rb^+, as gleaned from ab initio constrained classical molecular dynamics (CMD) simulations (for Na^+, Rb^+) and X-ray reflectivity measurements (for Rb^+) in fitting 25°C rutile surface titration data. We have extended this CD-MUSIC approach to rutile surface titration data collected to 250°C in NaCl, NaTr(Tr=triflate) and RbCl electrolyte solutions. CMD results that track Na^+ and Rb^+ adsorption by the 110 surface of rutile at 25, 150, and 250°C and several charge states are used to constrain the allowable CD-MUSIC model parameters and it is shown that the resulting SCM can adequately mirror most of the CMD results over the broad ambient to hydrothermal temperature range.

Discharge-driven harmful algal blooms in the NE Gulf of Mexico

H.L. MACINTYRE[1*], J.D. LIEFER[2], L. NOVOVESKA[2], W.C. BURNETT[3], N. SU[3], K.T. ELLER[3], W.L. SMITH[4], C.P. DORSEY[4], R.H. PETERSON[5] AND R.F. VISO[5]

[1]Dalhousie University, Halifax, Canada, hugh.macintyre@dal.ca (* presenting author)
[2]Dauphin Island Sea Lab, Dauphin Island, USA, jdl602@jaguar1.usouthal.edu, lucie.novoveska@gmail.com
[3]Florida State University, Tallahassee, USA, wburnett@fsu.edu, nisu1111@gmail.com, eller@ocean.fsu.edu
[4]Alabama Department of Public Health, Mobile, USA, billandelinor72@yahoo.com, Carol.Dorsey@adph.state.al.us
[5]Coastal Carolina University, Conway, USA, rpeters2@coastal.edu, rviso@coastal.edu

The state of Alabama (USA) has only 100 km of coastline but has had recurring harmful algal blooms (HABs) at two shallow-water hot-spots. Both are in the same hydrological unit on the eastern margin of Mobile Bay. The first, Weeks Bay, is a sub-estuary on the eastern margin of Mobile Bay and is the site of diverse dinoflagellate blooms that cause hypoxia and fish-kills. The second, the Gulf of Mexico shoreline adjacent to Little Lagoon, a shallow and saline lagoon, is the site of toxic blooms of the diatom *Pseudo-nitzschia* spp. Initiation of both dinoflagellate and diatom blooms is correlated with discharge from the aquifer.

Microalgal community composition appears to be driven by the interaction of temperature and submarine groundwater discharge. Dinoflagellates bloom in Weeks Bay during periods of low discharge in both winter (*Prorocentrum minimum*) and summer (*Karlodinium veneficum*). *Pseudo-nitzschia* spp. bloom predominantly in the spring after periods of high discharge [1], as part of a cohort of diatoms that includes other bloom-forming taxa [2]. Comparison of community composition with physico-chemical characteristics of Little Lagoon showed a very high correlation between the degree of dominance by diatoms and water age (inferred from the excess ^{224}Ra:^{223}Ra ratio) when subsurface resistivity showed that the water table was high. There was no correlation between community indices and water age when the water table was low.

The surficial aquifer is contaminated with very high N (up to c. 5 mM DIN plus DON) and the sediments in Weeks Bay and Little Lagoon have even higher concentrations of both N and P. Although the supply of nutrients by groundwater is important in supporting very dense blooms, the magnitude of discharge is likely as important in structuring the community. The conditions under which both dinoflagellate and diatom blooms occur are consistent with ordination of their niches in terms of habitat productivity and stability [3]. Because global climate change is predicted to alter seasonal patterns of precipitation, hence aquifer discharge, it is likely that the niches for these HAB taxa will expand.

Sediments in the Bull Creek Valley document the Pliestocene-Holocene transition, including the period corresponding to the Younger Dryas climate anomaly. Conflicting reports of nanodiamond presence/ absence, spatial/ temporal distribution, and polymorphic phase identification [e.g., 1,2] are perhaps not surprising given the challenges of recovering and identifying such materials within bulk sediments. Nanodiamonds form extraterrestrially; their distribution in Earth sediments may relate to the intensity of extraterrestrial bombardment. It has been suggested that a nanodiamond spike in Younger Dryas strata records an impact event, contributing to cooling on a global to regional scale [1].

For this study, sediments corresponding to alluvial, paleosol, and loess horizons were collected from multiple profiles across the Bull Creek Valley at approximately 10 cm intervals. Carbon dates ranged from ~33,000 years before present to recent. The clay fraction was separated from the bulk soil and then digested by a series of strong acid treatments. Residues were resuspended in ammonium hydroxide and prepared for transmission electron microscopy (TEM) by centrifugation onto grids with carbon support films. Grids were analyzed with TEM, high-resolution TEM (HRTEM), energy-dispersive x-ray analysis (EDS), and electron energy loss spectroscopy (EELS).

Nanodiamonds were identified in multiple horizons, including sediment dated to the Younger Dryas. Individual grains ranged from approximately 3-50 nm, although most grains were 5-10 nm. Most or all grains correspond to the n-diamond polymorph, as suggested by lattice fringe spacings. Lesser amounts of cubic nanodiamonds qwere also tentatively identified. EELS of these particles was consistent with sp^3-bonded carbon. Other micron-scale particles morphologically similar with those previously identified as hexagonal diamond [3] were graphene/graphane mixtures based on electron diffraction and EELS.

Reactive transport in compacted bentonite: porosity concepts, experiments and applications

URS MÄDER[1]*, ANDREAS JENNI[1], RAÚL FERNÁNDEZ[2], AND ISABEL DE SOTO GARCÍA[2]

[1]University of Bern, Geological Sciences, Bern, Switzerland

Porosity concepts and scales

Chemical and transport processes in compacted bentonite are operating at the nanometer scale of smectite interlayers but cannot be resolved at this scale by analytical or imaging techniques. Porosity concepts are treated as macroscopic averaged properties but are based on the microscopic scale using electrostatics and explicit or averaged Poisson-Boltzman theory for the distribution of electrolyte species adjacent to mineral surfaces bearing permanent charge. Implementation into reactive transport numerical models is debated, ranging from an averaged single-phase solid-liquid electrolyte [1] to complex multi-porous models assigning transport parameters specific to each type of porosity [2]. Here, we examine the relative merits and limitations of different multi-porous models as applied to experimental data of various complexity.

Reactive transport modelling of experimental data

A long-term multi-component advective-diffusive reactive transport experiment with compacted bentonite can be modelled satisfactorily with either a dual porous concept (small proportion of charge-balanced "free" eletrolyte, large proportion of interlayer-type electrolyte with Donnan approximation), or more complex model assigning separate porosities to the interlayers and a pore space close to external surfaces of smectite particles. Transport of the solvent was additionally constrained by a D_2O tracer.

Modelling of short-term simple major-component through-diffusion experiments is not discriminating between models of various complexity and leads to a strong dependency of transport coefficients on the porosity concept.

PHREEQC and Crunchflow were used as numerical models, both capable of treating multiple porosities, electrostatics in the form of diffuse-layer theory, and species-specific and porosity-specific transport properties.

Modeling Eu(III) sorption on granite

K. MAEDA[1*], K. FUKUSHI[1], Y. HASEGAWA[1], Y. YAMAMOTO[2], D. AOSAI[2] AND T. MIZUNO[2]

[1]Kanazawa Univeristy, Kanazawa, Japan, koushi@stu.kanazawa-u.ac.jp (presenting author)
[2]Japan Atomic Energy Agency, Mizunami, Japan

There have been very few researches for the trace elements sorption on complex mineral assemblages such as rocks, sediments and soils. In order to make predictions for the trace elements migration on geologic media, it is crucial to understand the nano-scale interaction of trace elements with complex mineral assemblages, and to construct the thermodynamic sorption models based on the molecular-scale information. In the present study, the batch sorption experiments of Eu(III) on granite were conducted as function of pH and ionic strength. The sorption behavior was modeled based on our microscopic observation (Hasegawa et al. this volume).

The granite sample was collected from a borehole at a depth of 400 m from the Mizunami Underground Research Laboratory constructed by Japan Atomic Energy Agency in central Japan. The granite was visually fresh. However, the microscope observation and the X-ray diffraction analysis of clay fraction show the occurrences of smectite, chlorite, vermiculate, calcite and hydrous iron oxides. Eu(III) sorption experiments on granite in the Teflon vessels were conducted as function of pH (2 to 8), ionic strength (I=0.01 and 0.1) and Eu concentration (1 and 10 uM) under ultra-pure N_2 atmosphere in room temperature.

The experiments and modeling results are shown in the Figure. Sorption ratio of Eu(III) was almost zero at pH 2. They abruptly increase with pH up to 3.5. Above pH 3.5, the sorption ratio indicates almost constant. The sorption strongly depends on ionic strength at the pH more than 3.5. Our microscopic observations show that Eu(III) is selectively scavenged by biotite and that sorption mode of Eu(III) is identified to be exchange reaction with inter-layer K in biotite and Eu(III). The sorption behaviors at pH more than 3.5 are consistent with the cation exchange reaction. At low pH conditions, less than pH 3.5, the release of the Al and/or Fe must occur with dissolution of minerals. The Al and/or Fe should be competed with Eu(III) on the exchange site of biotite. The sorption modeling is simply considering ion exchange reaction and solubility of hydrous iron oxide. The model reasonably reproduces the overall sorption behavior.

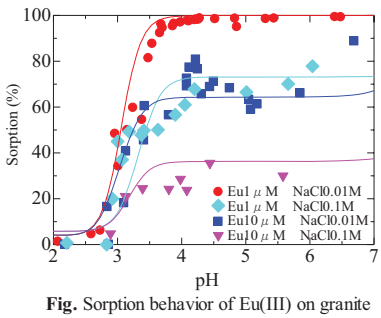

Fig. Sorption behavior of Eu(III) on granite

More than just "brown layers": Manganese in Quaternary Arctic Ocean sediments

C. MÄRZ[1,2,*], A. STRATMANN[2], J. MATTHIESSEN[3], S.W. POULTON[1], A.-K. MEINHARDT[2], S. ECKERT[2], B. SCHNETGER[2], C. VOGT[4], R STEIN[3] AND H.-J. BRUMSACK[2]

[3]Alfred-Wegener-Institut für Polar- und Meeresforschung, Bremerhaven, Germany
[4]ZEKAM, Fachbereich Geowissenschaften/MARUM, Universität Bremen, Germany

In Quaternary deposits of the Arctic Ocean, brown Mn-rich layers are well-known, widespread, but also debated features. Both glacial-interglacial climatic variations (in river runoff, bottom water ventilation etc.) and early diagenetic processes might explain the sedimentary Mn distributions. We applied inorganic geochemical analyses to pore waters and sediments of two sediment cores from the western Arctic Mendeleev Ridge (RV Polarstern Expedition ARK-XXIII/3) [1]. Our results show that most brown layers are associated with detrital (ice-rafted) and biogenic carbonate enrichments. In addition, all Mn-rich layers are enriched in Fe (oxyhydr)oxides, and in Co, Cu, Mo and Ni that were most probably scavenged by Mn/Fe (oxyhydr)oxides. Distinct bioturbation patterns (i.e., brown burrows into the underlying sediments) suggest these metal enrichments formed close to the sediment–water interface.

We infer that the metal-rich layers formed under warmer (interglacial/interstadial) conditions with an intensified continental hydrological cycle and only seasonal sea ice cover. Metals were delivered to the ocean by rivers/sea ice/coastal erosion [2], while seasonal productivity increased the reactive organic matter export to the sea floor. The coeval deposition of organic matter and Mn/Fe (oxyhydr)oxides triggered an intense diagenetic Mn and Fe cycling at the sediment-water interface. These climate-induced primary and secondary processes resulted in the enrichments of Mn/Fe (oxyhydr)oxides, scavenging of trace metals, and the degradation of labile organic matter. With the onset of glacial/stadial conditions, the riverine/erosive delivery of metals strongly decreased, a solid sea ice cover terminated the production and export of fresh organic matter, and gray-yellowish sediments with lower metal contents were deposited. Our data do not support glacial/stadial bottom water oxygen depletion that might have affected the Mn distribution.

Despite the climatic control on the composition of the brown layers, pore water data show that diagenetic redistribution of Mn and Mo is still affecting the deeper sediments. The degree of Mn remobilisation (potentially causing complete dissolution of existing, and formation of new Mn layers) largely depends on the availability and reactivity of Mn (oxyhydr)oxides and organic matter.

SIMS sputter pit volume estimation in SHRIMP zircon analysis using an $^{18}O_2^-$ primary beam

CHARLES W. MAGEE JR.[1*], JIM FERRIS[2], CHARLES W. MAGEE[2]

[1]Australian Scientific Instruments, Canberra, Australia, cwmagee@gmail.com (* presenting author)
[2]Evans Analytical Group, East Windsor NJ, USA

Abstract

A novel method of estimating the volume of sputtered material was discovered while performing SHRIMP (Sensitive High-Resolution Ion MicroProbe) zircon U/Pb geochronology using an $^{18}O_2^-$ primary beam. During analysis, the ratio of Th and U oxide isotopologues was found to be equal for each individual spot. Assuming that the $U^{16}O/U^{18}O$ (or $Th^{16}O/Th^{18}O$) ratio was equal to the $^{16}O/^{18}O$ ratio of the sputtered material, multiplying this by the total ^{18}O primary beam fluence (true beam current times analytical time) yields total sputtered oxygen. Dividing by the density of oxygen in the zircon crystal lattice (about 63 atoms per nm^3) yields an analytical volume.

Comparison with pit volumes from AFM (Atomic Force Microscopy) shows that this isotopic volume estimation agrees with AFM pit measurements to within 10%. This relationship holds for primary beam impact energies from 5 to 15 kV.

This agreement in volume between isotopic and AFM measurements suggests that oxygen migration in the sputtering process is limited. As oxygen activity is crucial to governing the Pb/U vs UO/U calibration that makes accurate SIMS U/Pb geochronology possible, further investigations are planned into minerals such as baddeleyite, which calibrate poorly.

As the SHRIMP duoplasmatron consumes only \$50-\$100 of $^{18}O_2$ per day, this method appears to be cost-competitive with paying for analytical time on a second instrument for analytical volume determination. However, it requires that the sample and the primary beam are the only sources of oxygen in the sputtering process.

Measurement of nitrous oxide isotopologues and isotopomers by the MAT 253 Ultra

PAUL MAGYAR[1*], SEBASTIAN KOPF[1], VICTORIA ORPHAN[1] AND JOHN EILER[1]

[1]California Institute of Technology, Pasadena, CA, USA, pmagyar@caltech.edu (* presenting author)

The global budget of nitrous oxide is dominated by terrestrial and marine biological sources and atmospheric sinks. Details of the budget remain unclear, including the cause of increasing atmospheric N_2O concentrations. Marine sources of N_2O include denitrification and nitrification. Our understanding of the major microbial players in the nitrogen cycle has changed in recent years (for example, the nitrifying Archaea), and the overall contributions of these organisms to N_2O production and their isotopic signatures are poorly constrained [1].

Here we examine the suitability of the MAT 253 Ultra, a new high resolution gas source mass spectrometer [2], for measurements of rare, previously unanalyzed isotopologues and isotopomers of N_2O, including 'clumped' species and high-precision direct analysis of ^{17}O-substituted species. Such measurements could provide additional constraints to the global cycle of N_2O, and in particular offer a fresh opportunity for distinguishing among biosynthetic N_2O sources. Preliminary experiments include examining N_2O produced by pure cultures of denitrifying bacteria.

In the instrument's 'medium resolution' setting (16 μm entrance slit; resolving power ~16-18,000, M/ΔM), [$^{14}N^{15}N^{18}O$ + $^{15}N^{14}N^{18}O$] is well resolved from $^{13}C^{18}O^{16}O$ and the $^{15}N^{18}O$ fragment from $^{17}O^{18}O$. In zero-enrichment measurements, precision of 0.2‰ was achieved for mass 47 species and 0.4‰ for $^{15}N^{18}O$; both equaled counting statistics limits for the integration times used (11 and 17 minutes, respectively) and should be improved by increasing the source pressure, reducing resolution (e.g., using a 20 μm entrance slit) or increasing counting time. At mass 45, $^{14}N_2{}^{17}O$ is well resolved from [$^{14}N^{15}N^{16}O$ + $^{15}N^{14}N^{16}O$], with external precision of 0.03‰ achieved after 11 minutes of integration (again, counting statistics limited and potentially improvable).

By measuring both these species (as well as unsubstituted and singly substituted isotopologues), the position-specific clumping (i.e., clumping of ^{15}N with ^{18}O, and its dependence on site preference of ^{15}N) can be examined. Such measurements will complement the information already available from N_2O site preference measurements alone. Calculations suggest that site preference of ^{15}N in thermodynamically equilibrated N_2O will differ by ~1‰ between ^{16}O and ^{18}O isotopologues [3]. A larger range of signals could arise from photochemical and biological fractionations. Precise measurement of ^{17}O will enable detection of even subtle contributions of atmospheric mass-independent fractionation, or study of variations in mass laws of biological and other fractionations.

Oxygen isotopes from Chinese caves: records not of monsoon rainfall but circulation regime

BARBARA A MAHER [1] * , ROY THOMPSON [2]

[1]University of Lancaster, Lancaster, UK, b.maher@lancaster.ac.uk (* presenting author)

[2]University of Edinburgh, roy@ed.ac.uk

Current interpretation of cave $\delta^{18}O$ records

Oxygen isotope variations in Chinese stalagmites have been widely interpreted as a record of the amount of East Asian summer monsoonal rainfall. This interpretation infers decreasing monsoonal rainfall from the mid-Holocene and large, dipolar rainfall oscillations within glaciations. However, the cave $\delta^{18}O$ variations conflict with independent palaeoclimate proxies (cave $\delta^{13}C$, loess/palaeosol magnetic properties, n-alkanes), which indicate no systematic decline in rainfall from the mid-Holocene, and no glacial rainfall maxima.

Mass balance calculations show moisture source is key control

Using mass balance calculations, we demonstrate that the cave $\delta^{18}O$ variations cannot be accounted for by summer rainfall changes, nor rainfall seasonality nor winter cooling, but instead reflect changes in moisture source. A possible driver of the $\delta^{18}O$ variations in Chinese stalagmites is precessional forcing of inter-hemispheric temperature gradients, in a mechanism similar to that of the modern day Indian Ocean dipole. Through such forcing, Indian monsoon-sourced $\delta^{18}O$ may have dominated at times of high boreal summer insolation, local Pacific-sourced moisture at low insolation. Suppression of summer monsoonal rainfall during glacial stages may reflect diminished sea and land surface temperatures and the radiative impacts of increased regional dust fluxes.

Defining the chemical and physical length and time scales that control chemical fluxes from landscapes

KATE MAHER[1*], CLAIRE KOUBA[1], ALEX K. HEANEY[1] AND VALERIE B. ROSEN[1]

[1]Dept. of Geological and Environmental Sciences, Stanford University, Stanford, CA, USA, kmaher@stanford.edu (* presenting author)

As fluids move through the subsurface they acquire solutes at a rate that is controlled primarily by the available surface area, the reaction kinetics of the individual minerals and the thermodynamic departure from chemical equilibrium [1]. As a result, both the physical length scale (or cumulative mineral surface area) and the time available for the fluid to react (or the fluid residence time) should exert a coupled influence on the solute fluxes from a given landscape. For example, if actual fluid residence times exceed the theoretical time required to reach chemical equilibrium, then the solute fluxes are optimized. However, because rivers and streams average over spatial domains that include an array of length scales and fluid residence times, determining the length and time scales that control solute generation has proven difficult. Defining and linking these length and time scales presents a key challenge to fields of geochemistry, geomorphology, biology and hydrology. Yet, if the length and time scales that control solute fluxes could be defined, this knowledge may provide a mechanistic approach for interpreting catchment to global-scale solute fluxes.

A comparison between soil profile solute evolution from stable and eroding landscapes, and concentration-discharge relationships (C-Q) both for small rivers from the U.S. Geological Survey's Hydrologic Benchmark Network (HBN) and large rivers from the Global Environmental Monitoring System (GEMS) database suggests that even with increasing discharge and catchment area, the ratio between the physical and chemical length scales may remain relatively constant. Catchments that show little variability in concentration with discharge (or "chemostatic behavior") are characterized by average fluid residence times that exceed the time required to reach chemical equilibrium. Chemostatic rivers may also represent rivers that are at their optimal solute flux. Conversely, decreases in concentration with increasing discharge are explained by average residence times shorter than required to approach chemical equilibrium, resulting in dilution. In these systems, if fluid residence times increase or chemical equilibration lengths decrease, solute fluxes are expected to increase to the optimum level. The fluid residence time model could provide an alternative framework for assessing both the relationship between discharge and concentration for individual catchments and controls on the solute fluxes of larger rivers. However, more detailed studies of the chemical and physical length and time scales and the development of scaling approaches are necessary to refine the simple model presented here. In particular, the time required to reach chemical equilibrium is perhaps the most poorly constrained variable in the fluid residence time model.

Assessing limitations for PAH biodegradation in long-term contaminated soils using bioavailability assays

NAGISSA MAHMOUDI[1*], GREG SLATER[1] AND ALBERT JUHASZ[2]

[1]School of Geography and Earth Sciences, McMaster University, 1280 Main St. W., Hamilton, ON, Canada (*mahmoun@mcmaster.ca) (gslater@mcmaster.ca)

[2]Centre for Environmental Risk Assessment and Remediation (CERAR), University of South Australia, Adelaide, SA, Australia (Albert.Juhasz@unisa.edu.au)

Polycyclic aromatic hydrocarbons (PAHs) are a class of organic contaminants that are ubiquitous in the environment through the incomplete combustion of organic matter such as diesel, coal and wood as well as being present at industrial sites due to use in a range of industrial processes. Once PAHs enter the environment, the predominant mechanisms for removal are biological via microbial activity, although physiochemical processes such volatilization can reduce the concentration of some PAHs. However, due to their hydrophobic structure, PAHs have the potential to partition onto soil organic matter thereby decreasing their bioavailability to microorganisms and limiting their degradation in the environment. This explanation was felt to be the reason for a lack of evidence of PAH biodegradation in a study of long-term contaminated soils. Instead, natural organic matter was being utilised as a carbon source resulting in the persistence of PAHs at this site [1].

Although biodegradation may be limited by a variety of environmental factors, bioavailability is considered to be a major limitation in contaminated soils. To test the hypothesis that bioavailability was the limiting factor for biodegradation in theses soils, PAH bioavailability was determined using non-exhaustive extraction (propanol, butanol, hydrooxypropyl-β-cyclodextrin) and oxidation (persulfate) methodologies designed to determine the fraction of contaminants within soil which are available for biological uptake [2, 3]. By comparing the initial PAH concentrations to the residual PAH concentrations following each assay, it was determined that the majority of PAHs in the soils were inaccessible to microorganisms which suggested that bioavailability limitations were the primary cause for the lack of observed biodegradation at this site.

These results highlight the importance of bioavailability to PAH degradation as well as the effectiveness of these assays as a rapid, and inexpensive method for determining the endpoints of PAH bioremediation. Such assays have the potential to provide a decision making tool on the suitability of bioremediation for soil treatment with minimal cost and time impacts and high accountability.

[7]Earth and Planetary Sciences, University of California, Santa Cruz, United States

Aerosols play an important role in our understanding of the Earth's climate through direct interactions with atmospheric radiation and indirect interactions by modifying cloud properties. These impacts take place on timescales in the troposphere of days to weeks. Longer timescale impacts of aerosols on climate through biogeochemical feedbacks are less well understood. Aerosols transport mass which may include nutrients or toxins across long distances and have been shown to effect the production of ecosystems that are distant to the aerosol source. The purveyors of these important nutrients are often naturally emitted aerosols such as mineral dust, volcanic ash, or biomass burning aerosols. Natural aerosols have generally received less study than anthropogenic aerosols, but here we use model simulations of preindustrial and present day aerosols to isolate the relative importance of different aerosol types for various climate impacts. Radiative forcings for the different aerosol types are estimated from the literature. We also give estimates for the contributions of various aerosol sources and types to nutrient transport in the atmosphere.

The impacts of aerosols on ecosystem production feedback onto the climate by changing the amount of carbon emitted or sequestered by the affected ecosystem. In addition, aerosols modify the carbon uptake capacity of the land surface and the ocean by altering climate through these biogeochemical effects and the more commonly referenced direct and indirect cloud effects.

Here we present the first quantitative assessment of the total indirect effects of aerosols onto climate through their effects on biogeochemical cycles. The aerosol indirect biogeochemistry effect is found to be similar in magnitude to the aerosol direct effect, with higher uncertainties, and yet the impacts on climate could be even greater because the biogeochemical impacts take place over longer time scales. The cooling influence of the indirect biogeochemical effects suggests that abatement costs for projected CO_2 concentrations could be underestimated. Due to the potential importance for our understanding of the land-atmosphere-ocean coupled climate and for policy, aerosol indirect effects on biogeochemistry warrant greater consideration in studies of aerosol and climate interactions.

Characterization of Corn Rhizosphere (*Zea mays*) Grown in Metal-contaminated Soil

NAHED MAHROUS[1]*, SHEILA MACFIE[1] AND GORDON SOUTHAM[1,2]

[1]Department of Biology, The University of Western Ontario, London, Canada, N6G 5H4, nmahrous@uwo.ca (*presenting author)
[2]Department of Earth Sciences, The University of Western Ontario, London, Canada, N6G 5H4

As industrialization encroaches on agricultural settings, it has become increasingly more important to investigate the microbe-mineral interactions within the rhizosphere. Currently, there is an incomplete understanding of metal contaminants and distribution (i.e., the bioavailability of different forms of metals) in soils that result in the uptake and accumulation in plants [1]. A more focused study on metal concentrations in edible plants is important to avoid possible risks to human health [2]. In this study, the examination of the rhizosphere was made possible by developing a new embedding procedure resulting in successful preservation of the inorganic and organic materials, i.e., structure and chemistry, within the rhizosphere (Figure 1).

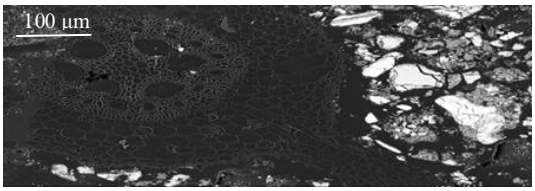

Figure 1: A BSE-SEM micrograph of a soil core containing roots and soil, i.e., rhizosphere.

ICP-AES analysis demonstrated that concentrations of bioavailable metals (Cd, Cu, Pb and Zn) were higher within the rhizosphere than the bulk soil. While the bacterial communities within the bulk soil and rhizosphere were capable of using similar types of carbon for growth, i.e., biodiversity was not affected by the growth of corn, the activity of the bacterial community inhabiting the rhizosphere (measured by using the Biolog Ecoplate™ system) was greater than the soil control. This increase in activity, which was reflected by a decrease in pH in the rhizosphere, can presumably be expected to influence heavy metals uptake by plants. The use of scanning electron microscopy combined with energy dispersive spectroscopy (SEM-EDS) and wavelength dispersive x-ray spectroscopy (SEM-WDS) revealed the presence of particles containing lead (Pb). Under these conditions, the use of micro-synchrotron x-ray fluorescence (micro- XRF), x-ray absorption fine structure (XAFS) and x-ray absorption near edge structure (XANES) are required to probe the spatial and chemical relationships of plant roots and the soils in which they grow.

U(VI) sorption on montmorillonite in the presence of phosphate.

F. MAILLOT[1]*, J.G. CATALANO[1], D.E. GIAMMAR[2]

[1]Earth & Planetary Sciences, Washington Univ., St. Louis, MO 63130, USA, fabien.maillot@wustl.edu (*presenting author), catalano@wustl.edu

[2]Energy, Environmental and Chemical Engineering, Washington Univ., St. Louis, MO 63130, USA, giammar@wustl.edu

Uranium (U) contamination of soils and groundwater is a serious environmental concern due to past mining, processing, and waste disposal activities. In oxidizing environments, U(VI) is the most stable valence state for uranium, occurring in the linear uranyl ion, UO_2^{2+}. Among the in-situ remediation strategies for oxic subsurface environments, phosphate-based treatments have generated significant interest. U(VI) has a strong affinity for phosphate, which can lead to the nucleation of low-solubility U(VI)-phosphate minerals or enhance U(VI) sorption to subsurface minerals via the formation of ternary surface complexes. In addition, U(VI)-phosphate associations are common forms of U(VI) in contaminated soils and sediments at U.S Department of Energy (DOE) facilities, and have been observed in the Hanford 300 Area, the Oak Ridge Reservation, and the Fernald Site. However, the molecular mechanisms controlling U(VI) speciation in heterogeneous phosphate-bearing systems are currently poorly constrained, which hinders the design of efficient remediation strategies and the prediction of uranium transport in treated systems.

Previous work by coworkers in the U(VI)-PO_4^{3-}-goethite (α-FeOOH) system [1] has pointed towards the existence of ternary surface complexes at the goethite surface. The characterization of these species was possible thanks to the use of extended X-ray absorption fine structure (EXAFS) spectroscopy at the uranium L_{III}-edge. Following a similar approach in the present work, we investigated the effect of phosphate on U(VI) sorption on montmorillonite, a dioctahedral 2:1 clay mineral. Montmorillonite was chosen because phyllosilicate clays are a common component of the fine fraction of soils and sediments at many DOE sites. Previous work has also shown that montmorillonite is a strong sorbent for U(VI) [2,3].

In order to identify chemical divides that separate regimes where specific mechanisms (e.g. ternary surface complexation or precipitation of U(VI) phosphates) dominate, we determined U(VI) adsorption isotherms as a function of [PO_4^{3-}], pH, P_{CO2}, and electrolyte cation. To further characterize the nature of U(VI) speciation in these separate regimes, relevant samples were analyzed in more detail using EXAFS and XRD. Besides providing new knowledge of the U(VI)-PO_4^{3-}-montmorillonite system, comparison with the previously studied goethite system will allow determinations of how sorbent structure influences uranium-phosphate reactions in heterogeneous systems, which is fundamental for potential remediation applications involving real soils and sediments.

Abstract

It is generally agreed that microbial respiration drives the release of arsenic from the sediment to water in drinking water aquifers throughout Southeast Asia. This microbial respiration requires organic carbon, and it is this source of organic carbon that is poorly constrained. It has been hypothesized that the carbon could be derived from: 1) young anthropogenic sources, 2) carbon deposited with the sediments, 3) carbon from organic rich peat lenses, or 4) older petroleum byproducts. However, no method is currently available to directly determine the source of organic carbon. In order to better constrain the source of organic carbon we developed a method to determine the radiocarbon signature of microbial DNA and phospholipids fatty acids (PLFAs) from groundwater samples. The radiocarbon signatures of the DNA and PLFA will reflect the source of organic carbon utilized by heterotrophic microbes. For DNA, the method includes filtering over 2,000 liters of groundwater onto a 0.2 µm filter followed by DNA extraction and purification. For PLFAs the method includes filtering over 1,000 liters of groundwater onto a newly developed carbon free filter. The DNA method enables us to collect, extract, and purify over 150 µg of DNA with an absorbance at 260/280>1.8 and an A260/230>2; indicating pure DNA. The new method was utilized at Site F in the Lashkardi Village, Araihazar, Bangladesh. The site represents an area where rapid recharge of anthropogenic carbon might occur. Results indicate that in the Holocene Aquifer the DNA is significantly older than groundwater ages and does not contain modern carbon but is younger than estimated sediment ages. We hypothesize that the carbon in the aquifer is recharged at the water table and is significantly retarded as it is tranported to depth. Further utilization of this novel method should help to better constrain the carbon sources driving arsenic release in the shallow aquifers of Southeast Asia.

Constraining E- and N-type components in Baffin Island picrites

MELISSA MAISONNEUVE[1*], DON FRANCIS[2], AND JOHN STIX[3]

[1]McGill University, Earth and Planetary Sciences, melissa.maisonneuve@mail.mcgill.ca (* presenting author)
[2]McGill University, Earth and Planetary Sciences, donald.francis@mcgill.ca
[3]McGill University, Earth and Planetary Sciences, john.stix@mcgill.ca

The Baffin Island picrites are interpreted to represent primitive magmas (up to ~22 wt% MgO) that are minimally changed since leaving their mantle source. Lead and neodymium-samarium isotopes indicate that these lavas may be melts of a primordial mantle reservoir (~4.45-4.55 Ga). Silicate melt inclusions (MIs) trapped within olivine crystals during their crystallization are considered to be aliquots of their parental melts and thus their compositions provide a unique insight into the geochemical nature of the oldest known terrestrial mantle reservoir.

In this study, the ratio of potassium to titanium (K/Ti) is used as an analog for trace element enrichment as both these elements are incompatible in the olivine and plagioclase phenocrysts present in these lavas. We define depleted glass compositions (N-type) as those with K/Ti < 0.2 and enriched glass compositions (E-type) as those with K/Ti > 0.2, based on an apparent population minimum at ~ 0.2. The N-type MIs are characterized by low K/Ti, La/Lu, Zr/Y and chlorine contents (Cl ≤ 50 ppm) while the E-type MIs appear to be mixtures of two distinct liquids, one a depleted end-member similar in composition to the N-type MIs and the other an enriched end-member characterized by high K/Ti, La/Lu, Zr/Y and chlorine contents (50 ≤ Cl ≤ 200 ppm). The chlorine concentration increases with trace element enrichment in E-type MIs which may indicate a relatively high Cl content in the E-type component. Whereas N-type MIs are hosted in olivines with a narrow range of forsterite contents, from Fo_{89} to Fo_{87}, the E-type MIs are found mostly in olivines with lower Fo contents (Fo_{87}-Fo_{83}), suggesting either the incorporation of the E-type component occurred later in the crystallization history of the N-type magmas or that the E-type component was less magnesian.

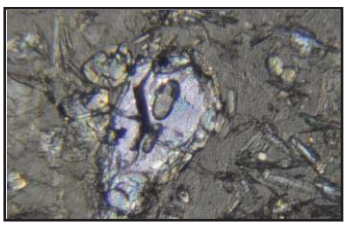

Figure 1: Melt inclusions in olivine crystal. Field of view is approximately 1 mm.

The large variation in K/Ti (0.05 to 0.6) in multiple melt inclusions within single olivine crystals suggests either that the growth of olivine phenocrysts during the magmatic differentiation of the N-type magma records the incorporation of the E-type component, or that the E- and N-type components were intermixed on a fine scale. The presence of two finely intermingled magmatic components in the mantle source of the Baffin picrites implies that Earth's primordial mantle was as heterogeneous as the asthenospheric source of modern-day mid-ocean ridge basalts.

Identity of oxidation products on surface of metallic antimony

FRANTISEK MAJS[1*], ANASTASIA G. ILGEN[1], AMANDA J. BARKER[1,2], THOMAS A. DOUGLAS[2], AND THOMAS P. TRAINOR[1]

[1]University of Alaska Fairbanks, Chemistry and Biochemistry, fmajs@alaska.edu*, anastasia.ilgen@alaska.edu, ajbarker@alaska.edu, tptrainor@alaska.edu

Introduction

Small arms bullets are predominantly made of lead (Pb) but antimony (Sb) is commonly used to harden bullets and can comprise up to 10% of the total mass. The fate of Pb in firing range soils has been investigated in a number of studies while the fundamental geochemical processes controlling the fate of Sb in soils and surface water are largely unknown. Anthropogenic deposition of Sb to soils on military and recreational shooting ranges represents an environmental risk due to Sb toxicity. Oxidation of bullet fragments containing metallic antimony under surface soil conditions ultimately leads to the release of Sb(V) to the soil solution and an accumulation of Sb(V) in soil. While Sb(III) is usually absent from soil solution or contaminated soil, its oxide (Sb_2O_3) precipitates readily during oxidation of Sb(0) under model conditions with deionized water and simulated groundwater. Mechanisms controlling speciation of precipitated Sb_2O_3 as well as relationship between solid and aqueous Sb speciation are not clearly understood.

Methods

The experimental study focused on understanding the effect of common cations (Na^+, Ca^{2+}) on the formation of precipitates on an Sb(0) surface during oxidation in simulated groundwater. Solutions were prepared at fixed ionic stregth (I = 0.01 mol L^{-1}) and a range of environmentally relevant pH values. We compared these results to the same processes in background solutions containing either deionized water or 30% hydrogen peroxide (H_2O_2). We determined the speciation and preferred orientation of the precipitates with grazing incidence x-ray diffraction and texture measurements, respectively. Results of the laboratory experiments were compared to Sb(0) weathered under field conditions in soils of varied texture and pH.

Results and Conclusion

The surface of Sb(0) oxidizes rapidly and within 24 hours we observed the formation of cubic and orthorhombic polymorphs of Sb_2O_3 (senarmontite and valentinite) of which valentinite exhibited strong preferential orientation with the *a* axis normal to the Sb(0) surfaces. An oxidation end member, hydrated Sb_2O_5, precipitated on Sb(0) surfaces only under the extremely oxidizing conditions of the H_2O_2 solution. The valentinite fraction in the precipitate increases with increasing solution pH but no measurable difference in speciation was found between Na^+ and Ca^{2+} background solutions. Drawing a connection between environmental conditions like soil pH and Sb(0) oxidation mechanisms helps to predict the fate of spent bullets and assists land managers in identifying appropriate soils to use in constructing new shooting ranges.

Thermodynamic prediction of aqueous As concentration in scorodite-rich tailings

JURAJ MAJZLAN

Institute of Geosciences, Burgweg 11, Friedrich-Schiller University, D-07749 Jena, Germany, Juraj.Majzlan@uni-jena.de

Hydrometallurgical processing of As-rich ores for the extraction of gold or other metals produce voluminous fine-grained, As-rich waste which is disposed of in the tailing ponds and stored in these facilities over a long time. Under predominantly acidic conditions, the principal As carrier in these tailings is the mineral scorodite, $FeAsO_4 \cdot 2H_2O$. Field and laboratory studies revealed a wide variation of the aqueous As concentrations in such tailings or in aqueous solutions with scorodite. This study explains these concentrations and their large scatter by thermodynamic modelling of scorodite-rich waste.

For the calculations, we have used recently measured or estimated thermodynamic properties from our work of As-rich hydrous ferric oxide (As-HFO) [1], scorodite [2], crystalline iron oxides goethite and lepidocrocite [3], and ferrihydrite [4].

At pH < 2.5, scorodite dissolves congruently and controls and aqueous As concentrations in the tailings. In this region, most of the experimental studies agree with respect to the measured and predicted As concentrations.

Above pH of ~2.5, Fe^{3+} phases (As-HFO, goethite, lepidocrocite, ferrihydrite) will start precipitating. These reactions drive the aqueous Fe^{3+} concentration down, force further dissolution of scorodite, and hence elevate the aqueous As^{5+} concentration. As each of these phases has a different stability in the environment of the tailings, the influence of each phase on the Fe^{3+} and As concentration is different. Yet, we show that the majority of the scattered experimental measurements fall into the field defined by the models where scorodite dissolves and Fe oxides precipitate. This field is bound for the curves which represent the scorodite-goethite (scorodite dissolves, goethite precipitates) and scorodite-ferrihydrite model. These two phases are expected to constitute the boundaries of the field because goethite is the most stable and ferrihydrite the least stable phase in the system.

Hence, using our data and models, we can reconcile all published experimental and field data with the thermodynamic values for the participating phases. We can also show that the As concentrations is likely to change in time as the Fe oxides age and transform to more stable phases or phase assemblages.

Abstract

This current study is associated with the Greenland Analogue Project (GAP), an international collaboration between the Nuclear Waste Management Organization (Canada), Posiva (Finland), and SKB (Sweden). The objective of this project is to further understand groundwater evolution in bedrock as influenced by the presence of a continental ice-sheet. Physical and chemical characteristics of secondary minerals within fracture networks in the bedrock were examined to provide insights into paleo-hydrological processes (e.g. hydrothermal, metamorphic, or glacial events).

Two boreholes were drilled into granitic gneiss near the margin of the Greenland ice-sheet. The first was drilled beneath a talik lake and instrumented to sample groundwater (GAP01). The second borehole was drilled to ~350 m to determine the depth of the permafrost (GAP03). Preliminary results, specifically, carbon ($\delta^{13}C$) and oxygen ($\delta^{18}O$) isotope geochemistry of carbonate fracture fillings, are now available (Fig. 1). Calcite analyses reveal a vertical $\delta^{18}O$ trend in the GAP01 borehole, indicative of hydrothermal carbonates. This is further corroborated by the ^{18}O depleted dolomite in that borehole. Dolomite in the GAP03 borehole corresponds to a fracture filling that is coated with a thin layer of calcite (arrow identifies isotopic signature in Fig.1), indicative of two different crystallization events based on the large difference in $\delta^{18}O$ values.

Ongoing fluid inclusion studies are anticipated to elucidate minimum carbonate mineral crystallization (trapping) temperatures and fluid salinities. Formation temperatures are used to calculate the isotopic composition of the parent fluids from which these carbonates precipitated. Estimates for $\delta^{13}C$ of DIC and $\delta^{18}O$ of paleo-fluids are powerful tools to distinguish meteoric or glacial water from fluids that have been subjected to water-rock interaction.

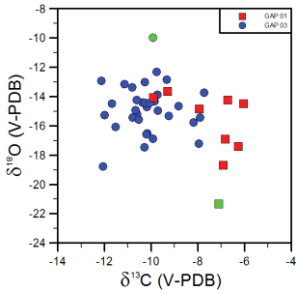

Figure 1: $\delta^{13}C$ and $\delta^{18}O$ isotope signatures of carbonates sampled from Greenland core - calcite (red and blue) and dolomite (green).

Detrital zircons from the Higo and Abukuma metamorphic terranes, Japan: implication for the sediment provenance

KENSHI MAKI[1*], MAYUKO FUKUYAMA[2], KAZUHIRO MIYAZAKI[3], TZEN-FU YUI[4], KUO-LUNG WANG[4], TADASHI USUKI[4], TAKAFUMI HIRATA[1], AND MARTY GROVE[5]

[3]Geological Survey of Japan, AIST, Tsukuba, Japan
[4]Academia Sinica, Taipei, Taiwan
[5]Stanford University, Stanford, California, USA

In the Cretaceous low-pressure and high-temperature metamorphic terranes of Japan, the Higo (south-west Japan) and Abukuma (north-east Japan) metamorphic terranes are characterized by the occurrences of peraluminous metapelitic rocks and impure marbles, and absence of chert, and zircon U-Pb age of ca. 260Ma, suggesting that these terranes might be the eastern extension of the North China-South China collision zone [1,2,3,4]. However, new results of our zircon SHRIMP and LA-ICP-MS U-Pb dating do not necessary support the possibility of eastern extension of the North China-South China collision zone. Lu-Hf isotopic data for the detrital zircon may imply that the possible provenance for the Higo and Abukuma metamorphic terranes is the South China Craton.

The metamoprhic age of ca. 260 Ma could not be replicated from the Higo and Abukuma metamoprhic terranes in this study. Detrital zircons from the Higo and Abukuma metamorphic terranes show an age peak around the Carboniferous to early Jurassic, wchich is agree with previous works [5,6; i.e. 330 to 184Ma and 280 to 200Ma, respectively]. These lines of evidence may imply that the age of ca. 260 Ma shows a protoligh age for the metamoprhic terranes. Moreover, the Permian-Triassic detrital zircons from the Higo metamorphic terrane are characterized by positive $\varepsilon Hf_{(T)}$ values ($+7 < \varepsilon Hf_{(T)} < +10$) with high Th/U ratio ($0.2 < Th/U < 0.5$). Many Permian-Triassic granites are present within the Yangtze and Cathaysia Blocks of the South China craton [7], and zircons with positive $\varepsilon Hf_{(T)}$ values were found in the Permian-Triassic felsic rocks of the Emeishan large igneous province [8]. We concluded that the provenance for the Higo and Abukuma metamorphic terranes may be indicative of the South China Block implying that they may not be the eastern extension of the North China-South China collision zone.

The spinel structure of magnetite has potential to carry unique chemical and petrographic signatures imposed by compositional and physico-chemical conditions during crystallization and subsequently during metamorphism or weathering. The chemical composition of detrital magnetite is applicable in provenance studies, in particular for mineral exploration. Its ubiquity in mineral deposits, its resistance to weathering and abrasion, and ease of magnetic separation have led magnetite to be considered an indicator mineral. This study aims to determine the usefulness of chemistry and petrographic features of detrital magnetite in mineral exploration in glaciated terrain. A total of 186 grains from the 0.18-2.0 mm ferromagnetic fraction of till deposited down-ice of the Halfmile Lake VMS deposit (Bathurst Camp) were investigated. To find out the effect of erosion of surrounding lithologies on the formation of till, 176 grains from hostrocks and magnetite alteration zones in the area were examined. Mineral grains were liberated from rocks using a small plate crusher. Minor and trace elements of the grains in till and bedrock (K, Ca, Al, Si, Ti, Mg, Mn, Cr, V, Cu, Zn, Ni) were measured using the Electron Probe Micro-Analysis. Various plots of these elements show that till samples generally form a cluster of very similar compositions that are different from magnetite in the Halfmile deposit country rocks especially because of their lower Si and higher Ti and V content. Electron microscopy and Mineral Liberation Analysis (MLA) are also applied to study these till and bedrock grains to evaluate relationships between mineralogy, abundances and associations of minerals. Results indicate that up to 90 percent of magnetite in both till and country rocks are polymineralic, and that detrital magnetite is Ti-bearing and is most often accompanied with titanomagnetite, ilmenite and hematite. In the Halfmile deposit bedrock samples, in contrast, magnetite is mostly in association with sulfide and/or silicate minerals. These heterogeneities in composition and mineral associations of till and most of rock samples suggest that magnetite in till is largely derived from distant sources. Detrital magnetite shows the greatest chemical similarities with magnetite from nearby granitic rocks.

Geochemical characterization of mineralized groundwaters in the Aquitaine Basin (SW France): lateral and vertical variability of the Eocene formations, hydrodynamic and geochemical processes of acquisition of the mineralization.

ELINE MALCUIT[1,3*], PHILIPPE NEGREL[2], EMMANUELLE PETELET-GIRAUD[2], OLIVIER ATTEIA[3], MICHEL FRANCESCHI[3], ALAIN DUPUY[3]

Section Heading: 22a. Tracing groundwater variability

In the sedimentary Nord Aquitaine Basin (SW France), the large Eocene aquifer, mostly confined, is one of the main resources for drinking water. In this aquifer, a large saline area has been identified, where the groundwaters show high values of mineralization and anomalous levels of critical elements, such as sulfates and fluoride, leading to difficulties of resource exploitation for drinking water supply. Geochemical and isotopic characterization of withdrawn groundwaters shows a common origin of the mineralization.

The Eocene aquifer formations include several geological layers, which have different lithological, mineralogical and hydrodynamic properties. Since the beginning of the century, many boreholes in the area for drinking water supply have locally modified the natural water flows of the system. Our investigation shows the need for a precise and detailed knowledge of the vertical distribution of the hydrodynamic and geochemical properties of each layer. Indeed, the average concentration in the borehole water depends on the centimetre scale variation of water fluxes and concentrations. Geochemical models fully explain the composition of groundwaters across the study area and improve the understanding of geochemical processes taking place at the borehole scale.

To understand the acquisition of the groundwaters' geochemistry, it is necessary to consider the lateral and vertical variations in facies and mineralogy, geochemical processes (mineral dissolution and/or precipitation, phenomenon of diffusion in contact with low permeability and mineralized layers) and local fluid mixing processes within the borehole and its immediate surroundings.

Cu-isotope systematic of magmatic PGE-Cu-Ni sulfide ores from the Talnakh and Kharaelakh intrusions, Noril'sk Province (Russia)

KRESHIMIR N. MALITCH[1*] AND RAIS M. LATYPOV[2]

[1]Institute of Geology and Geochemistry of the Uralian Branch of Russian Academy of Sciences, Ekaterinburg, Russia, dunite@yandex.ru (* presenting author)
[2]Department of Geosciences, University of Oulu, P.O. Box 3000, Oulu, Finland, rais.latypov@oulu.fi

We have undertaken for the first time the examination of the Cu isotope composition of primary high temperature Cu-Ni sulfde ores from world-class PGE-Cu-Ni sulfide deposits associated with the economic Talnakh and Kharaelakh intrusions and native copper ores from the Noril'sk Province (Russia). Copper isotope ratios are reported as $\delta^{65}Cu‰=((^{65}Cu/^{63}Cu_{sample}/^{65}Cu/^{63}Cu_{NIST\ 976\ standard})-1) \times 10^3$. The isotope measurements were carried out with an MC ICP-MS (ThermoFinnigan Neptune) using sample-standard bracketing as outlined by Larson et al. [1].

Main set of samples of this study form three major $\delta^{65}Cu$ clusters that well match $\delta^{65}Cu$ signatures of two distinct reservoirs as defined for iron meteorites and carbonaceous chondrites, respectively [2-4]. The mean $\delta^{65}Cu$ value of massive sulfide ores at Talnakh forms the first cluster around zero ‰ (-0.1 ± 0.15 ‰, respectively), close to the $\delta^{65}Cu$ signatures of the Bulk Earth and iron meteorites. Similarly, the mean $\delta^{65}Cu$ value of disseminated sulfide ores at Talnakh forms the second cluster around –0.7 ‰ (–0.7 ± 0.4 ‰), matching that of the carbonaceous chondrites. The third cluster with the mean $\delta^{65}Cu$ values, represented by massive and disseminated ores of the Kharaelakh intrusion (-1.52 ± 0.24 ‰ and -1.6 ± 0.4 ‰, respectively) lie very close to the light-isotope end of the $\delta^{65}Cu$ range expressed by the carbonaceous chondrites. A $\delta^{65}Cu$ value measured in a sample and a replicate represented by native copper from the Arylakh deposit of the Noril'sk Province gave indistinguishable result of -1.9±0.15 ‰.

The determined $\delta^{65}Cu$ variability is interpreted to represent a primary signature of the ores, though a magmatic fractionation of copper isotopes and/or assimilation of the ore material from external source (in case of the Kharaelakh ores) can not be ruled out.

The study was supported by the Academy of Finland (grant No. 131619) and the Uralian Division of Russian Academy of Sciences (12-U-5-1038).

Hafnium isotopic compositions of Abyssal Peridotites from the Southwest Indian Ridge

SOUMEN MALLICK[1], MICHAEL BIZIMIS[1,2*]

[1]University of South Carolina, EOS, smallick@geol.sc.edu, [2]mbizimis@geol.sc.edu (* presenting author)

We report Hf isotopic compositions of clinopyroxene mineral separates from abyssal peridotites from the 9-25° E segment of the Southwest Indian Ridge (SWIR). Peridotites from 15.4° E are plagioclase-free with low Na-Ti abundances and depleted chondrite normalized REE patterns in clinopyroxene (cpx) suggesting residual characteristics, The cpx show a limited variability and plot at the radiogenic end of the MORB field in Nd-Hf isotope space (ε_{Nd} ~ 13.1, ε_{Hf} ~ 18.5), consistent with the estimates for the DMM reservoir. However these peridotites are more radiogenic than spatially associated SWIR basalts, suggesting the presence of an enriched component in the source of these basalts. A regression line through these peridotites and co-located basalts in ε_{Nd}-ε_{Hf} space has a slope of 1.21 (R^2 = 0.94), similar to the slope of mantle array, suggesting that the enriched component must lie within the mantle array. The un-radiogenic extension of the regression line in ε_{Nd}-ε_{Hf} space passes close to the proposed local enriched endmember, similar to the Bouvet hotspot lavas. Assuming a Bouvet-like enriched composition in the source of the SWIR mantle, maximum 40% of the Hf budget in the basalts is contributed from the depleted peridotites (15.4° E), which translates to a maximum of 10% enriched component in the basalt source. In contrast, peridotites from 9.98° E and 16.64° E have relatively high Na-Ti contents, high LREE/HREE ratios and are often plagioclase bearing, suggesting re-fertilization. The cpx from both locations plot towards the un-radiogenic end of MORB field (ε_{Nd} = 4.8-7.9 ε_{Hf} = 9.9-14.2). They are however distinct in Nd-Hf space and overlap with their co-located basalts. The above data is consistent with variable degree of equilibration between these peridotites and local basalts. Model calculations show that 4% addition of local basalts-like melt to the most depleted (15.4° E) local peridotites can explain the Nd and Hf isotopic compositions of re-fertilized 9.98° E and 16.64° E peridotites, however, this estimate does not match the REE patterns of the re-fertilized peridotites. This could indicate that local melts have reacted with a protolith, which is a residue of variable degree of melting but has an Nd-Hf isotope ratio similar to 15.4° E peridotites.

The high Sm-Nd and Lu-Hf ratios of the depleted peridotites (15.4° E) combined with their DMM-like Nd and Hf isotopes suggest recent depletion of a DMM – type mantle, likely related to recent melting underneath the SWIR. This observation is in contrast to the recently reported highly radiogenic Hf isotopic compositions (ε_{Hf} up to 291) of abyssal peridotites from the Gakkel Ridge, which have been interpreted to reflect an ancient (> 1Ga) depletion and melt-rock interaction processes. Our observation, together with Gakkel Ridge peridotites indicates that earth's mantle is more heterogeneous than basalts suggest and investigation of Nd-Hf isotopic compositions of abyssal peridotites from other areas will help us to better constrain the upper mantle composition.

Genesis of alkaline magmas by reaction of MORB-eclogite derived carbonated melt with lherzolite

ANANYA MALLIK*[1], RAJDEEP DASGUPTA[1] AND VAIBHAV MISHRA[1]

[1]Rice University, Houston, TX, USA (*am33@rice.edu)

Ocean island lavas such as HIMU basalts are silica-undersaturated [1] and present evidence of recycled oceanic crust in their mantle source. Partial melts of neither volatile-free peridotite nor subducted oceanic crust (MORB-eclogite) can explain the degree of silica-undersaturation and high TiO_2 and high MgO, respectively of HIMU lavas. While reaction of MORB-eclogite derived, volatile-free melts with peridotite produce alkalic basalts at low melt-rock ratios [2], the reacted-melts are not low enough in SiO_2 and Al_2O_3 and high enough in FeO* and CaO to explain most of the HIMU lavas. Here we explore whether MORB-eclogite derived CO_2-bearing partial melts and volatile-free peridotite reaction can generate the required chemical attributes for primary HIMU-type magmas.

Reaction experiments were performed between lherzolite KLB-1 and two different MORB-eclogite-derived partial melts – (1) an alkalic melt with 8.5 wt.% CO_2 (G2CPM1; [3]) and (2) a basaltic andesite with 2 wt.% CO_2 (G2CPM2) – at 1375 °C, 3 GPa, a condition which is above the respective liquidii of both the melts but below the solidus of peridotite. The amount of melt, mixed homogenously with peridotite, was varied from 8 to 50 wt.%. In all the experiments, the original melt underwent partial reactive crystallization, leading to CO_2-enrichment in the reacted melt in equilibrium with a residue of garnet lherzolite to garnet-bearing olivine websterite. Reaction of G2CPM1-KLB-1 produced reacted melts which, on a volatile-free basis, show a decrease in SiO_2 from ~37 wt.% to ~35 wt.%, Al_2O_3 from ~7 wt.% to ~6 wt.%, FeO* from ~17 wt.% to ~12 wt.%, Na_2O from ~6 wt.% to ~3 wt.% and increase in TiO_2 from ~6 wt.% to ~8 wt.%, MgO from ~15 wt.% to ~21 wt.%, and Mg# from ~62 to ~75 with decreasing melt-rock ratio. The reacted melts produced from 25-33 wt.% G2CPM2 have ~39 wt.% SiO_2, 8.5-9.5 wt.% Al_2O_3, >10.5 wt.% FeO*, 15.4-16.5 wt.% MgO, 9-10 wt.% CaO, and Mg# of 72-73.

We demonstrate that carbonated MORB-eclogite derived mildly alkalic melt evolves to more primitive, strongly alkalic compositions with variable melt:peridotite ratio. More importantly, an andesitic melt with only 2 wt.% CO_2 evolves to melts similar to melilititic, nephelinitic, and HIMU lavas. At a given MgO content, the reacted melts evolved from G2CPM2 are a better match for alkaline ocean island lavas in terms of SiO_2, Al_2O_3, FeO*, CaO, and MgO as compared to partial melts of carbonated peridotites and eclogites. We suggest that percolative flow of siliceous or mildly alkalic carbonated melts in a subsolidus peridotitic mantle is a widely occurring process, causing partial reactive crystallization of the original melts and leading to formation of primary alkalic magmas. The reacted melts have the potential to erupt as alkalic OIBs or to act as metasomatic flux to shallower source regions.

[1]Kansas State University, Manhattan, KS, USA, mssankar@ksu.edu (* presenting author)

[2]Tulane University, New Orleans, LA, USA

[3]Virginia Water Resources Research Center, Virginia Tech, Blackburg, VA, USA

The assessment of incidence of arsenic (As) and the other major ions is evaluated in the groundwaters of Murshidabad, West Bengal. This work is executed over an area of about ~497 km^2. Water samples were collected from 39 hand pumped tube wells (~90-110ft), 9 ponds and 6 irrigation wells (~60-80ft) along with 4 sediment cores (~150ft) from these sites. Field sites are located east and west of the river Bhagirathi, a tributary of the river Ganges, flowing N-S through Murshidabad. The western part of Bhagirathi river is mainly occupied by Suja formation, older alluvium of Pleistocene age (oxidized ferruginous sand, silt and clay with caliche), whereas the eastern part of the river is occupied by Bhagirathi Ganga formation, newer alluvium of Holocene age (sand, silt and clay).

Comparative study of major water quality parameters reveal high As (10->500ppb) and low Mn (0.1-1.6ppm) in the areas like Beldanga, Hariharpara (east bank of the river) while low As (0-30ppb) and higher Mn (0.2-8ppm) is found in Nabagram, Kandi (west bank of the river). DO, NO_3^- and NH_3 do not show appreciable variation among the high and low As areas and they range from 1.5-5ppm, 0-2.7ppm and 0-0.06ppm respectively. TDS and conductivity do not show considerable variation among the high and low As areas and range from 0.001-6.2g/l and 2.6-988 µS/cm respectively. High As areas show a pH of 4.5-7.8 while pH in the low As areas is 5.1-8.2. Alkalinity values range from 10-18 mg/l at high and 10-180mg/l at low As areas. PO_4^{3-} values of high As areas range 0.2-11ppm and at low As areas the range is 0.3-1.3ppm. Cl^- values are higher at low As areas (40-148ppm) and lower at high As areas (10-60ppm). Fe^{2+} values at high and low As areas are 0.05-6ppm and 0.1-1.4ppm respectively. Analyses show positive correlation of arsenic with Fe^{2+}, PO_4^{3-} and TDS content in most of the high As areas, whereas the Mn and Cl^- ions are negatively correlated with high As in most areas. During field work it is observed that there is good correlation between tube well platform color and high As concentration areas which agrees with a recent study near Chakdaha, south of Murshidabad [2]. Stable isotope data from our sites show that groundwaters of this region are directly recharged by local precipitation without significant evaporation [3]. Organic matter within aquifer sediments drive dissimilatory iron reduction reaction and thus release As to the ground water [3].

The effect of Li on pegmatitic textures – experimental results

VICTORIA MANETA[1*] AND DON R. BAKER[1]

[1]McGill University, Earth and Planetary Sciences, Montreal, Canada, viktoria.maneta@mail.mcgill.ca (* presenting author), don.baker@mcgill.ca

Introduction

According to the most prevalent models that explain the genesis of pegmatites, crystallization takes place after appreciable liquidus undercooling in a medium rich in fluxing components, such as H_2O, B, F and P [1, 2, 3]. The present study examines the potential of Li as another fluxing agent and its effect on the formation of pegmatites.

Pegmatitic textures are developed in experimental samples that contain a starting material of common granitic composition, but enriched in Li_2O, 3% seed crystals of K-feldspar, albite and quartz, and varying amounts of H_2O. The experimental procedure involves initially heating the samples in a piston-cylinder apparatus to 1000˚C and 550 MPa for 1 hr, followed by cooling at 50˚C/min to temperatures from 600 to 900˚C and 500 MPa and keeping those conditions constant for 100 hrs.

The results show the formation of graphic intergrowths between quartz and K-feldspar that closely resemble the ones encountered in pegmatites. Additionally, numerous K-feldspar crystals exhibiting spherulitic and skeletal morphologies are formed in the experimental samples, suggesting rapid growth rates for the crystals that grow in the Li-enriched medium. The growth rates measured for the K-feldspar in the samples range from approximately 5 x 10^{-11} m s^{-1} to 2 x 10^{-9} m s^{-1}. Experiments conducted under the same conditions but with Li-free starting material do not exhibit the same tendency.

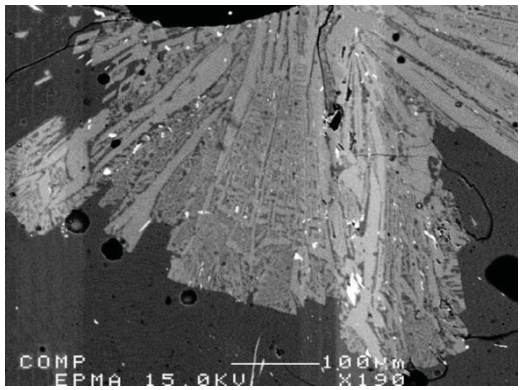

Figure 1: Graphic intergrowth between K-feldspar and quartz developed experimentally (2% added Li_2O, 12% added H_2O, P=500 MPa, T= 600˚C, t=100 hrs)

Conclusion

The experimental results indicate that the presence of Li in the system promotes the fast growth of crystals as well as the development of graphic quartz-feldspar intergrowths, both typical characteristics of pegmatites.

Response of methanogenic communities to glacial-interglacial climate changes in the Siberian Arctic

K. MANGELSDORF[1*], J. GRIESS[1,2], A. GATTINGER[3] AND D. WAGNER[1]

[1]GFZ Potsdam, Telegrafenberg, D-14473 Potsdam, Germany, K.Mangelsdorf@gfz-potsdam.de (* presenting author)

[2]AWI Potsdam, Telegrafenberg, D-14473 Potsdam, Germany

[3]Helmholtz Centre Munich, Ingoldstädter Landstr. 1, D-85758 Oberschleissheim, Germany

Introduction

The Arctic has gained specific attention within the current debate on climate change. With the thawing of permafrost large amounts of stored carbon become accessible again for microbial degradation and will form a potential source for the release of CO_2 and methane to the atmosphere having a positive feedback on the global warming. Therefore, it is of specific interest to understand the microbial driven greenhouse gas dynamics of the Siberian Arctic and their response to glacial-interglacial changes in the past.

Sample material was drilled on Kurungnahk Island (Russian-German expedition LENA 2002) located in the southern part of the Lena Delta and in lake El'gyggytgyn (ICDP-project) in Northeast Siberia. The Kurungnahk samples comprise Late Pleistocene to Holocene deposits, whereas the lake El'gyggytgyn samples cover Middle to Late Pleistocene sediments. Samples were investigated applying a combine biogeochemical and microbiological approach.

Results and Conclusion

The methane profile of the Kurungnahk core reveals highest methane contents in the warm and wet Holocene and Late Pleistocene (LP) deposits and correlates largly to the organic carbon (TOC) contents. Archaeol concentrations, being a biomarker for past methanogenic archaea, are also high during the warm and wet Holocene and LP intervals and low during the cold and dry LP periods. This indicates that part of the methane might be produced and trapped in the past. However, biomarkers for living microorganisms (bacteria and archaea) and microbial activity measurements of methanogens point, especially, for the Holocene to a viable archaeal community, indicating a possible *in-situ* methane production. Furthermore, warm/wet-cold/dry climate cycles are recorded in the archaeal diversity as revealed by genetic fingerprint analysis.

In contrast to the results from the Kurungnakh core, in general the bacterial and archaeal biomarker profiles from the lake El'gygytgyn deposits reveal no distinct glacial-interglacial variability. This might be due to the fact that the overlying lake water buffers the temperature effect on the lake sediments which never became permafrost. The microbial abundance rather correlates to the TOC contents in the sediments forming the accessible carbon and energy source for the indigenous microbial communities. Also the diversity of methanogenic archaea, being still active in 400 ka old sediments, appears to vary with the organic carbon content. TOC-rich lake intervals seem to sustain a divers microbial ecosystem independent from glacial-interglacial climate cycles.

Oxygen and di-nitrogen (N_2) dynamics in the hypoxic zone of the St-Lawrence Estuary

[5]University Southern Denmark, Odese, Denmark

Di-nitrogen (N_2) is the terminal end product of denitrification and annamox, microbial processes that eliminates fixed-Nitrogen (N) from ecosystems. N loss is critical given the key role of N in coastal eutrophication. The Lower St-Lawrence Estuary (LSLE) is a heavily stratified ecosystem, where persistent hypoxic conditions have established and steadily increased over the last 80 years. In order to estimate fixed-N loss, we tracked the change in N_2 concentrations along an isopycnal that progressively loses oxygen as it moves landward from the Laurentian Channel into the LSLE. We found a very strong relationship between N_2 excess and the O_2 deficit in the LSLE, where excess N_2 could be predicted linearly from AOU with an r^2=0.84. We estimate fixed-N losses from the change in N_2 excess along the isopycnal of around 685-1370 μmol N m^{-2} d^{-1}. Compared with other methods estimating fixed-N loss, we found that our lower estimate corresponds with the higher estimates determined in core incubations, whereas our higher estimate, corresponds to the lower estimate as predicted using N*. Using excess N_2 represents however the most integrative approach at the basin scale.

Geochemical, mineralogical and geomechanical effects of impure CO_2 on reservoir sandstones during the injection and geological storage: an experimental approach

HERWIG MARBLER[1], MICHAEL SCHMIDT[1], KIRSTEN P. ERICKSON[1], CHRISTOF LEMPP[1], AND HERBERT PÖLLMANN[1]

[1]Martin-Luther-University Halle-Wittenberg, Institute for Geosciences, Von-Seckendorff-Platz 3, 06120 Halle, Germany herwig.marbler@geo.uni-halle.de

Within the German national project COORAL* the behaviour of reservoir rocks from deep saline aquifers during the injection and geological storage of CO_2 with inherent impurities such as SO_X and NO_X is studied in laboratory experiments. Samples are taken from sandstone outcrops of possible reservoir formations of Rotliegend and Bunter Sandstones from the North German Basin. A combination of geochemical/mineralogical alteration experiments and geomechanical tests was carried out on these rocks to study the potential effects of the impurities within the CO_2 pore fluid. Mineralogical alterations were observed within the sandstones after the exposure to supercritical (sc)CO_2 with SO_X/NO_X and brine, mainly of the carbonatic, but also of the silicatic cements, as well as of single minerals. Besides the partial solution effects, secondary mineral precipitations of carbonates and subsidiary silicates were observed within the pore space of the treated sandstones. The evaluation of the chemical composition of the reaction fluid during the course of the autoclave experiments also indicate that dissolution and precipitation processes occur in the system fluid/rock/gas. The alterations affect the porosity and permeability of the treated sandstones and also weaken their grain structure. Results of geomechanical experiments on untreated samples indicate that the rock strength as well as the amount of injected $scCO_2$ is influenced by the chemical composition of the pore pressure fluid ($scCO_2$ + SO_X/NO_X). After long-term autoclave treatment with impure $scCO_2$, sandstone samples exhibit reduced strength parameters and modified deformation behaviour compared to untreated samples.

* The project "COORAL" ("CO2 Purity for Capture and Storage"; acronym derived from German project title) is supported by the German Federal Ministry of Economics and Technology on the basis of a decision by the German Bundestag. Third-party funding: Alstom, EnBW, E.ON, Vattenfall Europe, VNG.

Systematics of biodegradation of sulfur compounds in heavy oil reservoirs

MARCANO N.[1], OLDENBURG, T.B., MAYER, B[1].

AND LARTER S[1].

[1]University of Calgary, Department of Geoscience, Calgary, Canada

The growing trend of producing and refining large volumes of high-sulfur content petroleum leads to a need for exploring new ways of meeting environmental regulations regarding the allowable sulfur emissions and sulfur content of petroleum derivatives. Biodesulfurization is one of the new technologies currently being considered [1,2]. In this study, we use a natural biodegradation site to examine the systematics of biodegradation of sulfur compounds in oil at reservoir conditions. The biodegradation of alkylbenzothiophenes (alkylBT) and alkyldibenzothiophenes (alkylDBT) were investigated in oil columns with progressively biodegraded oil from top to bottom, using gas chromatography mass spectrometry and sulfur isotopic compositions of bulk oil and oil fractions. The concentrations of alkylBT and alyklDBT decrease from hundreds of ppm to almost complete removal in biodegraded oil columns with different ranges of biodegradation levels. The order of sensitivity to biodegradation was found to be generally dibenzothiophene (DBT), dimethylBT (DMBT) > trimethylBT (TMBT) > methylDBT (MDBT) > dimethylDBT (DMDBT). The preferential removal or preservation of some of the isomers gives insights into reaction mechanisms. Changes are also seen in alkylated high molecular weight S and mixed SNO species observed using Fourier Transform Mass Spectrometry (FTICRMS), providing evidence for dealkylation of even very high molecular weight S bearing species. Despite multiple changes at the molecular level in the thioaromatic and NSO fractions, the bulk sulfur content of the oil did not change significantly in the studied oil columns. The $\delta^{34}S$ values of bulk oil also did not change systematically with increasing biodegradation of sulfur compounds, while slight variations in the oil thioaromatic and asphaltene fractions may be related to the microbial alteration process. We propose a route forward for studying the natural and industrial scale sulfur systematics of biologically altered crude oils.

Making sense of large sets of XANES spectra

MATTHEW A. MARCUS[1*], THOMAS LENOIR[2], PHOEBE J. LAM[3], ALAIN MANCEAU[2]

[1]Advanced Light Source, Lawrence Berkeley Laboratory, Berkeley CA USA mamarcus@lbl.gov

[2]University of Grenoble 1 and CNRS Grenoble, France, thomas.lenoir@ifsttar.fr; manceau@ujf-grenoble.fe

[3]Department of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, USA, pjlam@whoi.edu

Natural materials are often heterogeneous, and must be sampled at many points to be understood. We demonstrate new PCA-based statistical techniques for estimating the number of end-member components required to describe a dataset. Also, we have developed a visualization tool which allows us to examine projections of the multidimensional dataset in such a way as to gain clues to the underlying statistical structure of the data. We show the example of the XANES analysis of Fe-bearing suspended marine particles from two regions, 214 spectra from particles collected in the Northwest Pacific, and 126 from the Southern Ocean. The data from the NW Pacific require more components to describe than those from the Southern Ocean. As shown in Figure 1, a well-chosen projection can let one identify distinct clusters of spectra having distinct features.

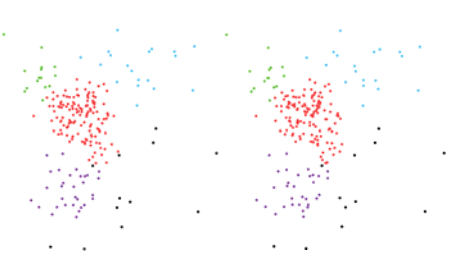

Figure1: Stereogram of 3D projection of the first 6 PCA components of the NW Pacific dataset, with groups of spectra colored in. Each dot represents one XANES spectrum, and nearby dots correspond to similar spectra.

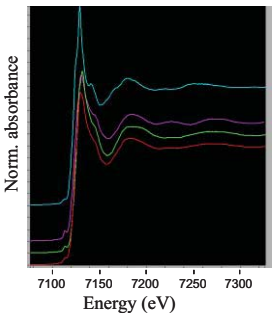

Figure 2: Averaged XANES spectra for the clusters shown above. The colors correspond to those in Figure 1.

Least-squares fits to the spectra shown in Figure 2 indicate clays+poorly-crystalline Fe oxyhdroxide (red), oxidized phyllosilicates (green), biotite+chlorite+clay (cyan) and magnetite+Fe^{2+} silicate+ Fe oxyhdroxide (purple).

Conclusion

Statistical tools can allow one to see patterns in data which would otherwise be invisible when examining spectra individually. We demonstrate how a complex XANES dataset can be simplified so that important characteristics such as dominant minerals and their distribution may be identified.

In situ Fe and multiple S isotope analyses of an Archean pyrite nodule

JOHANNA MARIN-CARBONNE[1,2*], CLAIRE ROLLION-BARD[3], AXEL HOFMANN[4], EMILIE THOMASSOT[3], KEVIN MCKEEGAN[1], ANDREY BEKKER[5] AND OLIVIER ROUXEL[6]

[6]Universite de Bretagne Occidentale, Ifremer, Brest, France, olivier.rouxel@univ-brest.fr

Studies of Fe and multiple S isotope composition of sedimentary pyrites have placed important constraints on the chemistry and the redox evolution of the ocean and the atmosphere over the geological time [1,2,3]. Additionally, Fe isotopes have been explored as a proxy for microbial metabolism [2]. Pyrite in black shales is predominantly formed either in the water column or during early diagenesis close to the sediment-water interface and so potentially records chemical evolution of the ocean. Previous studies mostly used bulk samples, although individual pyrite nodules often show complex internal textures such as concentric lamination. Large isotopic variability within individual nodules has been shown for S isotopes [4] but not yet for iron isotopes.

We have performed coupled situ Fe and multiple S isotope analyses of a pyrite nodule hosted by c. 2.7 Ga black shale from Zimbabwe. This mm-size nodule is composed of pure pyrite. Fe isotopes were measured with ims 1270 ion probes at both UCLA and CRPG [5]. We also performed multiple S isotope measurements with the ion probe ims 1280 HR2 at CRPG. The measurements performed at CRPG and UCLA are in agreement with a reproducibility better than 0.2 ‰ (2σ) in δ^{56}Fe. Reproducibility for δ^{34}S is ~ 0.2 ‰ (2 σ) and ~ 0.1 ‰ (2 σ) for Δ^{33}S.

The mean δ^{34}S and δ^{56}Fe values of this nodule are +2.9 ± 0.5 ‰ and -1.08 ± 0.7 ‰, close to the bulk values of +3.2 ‰ and -1.46 ‰, respectively. Two profiles have been performed in one nodule and show large variations in both δ^{56}Fe (~ 2.5 ‰) and δ^{34}S (~5 ‰). The δ^{56}Fe profile shows ^{56}Fe enrichment in the rim relative to the core. The δ^{34}S profile shows large isotopic variation that have no systematic relationship with the location. Δ^{33}S values are negative in the core and positive in the rim. The pyrite nodule was likely formed in a closed system during diagenesis, under reducing conditions but also record some iron oxidation in the water column. S isotopes reflect mixing and different reactivity of two sulfides pools (sulfate and elemental sulfur photochemically produced in the atmosphere) in sediments. Coupled S and Fe isotope composition at µm-scale provides new insights into Archaean ocean chemistry.

FREZCHEM: A geochemical model for cold aqueous solutions

GILES M. MARION[1*]

[1]Desert Research Institute, Reno, Nevada, USA, giles.marion@dri.edu (*presenting author)

FREZCHEM Model

FREZCHEM is an equilibrium chemical thermodynamic model parameterized for concentrated electrolyte solutions (to ionic strengths = 20 molal) using the Pitzer approach [1] for the temperature range from –100 to 25°C (CHEMCHAU version has temperature range from 0 to 100°C) and the pressure range from 1 to 1000 bars [2]. The current version of the model is parameterized for the Na-K-NH_4-Mg-Ca-Fe(II)-Fe(III)-Al-H-Cl-ClO_4-Br-SO_4-NO_3-OH-HCO_3-CO_3-HSO_3-SO_3-HS-S-CO_2-O_2-CH_4-NH_3-SO_2-H_2S-Si-H_2O system and includes 115 solid phases including ice, 16 chloride minerals, 36 sulfate minerals, 16 carbonate minerals, six sulfite minerals, five solid-phase acids, four nitrate minerals, seven perchlorates, six acid-salts, five iron oxide/hydroxides, four aluminum hydroxides, two silica minerals, two ammonia minerals, two gas hydrates, two bromide sinks, and one sulfide mineral (pyrite). Fortran codes and an Internet working model are available at http://frezchem.dri.edu.

Applications for FREZCHEM can be very diverse because of its extensive physical ranges. For example, if ammonia/ammonium and methane are prevalent on Titan, that can lead to interesting chemistries over the temperature range of 173-273 K (Fig. 1). Notice that SO_4 largely precipitates, but CH_4 (aq) increases, which may be why methane is a major component on the surface of Titan where the temperature is 94 K.

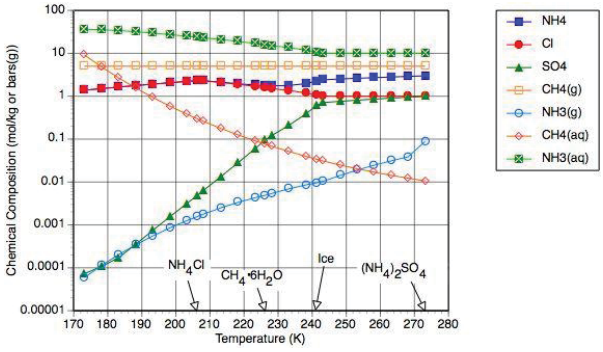

Figure 1. The chemical compositions as temperature decreases from 273 to 173 K beneath Titan surface. Arrows on the X-axis indicate when solid phases start to precipitate.

Post OIS6 climate-change records in the Lower Mississippi Valley and mid-Atlantic Coastal Plain

HELAINE W. MARKEWICH[1*], MILAN J. PAVICH[2], DOUGLAS A. WYSOCKI[3], RONALD J. LITWIN2

[1]U.S. Geological Survey, Atlanta, GA, helainem@usgs.gov (* presenting author)

[2] U.S. Geological Survey, Reston, VA, mpavich@usgs.gov , rlitwin@usgs.gov

[3] U.S. Department of Agriculture, National Soil Survey Center, Lincoln, NE, doug.wysocki@lin.usda.gov

Published and on-going investigations allow comparison of post OIS6 chrono- and pedo-stratigraphic and palynologic records in the Lower Mississippi Valley (LMV) and mid-Atlantic Coastal Plain (MACP) of the unglaciated USA. Data indicate that in both regions W-NW winds were responsible for loess and eolian-sand deposition and that in both regions depositional periods were coeval with Northern Hemisphere glaciations and characterized by boreal environments.

The LMV was the major meltwater conduit associated with the Laurentide Ice Sheet (LIS). Loess dominates the OIS6, 3, and 2 LMV stratigraphic record. Sand dunes are a minor component. The Susquehanna and Delaware rivers were conduits for glacial meltwater that had an impact on the Chesapeake Bay area of the MACP. Eolian deposits are more spatially and temporally restricted in this area than in the LMV and are most prevalent within 300 km of the glacial border. Eolian sand dominates the OIS 3 and 2 MACP stratigraphic record.

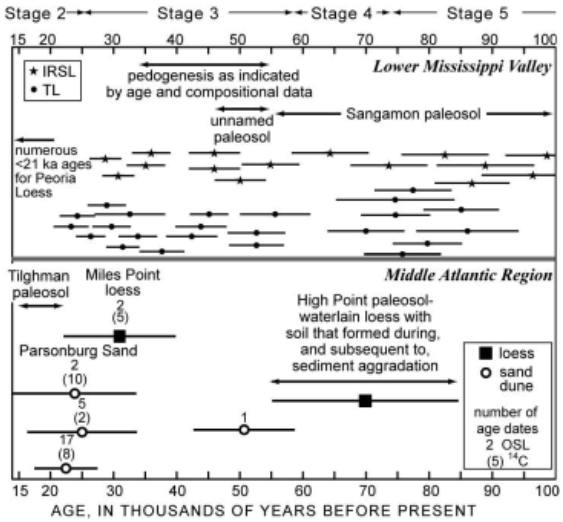

Figure 1: Age data for loess, eolian sand, and paleosols from the LMV[1] and the mid- Atlantic region[2][3][4].

Palynologic and paleowind data, along with the chrono- and pedo-stratigraphic records, are adequate to allow preliminary comparisons of late Pleistocene climates in the two regions.

Analysis of 33 Uranium Ore Concentrate Samples: A Case Study in Nuclear Forensics

NAOMI MARKS[1]*, IAN D. HUTCHEON[1], MARTIN ROBEL[1], LARS E. BORG[1]

[1]Lawrence Livermore National Lab, USA, marks23@llnl.gov (* presenting author)

Nuclear forensics is a scientific discipline interfacing law enforcement, nuclear science and non-proliferation. Information on the history and on the potential origin of intercepted nuclear material can be obtained through nuclear forensic analysis. Using commonly available techniques of mass spectrometry, microscopy and x-ray diffraction, we have gained insight into the processing and origin of a suite of uranium ore concentrate (UOC) samples.

The 33 UOC samples are in the form of ammonum di-uranate (ADU). The sample suite is thought to represent a time series collected at the same location over a number of years. The rare earth element (REE) patterns match the REE patterns for phosphorites reported in [1], implying that the samples are derived from a phosphorite deposit (Figure 1). The REE patterns are fairly consistent throughout the series, although absolute concentrations of REEs decrease through the time sequence (Figure 1) suggesting improvments in metallurgy with time.

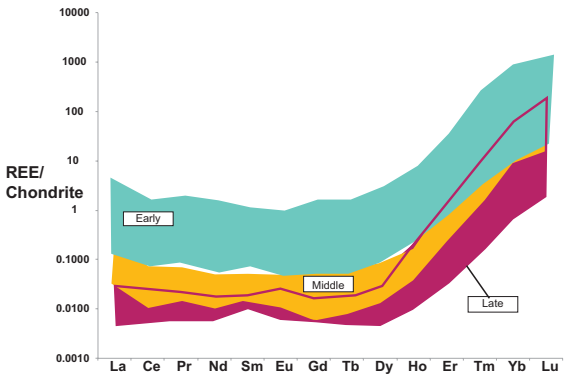

Figure 1: Chondrite normalized REE patterns for the suite of UOC samples.

The U purification process appears to be OPPA solvent extraction based on the form of the UOC (as ADU). The first few samples in the time series have higher concentrations of almost all impurity elements, and lower concentrations of U, than subsequent samples. Some of the later samples have on up to 40% higher concentrations of alkali earths and alkali metals, indicating slight variations in feedstock. The consistency in trace element patterns, however, suggests the samples are derived from geologically related ore bodies. This study illustrates one way in which nuclear forensic analysis can provide insight into the ore geology and production and purification methods used to produce UOC.

The Azores plateau, a bathymetric high seated on an anomalous mantle domain is located in the Azores Triple Junction where the American, EUR and AFR lithospheric plates meet. The cause for these anomalies is controversial but many authors consider the presence of an anomalously hot/wet enriched mantle probably supplied by a plume [1]. The origin, size and present location of the plume is under debate but an area near Terceira is the favoured plume centre [2]. The Terceira Rift (TR) defines the EUR/AFR plate boundary of the Azores triple junction. The TR is a 550 km long, generally ESE trending line of volcanic massifs (e.g. São Miguel, D. João de Castro, Terceira and Graciosa) alternating with deep basins (e.g. Hirondelle basin). The latter are interpreted to be volcanically unfilled rift valley segments [3]. Vesicular, porphyritic basalts were sampled along the Terceira Rift during Portuguese scientific cruises (EMEPC 2007-2009). Initial studies focused on the adjacent areas Don João de Castro - DJC (submarine volcano) and Hirondelle - Hir (basin). Major and trace element data of phenocrysts (olivine, clinopyroxene, plagioclase), groundmass and exposed melt inclusions in these vesicular lavas depict only slight differences between the two sites although DJC samples have somewhat higher Fo and Mg# in olivine and clinopyroxene, respectively. Chondrite-normalized REE data indicate that groundmass material is LREE-enriched in both Hir and DJC lavas. Exposed melt inclusions (MI) show similar REE patterns compared to their hosts. Clinopyroxene in both sites displays L-MREE enriched, HREE depleted sinusoidal patterns. MI were found in olivine, clinopyroxene and plagioclase phenocrysts. MI are glassy to completely opaque and devitrified, with one or more bubbles, and sulfide globules (SG). SG are spherical, depict two-phase lamellar intergrowths of Fe-Ni and Cu-Fe phases, and are ubiquitous in DJC and Hir lava samples. Some lavas display SG within clinopyroxene-hosted MI and dispersed in the groundmass. Preliminary data suggest that lavas found in these areas of the Terceira Rift were sulfur-saturated in different stages of their evolution; during early fractionation and prior to eruption. The geochemistry of melt inclusion will contribute to the understanding of mantle source, melting and mixing processes in the Terceira Rift, Azores.

Sorption of Lanthanides and trivalent actinides on montmorillonite in the presence and absence of carbonate

M. Marques Fernandes[1*], B. Baeyens[1], R. Dähn[1], T. Stumpf[2] and M. H. Bradbury[1]

The fate of released RNs in a deep geological radioactive waste repository is primarily controlled by sorption/desorption processes onto mineral surfaces. Clay minerals are major constituents in both the man-made engineered barriers and in the argillaceous host rock formations currently being considered for a deep high level radioactive waste (HLW) repository in Switzerland. In the near-field of HLW repositories, reducing conditions are expected to prevail and the RNs are present in their lowest oxidation states. Trivalent actinides such as Am(III), Cm(III) and Pu(III) make a significant contribution to the radiotoxicity of HLW. In natural environments, the predominant aqueous phase reactions of lanthanides and trivalent actinides (Ln/An(III)) are hydrolysis and complexation with dissolved inorganic ligands, such as carbonates. Such complexation reactions could potentially decrease the metal ion sorption and thus increase the migration rates of these RNs.

The sorption of Ln/An(III) on montmorillonite in the absence and presence of dissolved carbonate was investigated by a combination of different approaches. Batch sorption experiments, surface complexation modelling, Time-Resolved Laser Fluorescence Spectroscopy (TRLFS) and Extended X-ray Absorption Fine Structure (EXAFS) spectroscopy were applied to investigate the uptake of Ln/An(III) on montmorillonite at low surface loadings ($\leq$ 3 mmol·kg^{-1}). The macroscopic sorption experiments showed that the presence of carbonate leads to a pronounced decrease of Ln/An(III) uptake on montmorillonite. Modelling the experimental data with the 2SPNE SC/CE sorption model under the assumption that carbonate complexes do not sorb, clearly under predicted the experimental data, suggesting the formation of ternary Ln/An(III)–carbonate surface complexes. In order to verify this assumption, EXAFS and TRLFS were applied. The differences in the TRLFS spectra obtained for samples in the presence and absence of carbonate *i.e.* red-shift of excitation and emission spectra, as well as the increase of fluorescence lifetimes, unambiguously showed the influence of carbonate, and were fully consistent with the formation of Ln/An(III)(III) surface species involving carbonate complexes. The EXAFS parameters derived by fitting the spectra of the carbonate free sample were consistent with bond lengths from Am-O and Am-Si/Al backscattering pairs, and clearly indicated that An(III) forms inner sphere complexes at the montmorillonite surface. The EXAFS parameters obtained by fitting the spectra of the sample prepared in the presence of carbonate was consistent with the formation of an An(III) complex at the montmorillonite surface with 1 to 2 carbonate groups. The application of EXAFS and TRLFS clearly supported the macroscopic sorption experiments and modeling results and confirmed the formation of ternary Ln/An(III)-CO_3 complexes at the montmorillonite surface.

Comparison of grain size and BET surface area trends in modern glacial and non-glacial fluvial sediments as a proxy for deep-time climate

Kristen R. Marra[1*], Megan E. Elwood Madden[1], Gerilyn S.Soreghan[1], and Allison R. Stumpf[1]

[1]ConocoPhillips School of Geology and Geophysics, University of Oklahoma, kmarra@ou.edu (* presenting author)

Chemical and physical weathering in sediments is highly contingent upon erosion rates and climatic variables (temperature and precipitation). Sediment grain size and surface area also impose critical controls on mineral-water reaction rates, where finer grain sizes are correlated to higher surface areas and thus increased chemical weathering, even in glacial environments [1]. However, sediment surface area is generally not evaluated or reported for natural systems. Here we document grain size and BET surface area trends within the mud fraction (< 63 μm) of proximal fluvial sediments in a cold-arid, glacial (Clark Glacier Stream, Wright Valley, Antarctica) and a warm semi-arid, non-glacial (Blue Beaver Creek, Wichita Mountains, Oklahoma) environment. Both systems are of similar basin drainage size (40 km^2), relief (360-465 m), and bedrock lithology (granitoid).

In the polar glacial transect, the mud fraction coarsens with distance along transect, with a corresponding decrease in BET surface area, indicating rapid dissolution of fines. In the non-glacial transects, grain size decreases downstream while surface area increases, reflecting precipitation of clay-sized weathering products. Aqueous chemistry of stream water samples collected simultaneously with stream sediments supports the conclusion that silicate dissolution dominates in the glacial environment, whereas incongruent chemical weathering of silicate phases is predominant the non-glacial environment. The occurrence of opposing trends within climatically distinct settings indicates that the production and fate of fine-grained sediments may be diagnostic of glacial and non-glacial regimes and potentially evident in the rock record. Additionally, systematic quantification of sediment surface areas provides critical constraints on evaluating the effect of chemical weathering on modern and deep-time global carbon cycles.

Sulfur isotopes in high-pressure rocks

HORST R. MARSCHALL[1*], NOBUMICHI SHIMIZU[1]

[1]WHOI, Woods Hole, MA, USA, hmarschall@whoi.edu (* presenting author), nshimizu@whoi.edu

Models of the global sulfur cycle are afflicted with a lack of knowledge on the efficiency and isotopic effects of subduction processes. Primitive undegassed basalts, as well as sulfide inclusions in mantle xenoliths and in eclogite-type diamonds display a relatively large variation in $\delta^{34}S$ (Seal, 2006) providing evidence for significant mantle heterogeneities in S isotopes. It has been speculated that recycling of sulfur in subduction zones is in part responsible for these variations. However, models of the deep mantle sulfur cycle ignore any processes operating during subduction. Estimates on the subduction input into the mantle are reduced to using the compositions of un-metamorphosed oceanic rocks, because little is known on the behavior of sulfur and sulfur isotopes during high-*P* metamorphism and subduction zone devolatilization. This study aims to close this gap, and investigates the S isotope composition of sulfides in natural high-*P* rocks.

Sulfur isotope analyses were conducted by SIMS on pyrite and chalcopyrite. Based on petrographic evidence, the sulfides were attributed to formation during two contrasting stages of the subduction-exhumation cycle: (1) sulfides formed prior to or during subduction, and (2) sulfides in revolatilization zones formed during exhumation, probably by fluids released from the subducting slab. The first type bears on the isotopic composition of sulfur in different lithologies subducted to various depths, while the second type complements these data by reflecting the composition of fluids released from the slab.

Preliminary data from various samples investigated so far include both types of sulfide from various localities (Cycladic blueschist belt, Greece; Zermatt-Saas Fee, Italian Alps; Western Gneiss Region, Norway; New England Fold belt, Australia; Franciscan fm., California) and present the following picture:

(i) $\delta^{34}S$ values of prograde pyrite and chalcopyrite in eclogites are mainly positive: ~0 to +14 ‰, although some individual pyrite grains show negative values down to –3.4 ‰. The grains are typically unzoned in S isotopes.

(ii) prograde pyrite and chalcopyrite from a high-*P* metasediment shows grains unzoned in $\delta^{34}S$ with values as low as –31 ‰.

(iii) $\delta^{34}S$ values of retrograde pyrite show a heterogeneous picture with unzoned grains having negative (as low as –21 ‰) or positive values, as well as mm-sized grains with ~8 permil $\delta^{34}S$ core-to-rim zonation.

The results obtained to date suggest that altered igneous crust carries a positive $\delta^{34}S$ signal down to the UHP eclogite stage, while sediments are probably depleted in ^{34}S. Evidence for high-$\delta^{34}S$ fore-arc fluids is found in retrograde pyrite. However, some retrograde pyrite shows very low $\delta^{34}S$ values, which may be related to metasedimentary sources in the slab. High-*P* serpentinites and harzburgites will be one of the future foci of this ongoing study into the subduction zone sulfur cycle.

Palaeocene Arctic coal represents a unique terrestrial record of peatland processes and carbon storage during the last period of Arctic warmth. Modern high latitude warming is accelerated when compared to global averages [1] indicating future Arctic peatlands may bear closer resemblance to Palaeocene peatlands than those seen at the present time.The Svalbard coals formed around 60Ma at latitude 68°N. Previous studies of mid-latitude Paleocene coals, [2] provide evidence of significant methanogenic communities within peatlands before and during the PETM event. Modern high latitude methane fluxes have been linked to polar stratospheric cloud formation [3] and accelerated Arctic warming This study aims to use organic petrology and geochemistry to find evidence of such methane fluxes in Palaeocene, Svalbard and study the implications for modern peatlands

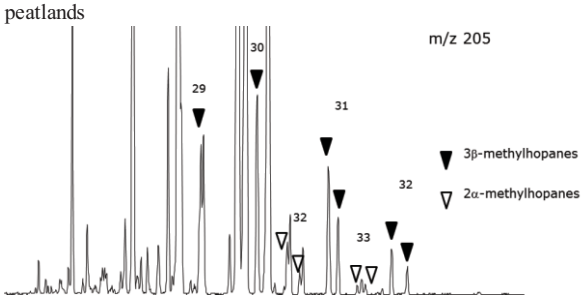

Figure 1: M/z 205 gas chromatograms showing 2 & 3 Methyl-hopanes in Svalbard coal extracts.

Total hopane concentrations (bacterial biomarkers) in Svalbard coals are 45- 125mg/g extract indicating the coals are massively enriched in microbial lipids compared to other source rocks (<2mg/g extract [4]). High detrovitrinite contents in the Svalbard coals also indicate high levels of biodegradation for the latitude. This is probably a feature of high peatland seasonality with winter productivity lowered but temperatures sufficient, to allow continued biodegradation.

Methanotrophic biomarkers, 3-methyl hopanes (figure 1) are enriched (1.26mg/g extract) significantly compared to other source rocks (<300µg/g extract, [4]). This increase is thought associated with the general increases in biodegradation shown by the hopanes. This is reflected by 3Me/Total Hopane ratios of 2-3%, which are consistent with other source rocks [4]. Consequently, if future Arctic peatlands evolve similarly, biodegradation would be expected to increase rapidly, increasing the Arctic terrestrial carbon flux and accelerating subsequent high latitude warming.

[3]Diamond Light Source, UK.

Geological disposal of the legacy of radioactive wastes stored at Earth's surface is now the accepted management pathway for these materials and is a task of importance for nuclear power generating countries. In many radioactive waste disposal scenarios, intermediate level wastes are grouted and the geological disposal facility (GDF) will have cement present as a ubiquitous engineering material. Further, cementitious grouts have been considered as backfill for the GDF. Therefore, post-closure leaching of cementitious materials in a GDF is expected to create hyperalkaline conditions in and around the repository. These high pH fluids will react with the repository components and host rock, resulting in mineral alteration and crystallisation. Iron within the host rock derived from the alkaline breakdown of Fe-bearing silicate minerals (e.g. biotite, chlorite) or corrosion products formed within the repository will form iron (oxyhydr)oxide minerals. The formation and re-crystallisation of these reactive minerals, which may sequester radionuclides through reduction to less soluble forms and/or incorporation to more stable secondary iron oxide phases [1], may prove key to the fate of radionuclides in such environments.

To evaluate the signficance of these processes, ferrihydrite was crystallised under CO_2-free oxic and anoxic conditions, in two U(VI) amended synthetic cement leachates, representing early (pH 13.1) and late (pH 10.5) stage cement evolution for a cementitious ILW GDF. Under oxic conditions ferrihydrite crystallised to hematite (pH 10.5) and goethite (pH 13.1). Under anoxic contitions in both leachates, and in the presence of Fe(II), ferrihydrite crystallised to magnetite. X-ray Absorption Spectroscopy was used to characterise uranium association with each of the iron (oxyhydr)oxide phases during the crystallisation reactions. Under oxic conditons at pH 10.5, U(VI) rapidly (hours) sorbed to the ferrihydrite. Thereafter, during crytallisation, analysis indicates that U(VI) became structually incorporated in the hematite lattice. At pH 13.1, U(VI) remained 0.22 μm soluble and did not sorb to either ferrihydrite or goethite. Under anoxic conditions, in both leachates, uranium was rapidly (minutes) removed from solution as the ferrihydrite crystallised to magnetite (catalysed by Fe(II) in solution). Here, U(VI) was reduced to U(IV) and XAS analysis suggests it was directly substituted into octhedral sites of the magnetite structure.

These data have significant implications for the safety case for uranium behaviour in alkaline conditions in a GDF and in contaminated land scenarios. Details of uptake and bonding mechanisms of uranium in the iron oxide phases will be presented.

23d. General geochemistry

Geochemical and R&D applications offer interesting analytical challenges in the sense that these materials can represent a wide elemental coverage, wide concentration ranges and varied sample matrices and sizes. Analytical performance of wavelength dispersive X-ray fluorescence (WDXRF) instruments is being constantly advanced in order to cope with such challenges.

While traditionally WDXRF technique has always demanded homogeneous samples, the latest developments permit analysis of small spots down to 0.5mm as well as mapping of a selected area of a sample. These new possibilities open up the WDXRF technique to heterogeneous samples where segregations, defects or inclusions can now be determined. Coupling these capabilities with standardless analysis permits quantification of up to 79 elements of the periodic table on selected points of the sample.

In this presentation, several examples will be presented and finally tied into one thorough application in which the power and flexibility of new WDXRF instruments are fully exploited.

Chemical weathering fluxes through a coastal aquifer, the Pingtung Plain, southwest Taiwan

CAROLINE MARTIN[1]*, ALBERT GALY[1], NIELS HOVIUS[1], MIKE BICKLE[1], IN-TIAN LIN[2], MING-JAME HORNG[3], DAMIEN CALMELS[4], HAZEL CHAPMAN[1] AND HONGEY CHEN[5]

[5]Dept. of Geosciences, National Taiwan University, Taipei, hchen@ntu.edu.tw

Tracing groundwater offshore has resulted in a wide range of submarine groundwater discharge (SGD) estimates for specific marine locations, but complementary, similarly-focused studies measuring potential throughput on land are few. We analysed the waters from 43 wells at varying depths through a 264 m window in the Pingtung Plain for major dissolved cations, anions, dissolved SiO_2, and stable isotopic composition of oxygen and hydrogen of water, and used Darcy's Law to compute their subsurface fluxes. Compared to chemical flux estimates from the adjacent Kaoping River, results show that 1.1 to 12.3 % of combined surface runoff and potential subsurface discharge to the ocean can be attributed to groundwater-derived weathering fluxes. Estimated propagated errors at 2σ on subsurface fluxes are ± 30 % assuming the hydraulic conductivity is known by ±10 %. Multi-year daily hydraulic head data gives the direction of groundwater flow through the plain, and indicates that pumping has led to episodic reversals of flow, facilitating seawater intrusion in the near-coast aquifer. Hydrological connectivity exists throughout the drilled depth of the basin, whereas chemical gradients suggest that stratified flow is in operation, with up to a two-fold increase in silicate-derived Na^+ seen in deeper horizons as compared to the near surface. For all ions except Ca^{2+} and SO_4^{2-}, the average concentrations of dissolved species in the distal groundwaters exceed those of the river, ranging from a factor of 1.2 in the case of Li^+, K^+ and Mg^{2+} to 5.4 in the case of Ba^{2+}. At 12.3 %, the relative groundwater flux of Ba^{2+} exceeds that of all other elements by at least a factor of two. Furthermore, Ba^{2+} concentrations in the near surface coastal aquifer exceed those in deeper horizons by up to a factor of 7.9. The observation of increasing Ba^{2+} in the shallow subsurface could be accounted for by a desorption mechanism. However, the correlation of Ba^{2+} and ionic strength is poor, requiring an additional mechanism that could affect Ba, (additional dissolution of Ba-bearing phases), and/or the ionic strength (~Na^+), such as reverse weathering. Results suggest that, with the exception of Ba^{2+}, submarine groundwater chemical fluxes into the Taiwan Strait are modest in comparison to those related to surface runoff. If reverse weathering is promoted in seawater-intruded aquifers, the silicate weathering fluxes in the Pingtung Plain would still be underestimated after the incorporation of SGD.

Isotopic insight into volcanic sulfate formation in the troposphere.

ERWAN MARTIN[1(*)], SLIMANE BEKKI[2], CHARLOTTE NININ[1], AND IYA BINDEMAN[3].

[1]ISTEP-UPMC, Paris, France. erwan.martin@upmc.fr, charlotte.ninin@etu.upmc.fr
[2]LATMOS-IPSL, Paris, France. slimane@latmos.ipsl.fr
[3]Dprt of Geological Sciences, Univ. of Oergon, Eugene, USA. bindeman@uoregon.edu

We present analyses of oxygen and sulfur isotopic composition of sulfate extracted from volcanic ash collected near volcanoes few hours or days after eruptions. This study is based 10 volcanic eruptions that occurred from the equator to 65°N.

Very significant variability is observed in the dataset with SO_4 concentration ranging from 350 to 7500ppm, $\delta^{18}O$ from 0.2 to 13.2‰, $\Delta^{17}O$ from -0.14 to 0.35‰ and $\delta^{34}S$ from 3.9 to 10.5‰.

While $\delta^{34}S$ of volcanic sulfate is expected to reflect processes that mainly occurred in the volcanic plume, the O-isotopes clearly trace the oxidation pathways of volcanic SO_2 in the atmosphere and more specifically in the troposphere for our samples.

Assuming that $\Delta^{17}O$ = 0‰ and $\delta^{18}O$ = 5-7‰ in SO_2 coming out from the volcanoes, the resulting sulfate $\Delta^{17}O$ would be significantly different from 0‰ only if a substantial fraction of SO_2 was oxidized via mass-independent fractionating oxidation pathways (reaction with O_3 or H_2O_2). On the other hand, the $\delta^{34}S$ of sulfate was expected to fall within the initial volcanic SO_2 range, which is $\delta^{34}S$ = 6-8‰. The fluctuations of about 2‰ outside this range in the measured sulfate may reflect some Rayleigh distillation processes in the volcanic plume.

The different volcanic events analysed here correspond to different environmental conditions (latitude, season…) for the oxidation of volcanic SO_2. We analyse, via 3-D chemistry-transport model calculations, the expected levels of SO_2 oxidants in the atmospheric column above the studied volcanoes. For each eruption, we are able to compare the measured $\Delta^{17}O$ with the $\Delta^{17}O$ estimated in sulfate produced by SO_2 oxidised in model-calculated background conditions.

Our results indicate that, for the vast majority of the cases, the main oxidant for volcanic SO_2 in the troposphere is OH radicals or, at least, that SO_2 is not significantly oxidised via a mass-independent fractionating channel. OH in the very dry stratosphere carries a substantial mass-independent isotopic anomaly while in the humid troposphere this anomaly is thought to be lost through isotopic exchanges with H_2O. It is likely that the low pH of volcanic aerosol clouds could reduce very significantly the heterogeneous oxidation via the mass-independent O_3 and H_2O_2 in the troposphere.

Fluid evolution along a cross section through the Central Alps, Switzerland

K. MARTINEK[1*], T. WAGNER[1], M. WÄLLE[1], AND C.A. HEINRICH [1]

[1]Geochemistry and Petrology, ETH Zurich, Clausiusstrasse 25, CH-8092 Zürich, Switzerland, klara.martinek@erdw.ethz.ch

The classical Alpine fissure veins, large cavities lined by occasionally giant quartz crystals, occur in regionally metamorphosed rocks in the Central Alps. They record important information about the composition and evolution of metamorphic fluids, and fluid sources and mass transfer during fluid-rock interaction. The fluid composition shows a distinct evolution with increasing metamorphic grade, where consecutive zones are dominated by (1) heavier hydrocarbons, (2) methane, (3) aqueous fluids, and (4) aqueous-carbonic fluids [1]. This study addresses the chemical evolution of fluids in Alpine fissure veins in the Central Swiss Alps by integrating field work, fluid inclusion studies (microthermometry and LA-ICPMS microanalysis of individual fluid inclusions), and geochemical modeling.

The field locations were selected along a cross section through the Central Alps that covers different lithologies and metamorphic conditions. This includes vein systems in the Aar massif (Gauli glacier, Gerstenegg vein, Tiefen glacier), the Bedretto valley, and the Cavagnoli and Faido region. The fluid inclusions from the Aar massif are low-salinity aqueous two-phase, whereas the Cavagnoli and Faido samples dominantly contain aqueous-carbonic fluid inclusions. The salinity increases from the Gauli samples with 4.5-5.0 wt% equivalent (eqv.) NaCl to those from the Gerstenegg and Tiefen glacier with salinities of around 10-11 wt% eqv. NaCl. The aqueous-carbonic fluids of the Faido and Cavagnoli region have very low salinities of around 3.4 and 0.4 wt% NaCl, respectively. This differences in salinity are also reflected in their major and trace element concentrations, as determined with LA-ICPMS. Higher salinities do systematically correlate with higher concentrations of elements that are largely complexed by chlorine such as the alkali and earth alkaline metals, and divalent transition metals [2]. The concentrations of base metals such as Pb, Zn and Ag are consistently higher in the fluid inclusions from the Gerstenegg and Tiefen glacier than in the Gauli samples. The Cavagnoli and Faido samples contain even higher concentrations of ore metals (up to several tens of ppm) and sulfur, reflecting their higher metamorphic grade. The measured fluid compositions will be compared with results from multicomponent-multiphase fluid-mineral equilibria modeling to evaluate the status of fluid-rock equilibrium along the metamorphic gradient.

Evidence for the accumulation of heterocyclic N compounds in temperate forest soils as a function of depth

CARMEN ENID MARTÍNEZ[1*], JOSEPH DVORAK[2]

[1]The Pennsylvania State University, Department of Crop and Soil Sciences, University Park, PA, USA, cem17@psu.edu (* presenting author)

[2] Brookhaven National Laboratory, National Synchrotron Light Source, Upton, USA, jdvorak@bnl.gov

Leaching of dissolved organic nitrogen (DON) from forest (organic–rich) surface soils is likely the primary vehicle for the observed movement of N into underlying mineral soils. Our goal is to understand the accumulation and storage of nitrogen in soils. The overarching hypothesis that drives this research is that heterocyclic N compounds derived from the decomposition of litter are transported and accumulate in the soil column. The analytical approaches typically used to study N-containing compounds are not sensitive to the presence of heterocyclic N. This has resulted in the general belief that amide-N (as in proteins/peptides) is the only N form important in N accumulation and storage in soils. Still, biomolecules such as DNA are composed of heterocyclic N containing subunits and these molecules, although in lower concentrations than amide-N in proteins/peptides, are chemically recalcitrant, sorb onto soil solids, and are thus expected to accumulate and persist in natural soil environments. In this investigation, we used an innovative technique, nitrogen X-ray absorption near edge structure (N-XANES) spectroscopy, to determine the N chemical forms in temperate forest soils as a function of depth and varying mineralogy.

Soil columns (down to approx. 1 meter) were collected from two forest locations in Pennsylvania. These include an Inceptisol soil with mineralogy dominated by illite and chlorite, and a Spodosol soil with mineralogy dominated by Fe oxides, illite and kaolinite, but that also contains organic matter accumulations at depths of about 25-50 cm. The N K-edge (409.9 eV) XANES spectra was collected at the National Synchrotron Light Source, BNL.

The N-XANES spectra of these forest soils can be divided into two regions: π* resonances at 398-404 eV and σ* resonances at 404-420 eV. Furthermore, the spectra reveal two well-resolved π* resonances, one (lower energy π*) corresponding to spectral features present in biomolecules such as DNA/RNA and their contituent nucleic acids, and a second resonance (higher energy π*) which is present in proteins and their contituent amino acids and polypeptides. We observed an increase in the lower energy π* resonace with soil depth that was mirrored by a decrease in the higher energy π* resonace. This trend is consistent for all soil columns, except when an accumulation of organic matter occurs in deep soil layers. The lower energy π* resonance originates from molecular structures with extended π-electron systems and indicate the presence of heterocyclic N compunds. Thus, our results indicate N long-term leaching processes result in the selective accumulation of heterocyclic N compounds at soil depths. The accumulation of heterocyclic N at soil depths might be a consequence of its presumed recalcitrance and/or bonding to mineral surfaces.

The Cam Pha area in Northen Vietnam is known for its coal mining activities. The Coc Sau open pit coal mine has been operative in this area for at least the past 50 years. Rice paddies located ~2 km away from the Coc Sau mine are irrigated with water contaminated by acid mine drainage. Bulk chemical analysis of rice paddy soil from the Cam Pha area shows relatively high concentrations of several toxic metals attributable for the most part to the coal mining activities, including Cr, Cu, Zn, As, Cd, and Pb (60, 27, 48, 14, 0.2, and 35 ppm, respectively).

Preliminary experiments with model *Oryza sativa* cv. (Asia) rice species exposed to contaminated paddy soil from the Coc Sau mining area showed a hindered growth as a function of increasing soil concentrations added to rice growth media under controlled laboratory conditions. Figure 1 shows a clearly a detrimental effect of this soil on the growth of model *Oryza sativa* cv. (Asia) rice species.

In the next step, we will perform sequential extraction analyses of the soil to determine the most mobile metals. Moreover, we are currently studying the effects of root iron plaques and the presence iron oxide mineral phases in regards to toxic metal immobilization.

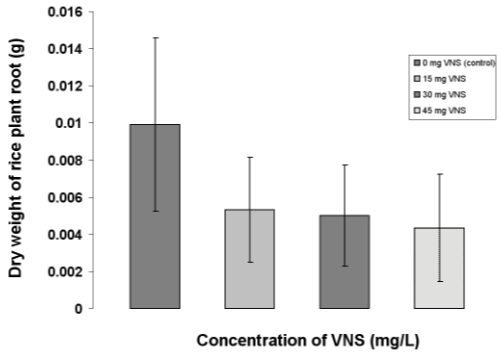

Figure 1: Plot of dry rice plant root weight as a function of concentration of Vietnamese rice paddy soil (VNS) from Cam Pha area.

δ^{11}B-based atmospheric CO_2 records during the Pliocene at orbital resolution

The Mid-Pliocene is the most recent time in Earth's history when mean global temperatures were substantially warmer and sea levels higher than they are today [1]. The subsequent intensification of the Northern Hemisphere Glaciation (iNHG) represents the key final step in the climatic transition from the warm Pliocene to the current "icehouse" climate. Recent modeling and proxy-based results [2-4] suggest that this climate shift was forced by a reduction in atmospheric CO_2 concentrations (pCO_2), which highlights the relationship between climate and this important greenhouse gas. Hence, there is significant potential in the use of the Pliocene as an analogue for future global warming in modeling studies and as a key period to study the role of CO_2 in driving major climatic shifts. Despite recent advances in the reconstruction of pCO_2 change during this important period [3-4], detail at the orbital scale is currently lacking.

Boron isotopes in planktic foraminifera are a proven proxy for surface oceanic pH [5], which has been shown to provide valuable insights into past changes in the ocean carbonate system and ultimately into past atmospheric pCO_2. Here we will provide foraminiferal δ^{11}B-based records to determine the temporal evolution of pCO_2 for an interval spanning the Pliocene Warm Period and the iNGH at orbital scale temporal resolution. Our record provides valuable insights into the causes and consequences of the changes in the atmospheric concentration of this important greenhouse gas.

Mercury methylation, pore water geochemistry and legacy mercury contamination along the floodplain of the Connecticut River

ANNA MARTINI[1*], JON WOODRUFF[2], DANIEL KEKACS[1], HANNA BOUBERHAN[1], AND CARYL ANN BERCERRA[1]

[1]Amherst College, Geology, Amherst, U.S., ammartini@amherst.edu (* presenting author)

[2]University of Massachusetts, Geosciences, Amherst, U.S., woodruff@geo.umass.edu

Mercury has long been stored in the fine-grained sediment along the various tributaries, ponds, lakes, and coves connected to the Connecticut River. Concentrations rose above background (<80 ppb) by the dawn of the Industrial Revolution and have, for the most part, mirrored the rise and fall of atmospheric mercury concentrations[1]. Total mercury concentrations in the sediment peak upstream in the Oxbow at approximately 500 ppb and near the mouth of the river, in Hamburg Cove, increase to nearly 3000 ppb. This sixfold rise is further exacerbated by the changing sedimentation rate from a low at the Oxbow (~1.5 cm/yr) to extremely high values for Hamburg Cove (~4.1 cm/yr)[1]. The rise in sedimentation rates towards the Long Island Sound are due to the influence of tidal pumping, allowing significant quantities of sediment fines to accumulate in these depocenters. In comparing mass accumulation rates (as $\mu g/m^2/yr$), Hamburg Cove accumulates mercury at nearly an order of magnitude greater than at the upriver Oxbow. In both locations, organic content ranges from 4 to 14%, but does not correlate well with mercury concentrations (R^2 = 0.2664). Although mercury readily adsorbs onto organic matter, the peaks in mercury concentration are more correlative with atmospheric loading and local mercury inputs than simply TOC. Methylmercury concentrations are also quite distinct in each location, with Hamburg containing over 1.5 ppb in its uppermost sediments while Oxbow concentrations never rise above 0.5 ppb. Variations in MeHg concentrations do not, however, correspond to those of total inorganic mercury, but instead suggest that SO_4 in pore water and the actions of SRB are needed to methylate the stored inorganic mercury. qPCR results also indicate the presence of sulfate reducers in these environments, just below the sediment interface. For Hamburg Cove this suggests that significant introduction of the bioavailable form of mercury is controlled by the occasional influx of salt water (with its high SO_4 concentration). With sealevel rise, it is likely that the magnitude of re-introduction of legacy mercury will increase and will eventually effect other floodplain waterbodies further up the Connecticut River Channel.

Abstract

Metal adsorption on mineral surfaces is a topic extensively pursued by researchers to improve the understanding of the environmental fate of metals, and provide natural low-cost adsorbents for remediation as this is an active mechanism in controlling the fate of metal ions in natural waters. Despite the wealth of available information focused mostly with basal surfaces, because edge surfaces are difficult to model, few studies were devoted to edge surfaces of clays.[1-3]

Pyrophyllite was chosen as a model because it is a non expanding phyllosilicate with neutral layers that do not require encapsulation of couter-ions, making it the best candidate for calculations that intend to discern such an important and complex problem.

The work presented herein follows on from experimental work done in our group,[4] and aims at interplaying with such results *via* the investigation of the metal adsorption mechanisms at the edge surface sites of pyrophyllite. Having been started with a non biased and systematic approach using atomistic simulation techniques, initially, the static simulation code METADISE[5] was used to cleave and hydroxylate low Miller index surfaces, and explore their structure and stability. Subsequent to ranking the cuts, classical modeling of the hydrated clay-edge surfaces showed that from the large set of Miller index planes cut, the (110), (-110), (010), and (100) surfaces are the most stable leading to a pseudo-hexagonal crystal shape generated with the first three surface planes, as documented for phyllosilicates. These edge surfaces were further optimised using DFT within the VASP code,[6] to calculate the energy of the diferent hydroxylated ensembles in oder to ascertain the most stable and hence the most likely for metal surface complex formation.

Nitrogen composition of the ancient atmosphere from fluid inclusion analysis of Archean quartz

B. MARTY[1*], L. ZIMMERMANN[1], M. PUJOL[1,2], R. BURGESS[3] AND P. PHILLIPOT[4]

[1]CRPG-CNRS, Université de Lorraine, Vandoeuvre les Nancy, France, bmarty@crpg.cnrs-nancy.fr
[2]ETH, Zürich, Switzerland, pujol@erdw.ethz.ch
[3]University if Manchester, UK, ray.burgess@manchester.ac.uk
[4]IPGP, Paris, France, philippot@ipgp.fr

Introduction

Knowning the composition of the Archean atmosphere is extremely important for a number of reasons. First, the Sun was ~25 % fainter than Today and, because there is no evidence of glaciation in the Archean, rhe lower solar energy delivery was presumably compensated by a stronger greenhouse effect. Such an effect is not recorded in geological proxies of the paleo partial pressure of CO_2, and it has been proposed that doubling the pN_2 in the Archean atmosphere could have broadened by Rayleigh scattering the adsorption line of radiatively active gases, strengthening the greenhouse effect [1]. Because nitrogen isotopes are fractionated by bacteria, the isotopic siganture of this element in old sedimentary rocks is used to investigate the early development of the biosphere. Thus the isotopic value of the atmosphere at different time periods is equally important to document. Previous works have proposed that it remained constant through time within a few permil [2].

Nitrogen and argon isotopes in irradiated Archean quartz

We have analyzed nitrogen and argon isotopes in 3.5 Ga old hydrothermal quartz from the North Pole area, Pilbara, NW Australia. In the same sample we have previoulsy determined a Ar-Ar plateau age of 3.0±0.2 Ga indicating that the age of trapped fluids is within 3.0-3.5 Ga. The Xe isotope signature intermediate between Chondritic and Atmospheric was interpreted as representing atmospheric Xe trapped ≥ 3.0 Ga ago [3]. Gases were extracted by vacuum crushing and heating of the remaining powder, nitrogen and noble gases were purified independently, and nitrogen and argon isotopes and abundances were sequentially analyzed by static mass spectrometry (overall $\delta^{15}N$ error : 1-2 ‰). In a first step we analyzed non-irradiated samples, and data are consistent with mixing between an hydrothermal end-member and a paleo-atmospheric component having a $\delta^{15}N$ value close to the modern one. We then irradiated a second batch of samples in order to quantify the chlorine and potassium contents of the extraction steps from ^{37}Ar, ^{38}Ar and ^{39}Ar and to correct data for mixing (and ageing for Ar). The $\delta^{15}N$ values are very similar to the ones obtained from the non-irradiated sample runs, showing neglible production of nitrogen isotopes during neutron irradiation. Premiminary results confirm $\delta^{15}N$ values between 0 ‰ and 5 ‰, and suggest a partial pressure of atmospheric nitrogen comparable to the present-day one.

The volatile element record of Earth's accretion

B. MARTY[1]

[1]CRPG-CNRS, Université de Lorraine, Vandoeuvre les Nancy, France, bmarty@crpg.cnrs-nancy.fr

Isotope signatures of volatile elements

The stable isotopes signatures of terrestrial nitrogen and hydrogen suggest strongly that most volatile elements on Earth originated from a cosmochemical reservoir that also sourced asteroidal bodies. However, in the Earth's mantle, a minor solar-like volatile component is present and best seen in the Ne (and possibly N and H) isotope composition(s) of mantle-derived rocks. Ne isotopes in minerals from mantle plume provinces discriminate against contribution of dust implanted with solar ions, and instead support trapping of volatile elements directly from the nebular gas. Atmospheric escape to space has been long advocated to account for the atmospheric $^{20}Ne/^{22}He$ isotope ratio lower than the Solar value. I shall argue instead that mixing between solar and chondritic components accounts well for Ne isotope variations in the Earth-atmosphere system. In a $^{20}Ne/^{22}Ne$ versus $^{36}Ar/^{22}Ne$ diagram, both the atmosphere and the MORB mantle plot on a mixing line joining the solar and the chondritic (A-type component) end-members [1].

Earth's accretion seen from volatile elements

The above geochemical compositions on one hand, and dynamical modelling of planetary formation [2] on another hand, are consistent with the following scenario. Planetary embryos of the size of Mars accreted and differentiated in a few Ma [3], while the nebular gas was still present. Solar-like atmospheres were gravitationnally bound and solar gases were dissolved in molten silicates, imposing reducing conditions that participated to metal segregation. Such conditions might have also permitted the trapping of minor amounts of solar, isotopically light, N and H. Such contribution is larger than the late veener advocated in the case of PGEs. Giant shocks that characterized the accretion of Earth, but not of Mars, did not completely dry up the proto-Earth : volatile elements were gravitationnaly bound as were less volatile, or non volatile, elements also vaporized during the Moon-forming impact. Delayed accretion of asteroidal bodies or of volatile-rich dust orginating from close to the snowline added chondritic-like volatiles : a contribution of 2±1% carbonaceous chondrite-type material is indeed sufficient to supply water, carbon, nitrogen, halogens, and most noble gases to the Earth (including the surface reservoirs) [1]. In the light of existing data, the contribution of comets might not have exceeded a few percents of that of asteroidal material. The isotopic fractionation of atmospheric xenon (and, to a lesser extent, of atmospheric krypton) is probably related to non-thermal escape processes involving selective ionization, possibly on embryos, or during the Hadean-Archean eons [4] when the young Sun was more energetic than Today in the far UV range [5].

Mercury stable isotope time trends in cryogenically archived ringed seal livers from the Alaskan Arctic

J. MASBOU[1*], D.POINT[1], J.E. SONKE[1], P.R. BECKER[2]

1 Observatoire Midi-Pyrénées, Geosciences Environnement Toulouse, CNRS-IRD-Université de Toulouse 3, France. jeremy.masbou@get.obs-mip.fr (* presenting author)

2 National Institute of Standards and Technology, Hollings Marine Laboratory, Charleston, South Carolina, USA

Because of its long residence time in the atmosphere, gaseous mercury (Hg) emitted from distant anthropogenic sources reaches high latitude regions carried by air flow [1]. Springtime atmospheric Hg depletion events (AMDEs) were early on recognized as a potential key control on Hg entering the Arctic ecosystem. Even if a large amount of AMDE Hg deposited is immediately re-emitted to the atmosphere, the remainder is mobilized by meltwater [2] and transformed by bacteria into methyl-Hg. This neurotoxic form is able to bio-accumulate along the trophic chain and high concentrations are observed in top predators. Global emission Hg trends and AMDEs alone are however unable to explain observed temporal trends in biota Hg in Western and Eastern Arctic sectors [4]. Marine mammal's exposure to MeHg therefore needs additional consideration of physiological, ecological and climate change factors such as feeding behavior, habitat utilization, and sea-ice dissappearance. Recent work on arctic seabird eggs [5] has shown a possible link between sea-ice cover and biota Hg isotope signatures. It was inferred that by blocking UV radiation the sea-ice diminishes photochemical breakdown of bioavailable surface ocean MeHg.

Here we further explore the potential influence of climate change on Arctic Hg biogeochemistry. We focus on ringed seals, a sea-ice dependent species considered as apropriate Hg biomonitors in the Arctic region. Indeed, their high degree of site fidelity allows spatio-temporal analysis of biomarkers. Hg speciation (inorganic Hg, MMHg) and stable isotopic composition (C, N, Hg) measurements were made on 53 ringed seal liver samples archived at the US Marine Environmental Specimen Bank. Sampling covers a period of 14 years (1988-2002), allowing an accurate time trend analysis. The isotopic signature Δ^{199}Hg, which is a tracer for inorganic or methyl Hg photochemistry in surface waters, varied from 0.05 to 1.04 ‰.This variation was not related to in-vivo metabolic effects or ecological effects such as feeding habitat (δ^{13}C) and trophic level (δ^{15}N). Δ^{199}Hg shift from +0.37±0.08‰ (SE, n=5) in 1988 to +0.59±0.07‰ (SE, n=7) in 2002, and show a significant increase of 4.8% yearly (R^2=0.70, p*<0.05) in this period. We suggest that this reflect the progressive decrease in sea-ice cover between 1988 and 2002. This is coherent with our previous study [5].

Characterization of combustion products from biomass pellets

CHRISTOPH MASCHOWSKI[1*], RETO GIERÉ[1], AND GWENAËLLE TROUVÉ[2]

[1] Universität Freiburg, Geowissenschaften, 79104 Freiburg, Germany, christoph@maschowski.de (* presenting author), giere@uni-freiburg.de

[2] Université de Haute-Alsace, Laboratoire de Gestion des Risques et Environnement, Mulhouse, France, gwenaelle.trouve@uha.fr

Two different types of biomass pellets (a DIN+ wood pellet and a new pellet made of the *Miscanthus* grass) and their combustion products (bottom ash and fly ash) were investigated by Atomic Absorption Spectroscopy (AAS), Scanning Electron Microscopy (SEM), Electron Microprobe Analysis (EMPA), and X-ray diffraction (XRD). Also, an attempt was made to characterize combustion-derived particles in the exhaust gas by using SEM images and EDX spectra.

The fuels were combusted in a glass tube reactor using a heating ramp (20-820°C @ 20°C/min). The particles were collected by an Electrical Low Pressure Impactor (ELPI) on twelve stages depending on their aerodynamic diameter. The main focus was put on the alkali, alkaline earth and silicon contents as these compounds commonly lead to the formation of corrosive deposits in biomass power plants and may also contribute to hazardous primary and secondary particulate matter in the atmosphere.

The results reveal relatively higher potassium and calcium contents in the Miscanthus fuel and its combustion products. On the other hand, the silicon contents of the fuel and the combustion products are almost identical for the two pellet types. The unexpected high silicon content in the wood pellet is inferred to result from contamination during harvesting and pellet production, a hypothesis supported by the presence of extraneous quartz grains observed by SEM. In the Miscanthus pellet potassium and silicon were also found inside the cells, and thus represent inherent inorganic material. In the bottom ash of the Miscanthus pellet, a multitude of mineral phases, predominantly lime, have been identified by XRD, and evidence for ash melting was obtained from SEM observations. In the bottom ash of the DIN+ wood pellet, only quartz and calcite were detected, with no indication for ash melting.

The inorganic particles collected from the flue gas were classified on the basis of their chemical composition and shape in order to assign them to a probable mineral phase. In the Miscanthus particulate matter samples, twelve different inorganic particle types with mean diameters from 1-20µm were identified. In the DIN+ particulate matter sample, a total of seven different particle types were found, but the main fraction (~80%) is represented by quartz grains with mean diameters > 10µm.

The major part of the inorganic (ash-forming) fraction of the DIN+ pellet is represented by extraeneous material, whereas significant amounts of the inorganic constituents of the Miscanthus pellet are located inside the biostructures. This may lead to higher reactivity during combustion and the formation of secondary phases such as lime and melilite, and the formation of a wide variety of particle types.

Speciation of commercial CeO2 nanocomposites during aging.

A. MASION[1,2*], L. SCIFO[3], P. CHAURAND1,[2], M.A. DIOT[1,2], J. LABILLE[1,2], M. AUFFAN[1,2], J.Y. BOTTERO[1,2] AND J. ROSE[1,2]

[1]CEREGE, CNRS-Aix Marseille Univ., France. masion@cerege.fr
[2]iCEINT, Aix en Provence, France
[3]TECNALIA, Montpellier, France

In many commercial nanoproducts, nanoparticles are surface modified to obtain new properties and/or to facilitate their dispersion in a matrix. Regular use, aging, and improper handling may cause the release of residues into the environment. As a consequence, assessing the risks associated with a given nanoproduct needs to take into account these residues throughout the entire life cycle of the product.

For example, outdoor wood paint contains CeO_2 nanoparticles as long-term UV-absorber to stabilize paints against degradation. The nanoparticles are citrate coated for better dispersion in the aqueous paint. This work aimed at investigating the transformation occurring at the nanoparticle surface during simulated aging in the lab.

Two sets of experiments were conducted: aging of the Ce based nanocomposite in aqueous suspensions, and aging of a paint containing CeO_2 nanocomposites.

In both cases, the experiments were carried out over several months, with UV/Vis illumination to simulate sunlight, and, in the case the paint samples, included rain cycles at fixed intervals. During the aging, the samples were analyzed in terms of leached Ce content (paint), and physical-chemical properties (size, charge...) and chemical nature of the residues using mainly microscopy and spectroscopy techniques.

Towards a new clinopyroxene geothermometer for alkaline, differentiated magmas

MATTEO MASOTTA[1*], SILVIO MOLLO[2], CARMELA FREDA[2], MARIO GAETA[1,2] AND GORDON MOORE[3]

[1]Sapienza Università di Roma, Rome, Italy
matteo.masotta@uniroma1.it (* presenting author)
[2]Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy
[3]Department of Chemistry and Biochemistry, Arizona State University, USA

In the last decades several clinopyroxene geothermometers have been proposed with the aim to constrain pre-eruptive conditions of volcanic systems [1]. However, the compositional bounds of the calibration dataset represent a serious limitation in their use. In fact, the more the composition of the investigated natural rocks deviates from the compositions in the calibration dataset, the larger the uncertainty in the estimate of temperature will be.

At the present, clinopyroxene geothermometers are mainly calibrated on magma compositions ranging from basalt to rhyolite, leaving poorly constrained or even unconstrained, alkaline differentiated composition. Moreover, the effect of melt-water content on phase compositions is usually neglected. Given the magnitude of the alkaline, explosive volcanism, these two factors cannot be ignored in future calibrations of geothermometers.

In this study, we present a new clinopyroxene geothermometer specifically calibrated for hydrous, alkaline compositions ranging from phonolite to trachyte. This model is based on a broad dataset consisting of 35 phase equilibria experiments, carried out at 200 MPa, in the temperature range 850-1000°C and at variable X_{H2O}-X_{CO2} (H_2O ranging from 0 to 6 wt.% and CO_2 ranging from from 0 to 0.5 wt.%). The equations have been obtained by means of least squares regression analysis of the experimental dataset, yielding a better accuracy of temperature estimate than previous models. Notably, the accuracy of the model largely increases by including the water-melt content parameter in the equations, whereas the presence of CO_2, which actually does not affect the composition of clinopyroxene and melt, scarcely influences the temperature estimate.

Introduction

A groundwater classification system, using the distribution of the two groundwater conservative parameters Cl and $\delta^{18}O$ was developed at Äspö Hard Rock Laboratory (Äspö HRL).

Groundwater from boreholes was sampled during the years 1987-2009 from a total of 284 packed-off sections representing depths of 8 m to 984 m below the sea level. The groundwater classification system was based on the conceptual hydrological understanding of the region, including five end-members which, in ascending order with respect to their age, are: deep saline water of old age [1] but unknown origin (referred to as "old-saline water"), glacial melt water formed during the last Pleistocene glaciation, Littorina Sea water (mid-Holocene), current meteoric water and Baltic Sea water.

Results and Conclusions

Most of the samples in Fig 1 plot in the Mixed class indicating influences from several end-members. The Meteoric, Marine and Saline classes are also well represented by the samples. Few samples plot close to the Littorina and Glacial end-member indicating less influence in the sampled water."

The groundwater classification and results presented here are relevant for recognition of conditions of importance in terms of bedrock disposal of toxic waste materials as technical barriers may be influenced by hydrogeological and hydrochemical changes over time.

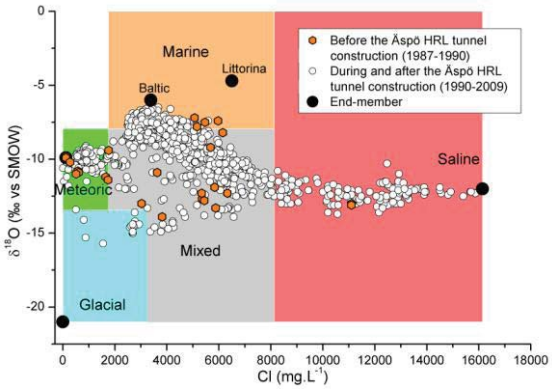

Fig. 1. Sampled groundwater plotted according to the established classes: Saline, Glacial, Marine, Meteoric and Mixed.

[3] Department of Geoscience, Interdisciplinary, Shimane University, Matsue, Japan
[4] Institute of Geology and Geoinfomation, AIST, Tsukuba, Japan

Matsue Alkaline Basalt

Matsue city located in Japan Sea coast side of southwest Japan arc. There are many alkaline basic-intermediate lavas that we called "Matsue Basalts" in Matsue city area. The activity of the Matsue Basalt is about 10 Ma ago. Matsue basalt basically consist of 6 basic lavas and some it's pyroclastic deposite (sandstone and tuff) [1, 2]. The purpose of this study is clarifying geochemical characteristics of Matsue basalt. We here report the Bulk rock chemical composition, and mineral assemblage and chemistry of Matsue Basalt. And we classified Matsue basalt into five groups. And we found chromian spinels from two groups. This study adds a new data and idea to the Tsubota and Matsumoto (2008) [2].

Results and discussion

Bulk rock chemical compositions of Matsue Basalt are divided into 6 groups, which are 3 basalt groups (Chausuyama, Hanamagari and Agenogi groupes), 2 basaltic andesite groups (Tsuda and Rakuzan groups) and 1 andesite group (Toukodai groupe) based on their volcanic Stratigraphy. However, Tsuda and Rakuzan groups are show same chemical feature. That is Matsue Basalt is chemically consists of 5 groups. Chausuyama and Agenogi basalts show particularly with respect to their low FeO*/MgO ratios and high Cr content. And these two basalts have chromian spinels in and around olivine grains. Chromian spinels from Chausuyama and Agenogi basalts have Cr# (Cr/(Cr+Al) atomic ratio) of 0.16-0.40, and olivines from these basalts have Fo of 88-76. Arai (1987, 1994) proposed that Fo-Cr# relations depend on the tectonic setting, due to differing melting conditions (pressure, temperature and water vapour conditions) [3, 4]. That is Chausuyama and Agenogi basalts of Matsue Basalt derived from the relatively depleted lerzolitic mantle. Furthermore, above two basalts may be the different magma origins by Cr and Ni bulk rock chemical composition.

After 5 Ma of activity of Matsue basalt, eruption of adakite magam enters active time at the almost same location as Matsue basalt [5]. That is, it may be able to explain the chemical diversity of Matsu basalt in which it is related also with motion of a Philippine Sea Plate and activity of adakite magma in Japan sea coast side south west Japan arc.

Zn isotope fractionation in Archean komatiites and associated lava-flows

N. MATTIELLI[1,*], P. HAENECOUR[1,2] AND V. DEBAILLE[1]

[1]Laboratoire G-Time, Université Libre de Bruxelles, Brussels, Belgium (*correspondence : nmattiel@ulb.ac.be)
[2]Laboratory for Space Sciences, Washington University in St. Louis, St. Louis, USA.

Komatiites are volcanic ultramafic rocks with high MgO content (>18Wt.%), which make up the first few blocks of the Archean crust and are indicative of the earliest stages of the Earth mantle dynamics.

The present study reports high-precision MC-ICP-MS measurements of Zn isotopic compositions in whole rocks and mineral separates from Fred's Flow and Theo's Flow, two thick Archean differenciated flows (2.7 Ga) located in the Abitibi greenstone belt (Munro Township, Canada). Fred's Flow has a komatiitic affinity, and is classified as Al-undepleted type, whereas Theo's Flow has an Fe-rich tholeiitic affinity and is classified as Al-depleted type. Their geographical relationship as well as their complementary geochemical compositions suggest that they are genetically related. Characterizing fractionation processes of their Zn isotope compositions would provide constraints on diffusion transport, crystallisation processes, and melting conditions involved in the komatiites petrogenesis.

Small but significant shift in δ^{66}Zn values for whole rocks is systematically observed between Fred's flow (mean δ^{66}Zn = +0.30±0.04‰ (2SD)) and Theo's flow profiles (mean δ^{66}Zn = +0.39±0.03‰). For each flow, the Zn isotopic profile is relatively monotonous, except for the gabbroic units with slightly lower δ^{66}Zn (down to +0.28±0.04‰) and the basal ultrabasic units where enrichments in heavy Zn isotopes are clearly obvious (δ^{66}Zn up to +0.55±0.05‰).

Zn isotopic compositions in mineral separates vary on a large range of 1.6 δ-unit, and their relative modal contributions can explain the whole rock isotopic trends. As a whole, mineral separates reproduce the same isotopic shift between the two flows, as previously shown by the bulk rocks, suggesting a fractionation control by the crystallisation/melting conditions. Individually, chromites show especially strong enrichments in light Zn isotopes, relative to the silicates. Olivine, clinopyroxene and plagioclase exhibit generally smaller isotopic fractionation with respect to each other, but are characterized by contrasted δ^{66}Zn values suggesting correlation with the polymerization degree. No relationship has been observed between the Zn isotope fractionation and (light) alteration degree of the lava flow or mineral.

Further analyses are needed to discriminate secondary Zn mobilization, crystallisation or cooling rate effects, and establish interesting comparison with Mg and Fe isotopic results reported by Dauphas et al. (2010) on Alexo komatiites.

Ni partitioning between olivine and high-MgO silicate melts: Implications for Ni contents of forsteritic phenocrysts in basalts

A.K. MATZEN, M.B. BAKER, J.R. BECKETT, E.M. STOLPER*

California Institute of Technology, Pasadena, CA, USA
ems@caltech.edu (* presenting author)

There has been considerable interest in the presence in basalts of forsteritic olivine (*ol*) phenocrysts with elevated NiO contents (i.e., up to 0.5-0.6 wt. % NiO, substantially higher than in normal peridotitic *ol*, [typically 0.35-0.40 wt. % NiO]). It is difficult to produce such high NiO contents in peridotitic *ol* via simple melting processes; so assuming that *ol* phenocrysts that crystallize at low P mimic the compositions of *ol* in deeper residual magmatic sources, the existence of phenocrysts with such elevated NiO contents would require that *ol* in these sources contain comparably elevated NiO contents. This has led to several hypotheses to explain NiO-rich *ol* in mantle sources of basalts (e.g., contamination of the lower mantle by the core; metasomatism of normal mantle by silica-rich melts of eclogite). If, however, the partition coefficient of NiO between *ol* and melt (D_{Ni}) depends strongly on T and/or P, *ol* phenocrysts that crystallize at lower P's and T's than those at which their host magmas last equilibrated with mantle need not mimic the compositions of *ol* in their residual sources. This would provide an explanation for NiO-rich *ol* phenocrysts that does not require NiO-enriched mantle *ol*.

We measured D_{Ni} between *ol* and picritic liquid at 0.001-30 kbar; by adjusting the T at each P, we kept liquid MgO contents similar (~17-18 wt. %) for all experiments. This experimental feature was critical because D_{Ni} is a strong function of liquid MgO content; so by keeping the MgO content essentially constant, we isolated the dependence of D_{Ni} on P and T from its dependence on MgO. D_{Ni} in our experiments decreases from 5.0 to 3.8 (by wt.) as T increases from 1400 to 1550°C. Our results are well described by a simple Ni-Mg exchange equilibrium assuming (1) ideal models for the liquid and *ol* and (2) the standard state ΔV and ΔC_P of the reaction are zero. Previous measurements of D_{Ni} are scattered, but the same model can describe simultaneously our isochemical results and the literature data in which T and MgO (and P) vary considerably.

Using our model, we calculated the NiO contents of Hawaiian *ol* phenocrysts that would crystallize at 1 kbar from primary magma separated from its residue at ~35 kbar. If the T difference between the residue and the conditions of phenocryst crystallization is ~150°C and the NiO content of residual *ol* is 0.37±0.02 wt. %, the calculated NiO content of *ol* phenocrysts is 0.47±0.025 wt. %. This is not as high as the highest NiO contents of Fo-rich Hawaiian phenocrysts, but it matches most of the data (0.44±0.07 wt. % NiO; 2σ). This simple calculation demonstrates that the effect of T on D_{Ni} can explain much of the range in NiO contents of Hawaiian *ol* phenocrysts without invoking processes that enrich mantle *ol* in Ni. Although such Ni-enrichment processes may operate, their contributions to basalt genesis need not be as large as suggested by models that do not consider the effects of T differences between source regions and the environments of phenocryst formation. A similar calculation reproduces the moderate enrichment in NiO in komatiitic *ol* assuming komatiitic magmas are dry, deep, and hot melts of the upper mantle.

Geochemical signature and evolution of granitic rocks in Sulawesi Island, Indonesia: evidence for Gondwana involvement

ADI MAULANA[1,4], KOICHIRO WATANABE[1], AKIRA IMAI[2], KOTARO YONEZU[1], TAKANORI NAKANO[3]

[1]Kyushu University, Fukuoka, Japan, adi-m@mine.kyushu-u.ac.jp (* presenting author)
[2]Akita University, Akita, Japan, akira@gipc.akita-u.ac.jp.net
[3]Research Institute of Human and Nature, Kyoto, Japan,nakanot@chikyu.ac.jp
[4]Hasanuddin University, Makassar, Indonesia, adi-maulana@unhas.ac.id

Tertiary granitic rocks from Sulawesi record series of complex history where subduction and collision occur and are still active. One of the products of these events is granitic magmatisms which are widely dispersed from southern part to northern part of the island. The granitic rocks were exposed to form a NS trending belt along the west to north plutono-volcanic arc province. The granitic rocks are of particular interest since they provide an insight into the geological processes that were operating at the eastern margin of Eurasian Plate.

In this study, major- and trace- element chemistry of granitic pluton from nine areas which represent the whole granitic distribution in Sulawesi Island were studied in order to elucidate the geodynamic evolution. In addition, the geochemical signatures coupled with isotopic results are used to determine the corresponding constraint on Gondwana involvement in the evolution of the island.

The results indicate that the granitic rocks ranges from acid to intermediate (granitic to tonalitic in composition) and are dominated by granodiorite with enclave of microdiorite and gabbro. They are identified as medium- to high-K, calc-alkaline, metaluminous and I-type granitoid emplaced as volcanic arc granites. With the exception of tonalitic rocks in Gorontalo area in the northern part of the island, all granitic samples resemble the upper continental crust pattern in their trace and rare earth element normalized pattern. Enrichment of large ion lithophile elements (Rb and Sr) and depletion of high field strength element (especially Nb and Ta) suggests an arc magma affinity. Negative Eu anomaly in most of the samples shows the occurrence of plagioclase fractionation in magma chamber. Most of the samples show high $^{87}Sr/^{86}Sr$ value but low $^{143}Nd/^{144}Nd$ suggesting strong upper crustal component source. In addition, they have high ^{206}Pb, ^{207}Pb and ^{208}Pb isotope ratios. However, microdioritic enclave and tonalitic rocks from Gorontalo shows lower $^{87}Sr/^{86}Sr$ value but higher $^{143}Nd/^{144}Nd$ and relatively higher ^{206}Pb, ^{207}Pb and ^{208}Pb value, significantly different from other samples.

The magma sources of these granitic rocks were interpreted derived from the upper continental crust. The most plausible nature of such affinity was Gondwana fragment which were dispersed during Cenozoic. They were then emplaced above subduction zone during the syn- to late collision stages with eastern part of Sundaland.

The overall geochemical signature of the Sulawesi granitic rocks suggests the evidence of Gondwana fragment involvement in geodynamic evolution of the island, particularly in the western and central Sulawesi.

Experimental investigations of the structural environment of metal (Nb, Ta) ions in silicate glass-water systems to high P-T conditions

ROBERT A. MAYANOVIC[1*], ALAN J. ANDERSON[2], MANELICH LUNA[1], GIULIO SOLFERINO[2] AND HAO YAN[1]

[1]Missouri State University, Springfield, MO, U.S.A., robertmayanovic@missouristate.edu (* presenting author)
[2]St. Francis Xavier University, Antigonish, NS, Canada, aanderso@stfx.ca

The study of silicate and aluminosilicate glasses and water systems at high P-T conditions has importance for understanding natural systems and for technological applications. The interrogation of the interaction of water in silicate melts and glasses on the structural level is critical for establishing a better understanding of the effect of dissolved water on the thermodynamic and physical properties of water-saturated magmas and of industrial glasses that are in contact with high P-T aqueous fluids. In this work, we discuss our *in situ* Ta L_3 and Nb K-edge x-ray absorption spectroscopic (XAS) investigations of the structural environment of metal (Nb, Ta) ions in haplogranitic glasses, water-saturated melts, and silicate-rich aqueous fluids at high temperatures and pressures. The starting materials, which consisted of water and a Ta (~1400 ppm)- or Nb (~5000 ppm)-bearing haplogranitic glass of peraluminous composition, were loaded into an hydrothermal diamond anvil cell and subjected to temperatures between 25 and 960 °C, and pressures up to 600 MPa. Pre-edge peak analysis of the Nb K-edge x-ray absorption near edge structure (XANES) measured from the Nb-bearing glass+water system to 760 °C shows a transition (in the 300 to 400 °C range) from a double to a single peak in the vicinity of the glass transition. In addition, the overall intensity of the pre-edge peak feature of the Nb-bearing glass+water system increases monotonically with increasing temperature. A doublet occuring in the white line feature of the Ta L_3-edge XANES is present in the spectra measured from the hydrous glass/melt to 700 °C and from the silicate-rich aqueous fluid at 960 °C. The white line feature results from dipole allowed transitions of the Ta $2p_{3/2}$ core electron to empty quasi-bound states in the continuum having Ta 5d atomic character. The Ta L_3-edge XANES spectra measured from a peraluminous silicate glass and water system have been analyzed using multi-peak fitting techniques. The normalized XANES spectra were fit in the vicinity of the white line using pseudo-Voigt peak functions. The relative intensities of the individual peaks in the Ta L_3-edge XANES white-line doublet vary with increasing temperature of the glass+water system, suggesting a shift in occupation of the electronic density of states in the vicinity of Ta 5d states probed by the $2p_{3/2}$ core photoelectron. *In situ* XANES is shown to be a sensitive probe of the modifications in the structural environment surrounding the metal (Nb, Ta) ion in the hydrated peraluminous glass/melt and in the silicate enriched aqueous fluid with increasing P-T conditions. We discuss the results of modeling of the XANES spectra and calculations of the projected angular momentum density of states (*l*-DOS) for the glass+water systems using FEFF code.

Pb and Hf isotope composition of hornblende-bearing lavas (Central European Volcanic Province): a lithospheric mantle source?

BERNHARD MAYER[1*], STEFAN JUNG[1], ROLF L. ROMER[2], CARSTEN MÜNKER[3]

[1] Universität Hamburg, Mineralogisch-Petrographisches Institut, Hamburg, Germany, Bernhard.Mayer@uni-hamburg.de (* presenting author)
[2] Deutsches GeoForschungsZentrum, Potsdam, Germany
[3] Universität zu Köln, Institut für Geologie und Mineralogie, Köln, Germany

Primitive alkaline mafic volcanic rocks – like the hornblende-bearing basanites from the Rhön area (Central European volcanic Province; CEVP) – provide important information about the chemical composition in the Earth's mantle. The presence of amphibole requires wet melting conditions; hence the source for the hornblende-bearing lavas is thought to be located in the lithospheric mantle. Strontium and Nd isotope compositions are well within the range commonly observed in CEVP magmas (εNd: +3.4 to +4.4; $^{87}Sr/^{86}Sr$: 0.7034-0.7041) and, although moderately evolved, are not indicative of crustal contamination.

Beside some differences in major and trace element geochemistry and Sr and Nd isotopes relative to other primitive volcanic rocks in CEVP, the Pb isotope composition is broadly similar to lavas from other volcanic centers located in the eastern part of the CEVP (i.e., Vogelsberg, Hessian Depression) in having $^{206}Pb/^{204}Pb$ ratios < 19.5, which contrasts to the Pb isotope composition of volcanic centers in the west (Eifel, Siebengebirge, Westerwald) with $^{206}Pb/^{204}Pb$ ratios > 19.5. The Rhön lavas have Pb isotope compositions ($^{206}Pb/^{204}Pb$: 19.1-19.4, $^{207}Pb/^{204}Pb$: 15.61-15.64, $^{208}Pb/^{204}Pb$: 38.9-39.2) that plot slightly above the NHRL (Northern Hemisphere Reference Line) in the $^{206}Pb/^{204}Pb$-$^{207}Pb/^{204}Pb$ and $^{206}Pb/^{204}Pb$-$^{208}Pb/^{204}Pb$ diagram, indicating that the source of the western CEVP must have a slightly higher U/Pb and Th/Pb ratio than the source of the eastern CEVP. In general, the Pb isotope compositions of the lavas plot at the unradiogenic end of Pb isotope range obtained on mantle xenoliths from the CEVP.

The hornblende-bearing lavas have initial εHf values ranging from +4.6 to +6.6, which is at least one εHf unit lower than in other lavas from the CEVP having similar εNd values and Pb isotope compostions. Since the Lu/Hf ratios of the hornblende-bearing lavas are similar to other lavas from the CEVP, the Hf isotope composition must be a source feature which is related to distinct Lu/Hf ratios in the mantle. The less radiogenic Hf isotope composition requires a source with a time-integrated lower Lu/Hf ratio relative to the mantle that produced other CEVP lavas with more radiogenic Hf isotope compositions. This inferred lower Lu/Hf ratio is compatible with a mantle with less or even no garnet, i.e. the spinel-bearing lithospheric mantle. Alternatively, participation of metasomatism-related minerals with low Lu/Hf ratios can explain the inferred slightly lower Lu/Hf ratios of the mantle source.

Sources and Seasonal Transformations of Nitrate in Lake Winnipeg (Manitoba, Canada)

BERNHARD MAYER[1]* AND LEONARD I. WASSENAAR[2]

[1]University of Calgary, Calgary, Alberta, Canada, bmayer@ucalgary.ca (* presenting author)
[2]Environment Canada, Saskatoon, Saskatchewan, Canada, current e-mail: L.Wassenaar@iaea.org

Lake Winnipeg (Manitoba, Canada) is in an eutrophic state from a century of increased riverine loadings from agricultural and urban nitrogen (N) and phosphorus (P) sources. This study investigated seasonal patterns of the isotopic composition of nitrate (NO_3^-) in Lake Winnipeg and its contributing rivers to gain insight into current N nutrient sources and in-lake N dynamics. Elevated NO_3^- concentrations in Lake Winnipeg tributaries between 0.36 and 2.44 mg/L NO_3^--N were associated with high $\delta^{15}N$ values between +5.0 and +13.9 ‰, while $\delta^{18}O_{NO3}$ values were <+15.0 ‰. The three major riverine inputs had distinctive mean $\delta^{15}N_{NO3}$ values of +8.1 ‰ for the Red River, -0.6 ‰ for the Winnipeg River, and +5.0 ‰ for the Saskatchewan River. The isotopic composition of NO_3^- in Lake Winnipeg was partly controlled by the isotopic composition of the riverine nitrate for instance via the predominant nitrate input to the South basin from the Red River. Nitrate assimilation and late season mineralization of phytoplankton and N_2 fixing cyanobacteria were identified as important additional processes affecting the isotopic composition of lake NO_3^- resulting in low $\delta^{15}N_{NO3}$ values, especially in the North basin. In the South basin, elevated $\delta^{15}N_{NO3}$ values in spring that changed to lower values by summer indicated a dynamic N cycle within the lake. This study demonstrates the need for sesoanlly resolved concentration and isotope analyses on samples from a large number of sampling sites to assess the highly dynamic in-lake fate of nitrogen inputs to Lake Winnipeg.

Delivery and release of organic carbon associated with iron oxyhydroxides in the Mississippi River-Delta

LAWRENCE M. MAYER[1]*, LINDA L. SCHICK[1], MARGARET L. ESTAPA[2], ROTA WAGAI[3], MATTHEW STEVENSON[1]

[1]University of Maine, Walpole ME USA Lmayer@maine.edu (* presenting author)
[2]Woods Hole Oceanographic Institution, Woods Hole MA USA mestapa@whoi.edu
[3]National Institute for Agro-Environmental Sciences, Tsukuba, Japan, rota@affrc.go.jp

Iron oxyhydroxides commonly associate with organic matter in terrestrial environments, but can become reductively dissolved in coastal environments. We examined the organic carbon content of these reducible phases using two carbon-free extraction approaches in Mississippi River suspended particulates and in its adjoining deltaic sediments. Contents of reductively dissolved iron decreased from river to depocenter and with distance from river outfall, and accompanied by similar losses of reductively soluble organic carbon. Both also decreased with depth in coastal cores. The ratios of organic carbon to iron released were less than the 0.22 g-OC g-Fe^{-1} that represents the approximate sorption limit of iron oxyhydroxides for dissolved organic matter, suggesting that the released organic matter was adsorbed. At these ratios, the solid phase iron and organic carbon are in approximate redox balance, so that import of either oxidant or reductant may not be necessary for metabolism. The reductively soluble organic carbon generally made up <5% of total organic carbon and its loss thus accounted for small fractions of total organic carbon losses during sediment transport and diagenesis. Extrapolation to global scale suggests a greater impact of perhaps 10% of global river delivery of particulate organic carbon in this form.

Hydrogen production from low temperature (55-100ºC) water-rock reactions

L. MAYHEW[1*], E. ELLISON[1], T. MCCOLLOM[2], AND A. TEMPLETON[1]

[1]University of Colorado-Boulder, Geological Sciences lmayhew@colorado.edu (* presenting author)
[2] University of Colorado-Boulder, Laboratory for Atmospheric and Space Physics

Hydrogen (H_2) produced from water-rock reactions at ~150-300ºC is known to support thriving microbial communities on Earth (e.g. Lost City hydrothermal vents [1,2]) and similar geochemical process have been suggested to occur on Mars and Europa [3,4]. However, the potential for mafic rocks and minerals to produce enough H_2 to support microbial life at temperatures below 100ºC remains a matter of debate (e.g. [4,5]) and is relatively unexplored in the laboratory.

We are conducting laboratory experiments to assess the potential of 12 rock and mineral substrates to produce H_2 when reacted with seawater under anoxic conditions at 55 and 100ºC. Time series measurements were obtained for key gaseous and aqueous constituents. Magnetite, hypersthene, fayalite, San Carlos olivine and San Carlos peridotite produce 20-180 nmol H_2/gram mineral at 55ºC. The same 5 substrates as well as chromite produce 50-210 nmol H_2/gram mineral at 100ºC. In contrast, hortonolite, hedenbergite, augite, enstatite, diopside, and basalt do not produce significant H_2. Our H_2 measurements agree with previously reported results from mineral-water reactions at 30, 50, and 70ºC [4,6]. However, previous studies did not conduct an analysis of the mineral products thus the reactions responsible for H_2 gas production are unknown. To address this issue and define the reaction pathways, we are using synchrotron-based μXRF and μXANES investigations to identify Fe-bearing secondary phases and to constrain the partitioning of Fe and the mechanisms of H_2 generation as a function of mineral composition and temperature. Investigations into the effect of the starting materials (e.g. surface area of the substrates and substrate and fluid composition) on H_2 production are also being undertaken. This work will allow us to constrain the reactions that produce H_2 under low temperature conditions and will provide insight into the potential for water-rock reactions to support microbial life in the deep subsurface and on other planetary bodies.

Carbon dioxide degassing and estimation of thermal energy release from White Island volcano , New Zealand

AGNES MAZOT[1],SIMON BLOOMBERG[2*], TRAVIS HORTON[2], CLINTON RISSMANN[3], CHRISTOPHER OZE[2], DARREN GRAVLEY[2] AND BEN KENNEDY[2]

[1]GNS Science, Wairakei, NZ
a.mazot@gns.cri.nz
[2]University of Canterbury, Geological Sciences, NZ
Simon.bloomberg@pg.canterbury.ac.nz*
[3]Environment Southland, Invercargill, NZ

Accurate quantification and mapping of the total carbon dioxide (CO_2) emitted from a variably permeable volcano still remains a challenge. We used high resolution measurements of CO_2 flux and heat flow within the crater floor of White Island to characterise the mass (CO_2 and steam) and heat released. White Island is an andesite stratocone and New Zealand's most active volcano. Frequent phreatic, phreatomagmatic and magmatic eruptions have occurred throughout the 19th and 20th century. White Island's most recent magmatic explosive eruption occurred in 2000. Currently, the hydrothermal system is manifested by localised vigorous fumarolic activity, mud pools and mounds, and an acidic (pH ≈–0.4) 200 m diameter crater lake, and diffuse degassing through the crater floor.

CO_2 flux degassing and thermal budget

In 2011, we performed 691 measurements of CO_2 flux using the accumulation chamber method. CO_2 flux values measured were ranged between of 0.1 – 29,896 g m^{-2} d^{-1}. Total CO_2 emission rate estimated by stochastic simulation was 116 ± 2 td^{-1} within the crater floor (0.31 km^2). The $\delta^{13}C$ range (-10 and -2‰) reflects the spatial variance in magmatic CO_2 contribution. Based on CO_2 flux data and a mean H_2O/CO_2 wt ratio of 15.3, the flux of thermal energy released from the crater floor totals 54 ± 1MW. The associated rate of steam condensation is 1760 ± 25td^{-1}. The spatial distribution of surface heat flow, soil gas $\delta^{13}C$, surface hydrothermal features and CO_2 flux indicates high gas and thermal permeability at old crater margins, and breaks in slope (crater floor/wall, crater floor/mound). We suggest that areas of high degassing are associated with advective gas transport adjacent to persistent fumarole pathways. Areas of low permeability are associated with sulphur/anhydrite and iron oxide-silica precipitation crusts which limit gas diffusion to the surface. In addition, we explore the influence of sea water and meteoric water influx into the hydrothermal system.

Evidence of paleo sulfate methane transition zone in marine sediments

A.PEKETI[1], A. MAZUMDAR[1*] , R. K. JOSHI[1], H. JOAO, D. J. PATIL[2], L.S. SRINIVAS[2], A. M DAYAL[2]

[1] Gas Hydrate Research Group, Geological Oceanography, National Institute of Oceanography, Donapaula, Goa-403004, India maninda@nio.org (* presenting author)
[2]National Geophysical Research Institute, Uppal Road, Hyderabad-500606, India

The sulfate methane transition zone (SMTZ) denotes a redox interface within the anoxic sediment column where pore water sulfate and methane concentration profiles intersect and are depleted to non detectable concentrations. This depletion in sulfate and methane concentrations are attributed to the anaerobic oxidation of methane (AOM) performed by a syntrophic consortium of CH_4-oxidizing archaea and sulfate-reducing bacteria [1]. AOM causes marked enrichment in H_2S and HCO_3^- ion concentrations in the porewaters within the SMTZ, resulting in precipitation of Fe-sulfides, Ca-Mg-carbonates. Sulfate concentration profile, depth to SMTZ and thickness of SMTZ depend on the methane flux. High methane flux results in linear sulfate concentration gradient and shallow SMTZ and vice versa. In the Krishna-Godavari (K-G) basin, Bay of Bengal, seismic data [2] show regional presence of gas hydrates manifested in the form of a bottom simulating reflector (BSR). Sediment cores for the study were collected on-board Marion Dufresne and JOIDES Resolution as part of the gas hydrate exploration program in the K-G basin offshoe. Our results show multiple carbonate bearing zones in the sediment with pronounced carbon isotopic depletion typical of AOM. Biogenic methane with $\delta^{13}C$ ranging from -80 to -100‰ (VPDB) have earlier been reported [3] from K-G basin. In contrast, we have not recorded any appreciable barium front in any of the cores. The barium front possibly diappeared whenever the SMTZ moved up across an existing Ba front. However carbonate layers are not subject to such dissolution. The zones with deplted carbon isotope ratios are enriched in pyrite with heavy sulfur isotope ratios suggesting Rayleigh fractionation in a closed system. The sharp rise in $^{34}S_{CRS}$ indicate focussed sulfate reduction in SMTZ. In the long core NGHP-01-10D several such zones with heavy sulfur isotope ratios have been noted indicating paleo SMTZ transition zones We propose that content and stable isotope ratios of authigenic carbonate and pyrite in marine sediments may serves as an ideal tool to detect fossil sulfate methane transition zone in the absence of barium front.

Pore-water chemistry in clays and shales: Methods and applications

MARTIN MAZUREK[1*], H. NIKLAUS WABER[1] AND TAKAHIRO OYAMA[2]

[1]Institute of Geological Sciences, University of Bern, Switzerland, mazurek@geo.unibe.ch (*presenting author), waber@geo.unibe.ch
[2]CRIEPI, Abiko-shi, Chiba, Japan, ooyama@criepi.denken.or.jp

A suite of techniques to extract pore waters from clays and shales and to analyse them for major ions and isotope ratios have been developed over the last decade. Sophisticated techniques are needed to obtain the full pore-water composition, while simple crush/leach tests and other laboratory protocols provide information on conservative chemical constituents, such as Cl^-, Br^-, $\delta^{18}O$, δ^2H and dissolved noble gases. Concentration profiles of these constituents across shale formations are typically curved, indicating a transient state of diffusive exchange with the embedding aquifers. Transport modelling is used to quantify the time scales related to this process, using initial and boundary conditions based on palaeo-hydrogeological evidence [1]. This procedure provides insights on transport processes and on the upscaling of laboratory-derived transport parameters to the formation scale.

A comprehensive set of pore-water data has been obtained from drillcores of the Schlattingen borehole, penetrating a Mesozoic, clay-mineral rich, low-permeability sequence in NE Switzerland. Squeezing tests at 200-500 MPa yielded sufficient water for chemical and isotopic analysis (Fig. 1), in spite of low water contents (3-5 wt.-%). Salinity decreases with squeezing pressure, which is an artefact related to the membrane properties of the rocks. The decline of salinity in the lower part of the profile indicates the presence of a low-salinity boundary below 1000 m depth, leading to out-diffusion of Cl^- from the low-permeability sequence. The time scales related to this process are evaluated by transport modelling.

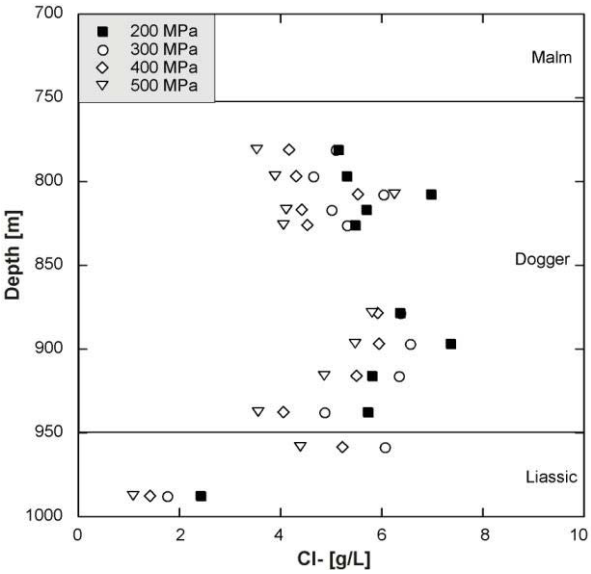

Figure 1: Cl^- concentrations in pore waters from the Schlattingen borehole obtained by squeezing experiments

Investigating marine corrosion communities using tagged pyrosequencing and single cell genomics

JOYCE M. MCBETH[1*] AND DAVID EMERSON[1]

[1]Bigelow Laboratory for Ocean Sciences, East Boothbay, ME, USA jmcbeth@bigelow.org (* presenting author) demerson@bigelow.org

It was recently discovered that members of the Fe(II)-oxidizing *Zetaproteobacteria* (*Zetas*) rapidly colonize mild steel surfaces that represent a ready source of Fe(II) [1], and that a robust microbiologically influenced corrosion (MIC) community develops on steel that includes *Zetas* and *Epsilonproteobacteria* [2]. Here we summarize our efforts to expand our understanding of marine steel MIC bacterial and archaeal communities. We present results from two time series incubations, the first conducted in Great Salt Bay salt marsh in summer 2010, and the second conducted below the marine intertidal zone in Boothbay Harbor, ME in summer 2011.

We used tagged pyrosequencing (V4 region, SSU rRNA gene) to examine bacterial and archaeal communities on mild steel surfaces from the salt marsh time series (2010). *Zetas* were identified in both sediment and steel sample pyrosequencing libraries, and unique *Zeta* OTUs on the steel reflected the numbers observed in the sedimentary *Zeta* communities we analyzed. *Epsilonproteobacteria* (in particular *Sulfurimonas* and *Arcobacter* relatives) were enriched on the steel in comparison with sediments. Unique *Deltaproteobacterial* OTUs present increased with incubation time to near sediment levels, likely reflecting colonization of the steel by Fe(III)-reducing and sulfate-reducing bacteria (SRB). Archaeal results were dominated by a potentially novel order of *Euryarchaeota*, most closely related to the *Thermoplasmatales*. Quantiative PCR of these samples and associated sediments with 16S rRNA gene primers for *Zetas* and functional gene primers for SRB showed that, on average, *Zeta* gene copies in sediments were an order of magnitude less abundant than SRB. *Zeta* gene copies on the steel increased rapidly over the first 10 days, exceeding copies quantified in the sediment by an order of magnitude. The SRB numbers on the steel were 10 fold lower than in sediments during the first days of incubation, but increased to near the sediment levels by 40 days.

A 9 day sample from the 2011 time series was subjected to whole genome amplification. Screening of single amplified genomes (SAGs) for bacteria identified 148 bacterial SAGs; 18 (12%) *Zetas*, 61 (42%) *Epsilonproteobacteria* (near relatives of *Sulfurimonas* sp.), and 46 (32%) *Gammaproteobacteria* (notably 15 relatives of *Hydrogenovibrio* sp., an autotrophic H_2-oxidizing bacterium).

When compared to previous work [2], this study provides evidence for rapid development of a core corrosion community on mild steel. Use of tagged pyrosequencing and single cell genomics enhances our understanding of MIC community richness and provides the possibility of exploring the genomes of individual community members.

The origin and composition of polyphase inclusions in tourmaline from the Greenbushes pegmatite

TRAVIS J. MCCARRON[1*] and ALAN J. ANDERSON[2]

[1]Carleton University, Ottawa, Canada, tmccarro@connect.carleton.ca (* presenting author)
[2]St. Francis Xavier University, Antigonish, Canada, aanderso@stfx.ca

The (2.527 Ga) Greenbushes rare-element pegmatite in Western Australia is an important source of lithium and tantalum. The pegmatite, which was emplaced syngenetically into the Donnybrook-Bridgetown shear zone within the Western Gneiss terrain of the Yilgarn Craton, consists of five distinct petrologic zones. Zoned tourmaline crystals in the Ta-rich albite zone of the pegmatite contain numerous solid-liquid-vapor inclusions. The inclusions occur within an inner brown-green pleochroic growth zone and are distributed as planar arrays in healed microcracks, oriented subnormal to the c-axis, and as isolated groups. The inclusion-bearing tourmaline is overgrown by an inclusion-free blue-green growth zone. Solid phases in the inclusions were identified using Raman spectroscopy and one representative polyphase inclusion was analysed using a dual beam focused ion beam-scanning electron microscope (FIB-SEM) for three-dimensional textural and chemical characterization. Fluid inclusion assemblages (FIA) show highly variable liquid-vapor-solid phase proportions. Measurements of phase ratios using a petrographic microscope and image analysis system show a direct relationship between inclusion size, percent volume solids and mineralogy. Large inclusions (>300μm^2) containing >50% volume solids are dominated by a silicate assemblage, which may contain quartz, pollucite, lepidolite, zabuyelite and an arsenic-antimony rich phase (predominantly native arsenic, senarmontite, paakonenite and/or arsenolite) and aqueous carbonic fluid. Intermediate sized inclusions ranging from 5-50% volume solids may contain zabuyelite, an arsenic- bearing phase and aqueous carbonic fluid. The smallest inclusions (<100μm^2) have less than 5% volume solids and contain aqueous carbonic fluid and an arsenic-bearing solid phase. Rare nahcolite and lithiophosphate were also identified in some inclusions. The variability in inclusion size and phase proportions within a FIA is attributed to mineral precipitation prior to trapping and inclusion necking. The inclusions are interpreted to represent the products of a silicate-rich aqueous carbonic fluid that was entrapped during the growth and recrystallization of the early brown-green tourmaline.

Extreme Fractionation of Rare Earth Elements in Volcanogenic Massive Sulfides of the Bathurst Mining Camp: Evidence from Europium Anomalies in Hydrothermal Apatite

SEAN MCCLENAGHAN[1*], DAVID LENTZ[2], AND PAUL SYLVESTER[3]

[1]New Brunswick Geological Surveys Branch, Bathurst, Sean.mcclenaghan@gnb.ca (* presenting author)
[2]University of New Brunswick, Department of Earth Sciences, Fredericton, Dlentz@unb.ca
[3]Memorial University of Newfoundland, Department of Earth Sciences, Psylvester@mun.ca

Rare earth element (REE) mobility in hydrothermal systems has been the focus of numerous studies [1,2], with the most direct evidence coming from active hydrothermal vents [3], which display prominent enrichments in Eu and LREE. Exhalative sedimentary rocks generally contain small quantities of REE when compared to volcanic and clastic sedimentary lithotypes; *e.g.*, massive sulfides of the Bathurst Mining Camp (BMC) have ∑REE contents that average 36.8 ppm, and range from 0.93 to 249 ppm. Nevertheless, REE in massive sulfides of these exhalative horizons can exhibit considerable fractionation, with chondrite-normalized REE profiles [4] displaying prominent Eu anomalies. Values of Eu_N/Eu^* calculated for massive sulfides are consistently positive with values as high as 36.7 (ave., 6.26). A positive Eu_N/Eu^* correlation (n=286) with Sn (r'=0.55) and In (r'=0.40) suggests enrichment in primary hydrothermal fluids associated with base-metal sulfide precipitation.

Petrography and micro-analytical data for massive sulfides have shown that exhalative gangue and accessory minerals, in particular phosphates control REE contents; this is supported by a strong correlation (bulk) between ∑REE and P_2O_5 (r'=0.53). Fluorapatite is the most abundant phosphate in exhalites of the BMC, occurring as nodular to colloform masses and intimate mixtures with carbonate and sulfide minerals. Imaging of fluorapatite reveals a distinct cathodoluminescence consistent with the substitution of Mn^{2+} and Eu^{2+} in the fluorapatite mineral structure and suggests formation under reducing hydrothermal conditions.

In situ laser-ablation ICP–MS analyses (n=169) reveal elevated ∑REE contents in fluorapatite, averaging 1,548 ppm, and ranging from 250 to 24,038 ppm. Europium accounts for approximately ¼ of all REE substitution in apatite, with Eu contents as high as 1,554 ppm (ave., 295 ppm). Chondrite-normalized REE profiles display prominent enrichment in Eu, with Eu_N/Eu^* values as high as 222 (ave., 19.0). To date, these anomalies represent the largest reported fractionation of Eu in the solar system, exceeding values for mesosiderites, and both terrestrial and lunar anorthosites [5]. This extreme fractionation of Eu suggests protracted growth of apatite or some precursor phase (i.e., francolite) under reducing (low fO_2) and high temperature hydrothermal (>250ºC) conditions, further corroborated by the prevailing pyrrhotite-pyrite-chalcopyrite stockwork assemblage. Apatite associated with lower temperature assemblages exhibits diminished Eu signatures, reflecting a more-distal hydrothermal environment and defining a vector for mineralization.

Serpentinization and the flux of reduced volatiles to the seafloor

THOMAS M. MCCOLLOM[1*], FRIEDER KLEIN[2], WOLFGANG BACH[3], BRUCE MOSKOWITZ[4], THELMA BERQUÓ[5], AND ALEXIS TEMPLETON[1]

[1]University of Colorado, Boulder, CO, USA, mccollom@lasp.colorado.edu (* presenting author)
[2]Woods Hole Oceanographic Institution, Woods Hole, MA, USA
[3]University of Bremen, Bremen, Germany
[4]Institute for Rock Magnetism, University of Minnesota, Minneapolis, MN, USA
[5]Concordia College, Moorhead, MN, USA

Serpentinization of ultramafic rocks has long been recognized to be a source of reduced volatile compounds, particularly hydrogen (H_2) and methane (CH_4). Over the last couple of decades, there has been increasing scientific interest in the capacity of these reduced compounds to support chemolithoautotrophic biological communities, both now and on the early Earth. In the deep sea, serpentinization of ultramafic rocks can serve as a source of H_2 and CH_4 to biological communities living within the ocean crust, at the seafloor where fluids are discharged from serpentinites, and in the overlying water column. The abundance and spatial distribution of serpentinite-supported autotrophic communities depends on when, where, and how much reduced volatiles are generated.

The production of reduced volatiles during serpentinization depends strongly on the fate of Fe as the reaction proceeds, since the generation of reduced compounds is directly linked to the oxidation of Fe(II) to Fe(III). Serpentinization is often portrayed as a fairly straightforward process whereby ultramafic rocks are converted to a limited set of minerals dominated by serpentine polymorphs, brucite, and magnetite. Within this rather simple framework, however, there is a lot of room for complexity. In particular, it is increasingly clear from petrologic studies, laboratory experiments, and numerical modeling that the distribution of Fe among reaction product minerals, and the oxidation state of Fe in those products, is highly variable, and is dependent on a complex mixture of factors including temperature, kinetics of dissolution, precipitation and diffusion, bulk rock and mineral compositions, extent of reaction, and thermodynamic constraints. A recent bevy of laboratory experiments by both ourselves and others [e.g., 1-3] focusing on the fate of Fe during serpentinization is providing new insights into pathways leading to generation of H_2 and other reduced compounds, and will provide the basis for improved models of the flux of reduced volatiles from serpentinization environments within the ocean crust. We will present results from a series of experiments that examine production of H_2 and concurrent mineral alteration during serpentinization of olivine and peridotite at temperatures from 230 to 320 ºC.

Investigating biomineralized structures and morphology associated with laminated freshwater stream terraces: Stromatolites?

C. MCCORT[1]*, E. CHI FRU[2], S. GOUDEY[3], AND C.G WEISENER[1]

[1]Great lakes Institute for Environmental Research, University of Windsor, Windsor, Canada, candace.mccort@gmail.com; weisener@uwindsor.ca

Introduction

Biogeochemical cycles are considered the driving force behind how elements are transported and buried in sediments. A principle mechanism in the addition and removal of elements in biogeochemical cycles involves biomineralization. In the strict context we can classify biomineralization as extracellular, intracellular or as catalytically induced depending on the organisms in question. Investigation of the Erickson Creek watershed BC Canada, has led to the discovery of interesting phenomena involving cementation of the streambeds possibly affecting aquatic habitats adjacent to coal mine impacted riparian zones.

These mineralized mats are calcareous in nature and have managed to form densely layered sequences associated with proliferation of freshwater mosses/biofilms. The streams support localized assemblages charaterized by benthic, alkaliphilous diatoms with relatively low species richness. To investigate the process attributing to the biomineralized event, samples were collected to determine the casual relationships been the mosses, bacteria and the *in situ* mineralization that is taking place (Figure 1). SEM and Raman microscopy provide structural, morphological, and chemical information about the biomineralized structure within aged layers. In addition, DNA extraction, species richness and identification, was used to determine biological composition.

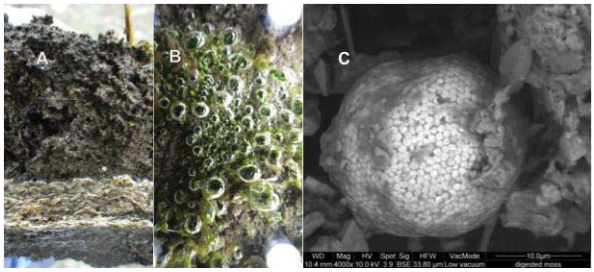

Figure 1: (A) laminated structure of biomineralized mat, (B) top down surface showing freshwater moss, (C) SEM micrograph suggesting the existence of localized chemically reduced microhabitats with S/Fe precipitation.

Conclusion

This data will provide insight and address questions pertaining to the cementation process at this location and its affects on aquatic habitats influenceing the biogeochemistry and microorganisms that live in this environmental system.

Microbially-accelerated carbon sequestration

JENINE MCCUTCHEON[1*], IAN M. POWER[2], ANNA L. HARRISON[2], GREGORY M. DIPPLE[2] AND GORDON SOUTHAM[1]

[1]Department of Earth Sciences, The University of Western Ontario, London, ON CANADA, jmccutc3@uwo.ca (*presenting author)
[2]Department of Earth and Ocean Sciences, The University of British Columbia, Vancouver, BC CANADA

This investigation modelled microbially-accelerated carbon sequestration through the precipitation of carbonate minerals. A microbial consortium, collected from a natural hydromagnesite playa near Atlin, British Columbia, Canada, was used to inoculate a 10 m long flow-through bioreactor. The consortium contained cyanobacteria, which are able to mediate magnesium carbonate precipitation by changing the water chemistry, particularly by increasing pH. A bicarbonate-rich nutrient solution containing 1 g/L Mg was added to the bioreactor at a rate of 5 L/day for 7 weeks. Major ion concentrations, pH, dissolved oxygen, and conductivity were monitored weekly along the length of the bioreactor. The concentration of Mg^{2+} and other major cations was determined using inductively coupled plasma atomic emission spectroscopy, while ion chromatography was used for major anions. An alkalinity titration was used to quantify the bicarbonate concentration. The precipitation of carbonate minerals was inferred by the measured decrease in [Mg^{2+}] and alkalinity along the length of the bioreactor. Carbonate precipitation occurred, primarily as dypingite, which was confirmed using light microscopy, scanning electron microscopy, and x-ray diffraction. The first 3 m of the bioreactor, dubbed the active zone, was responsible for removing over 37% of the Mg added to the bioreactor from solution, versus 61% Mg removed from the entire system. A mass of 0.362 kg of Mg carbonate precipitated in the active zone via microbially-mediated mineralization. This amount of mineral precipitation over the course of the experiment translates to a carbon sequestration rate of 5.88 kg of CO_2/m^2 of microbial mat/year.

This investigation demonstrated the process of microbe-induced carbonate precipitation on a larger scale than previous studies [1,2]. This biogeochemical process may have industrial applications if it can be implemented on the scale of mine tailing storage facilities such as those at the Mount Keith Nickel Mine in Western Australia. Magnesium weathered from ultramafic waste rock would react with CO_2 in the presence of the microbes and aqueous chemistry conditions studied in this investigation. The Mount Keith Mine produces tailings at a rate of 11 Mt/year, with tailings covering an area of ~19 km^2 [2,3]. Application of the biogeochemical process studied in this investigation to the Mount Keith Mine could result in a CO_2 sequestration rate of over 111 700 t/year. Globally, there are many mine sites with microbially-accelerated carbon sequestration potential, making the results of this study relevant to the current efforts to reduce net greenhouse gas emissions.

Compositional models of the Earth and early planetary evolution

WILLIAM F. MCDONOUGH

Geology, Univ Maryland, College Park, USA mcdonoug@umd.edu

New chemical data along with a broad range of other chemical, isotopic and physica data that have come to light over the last decade will be integrated into a coherent planetary model. Present day compositional models for the planet are non-unique and strongly influenced by the method used in its construct: cosmochemical, geochemical/petrological, and geophysical. Cosmochemical models examine candidate accretion materials (i.e., chondrites) from which the Earth was built and compares these compositional input against physical data that describes the planet to minimize the misfit. Geochemical models deconvolve compositional data from samples of the mantle and crust to estimate the concentration of elements in the primitive mantle and then compares these input against chondrite data to describe the core composition with a minimum misfit. Geophysical models use the present day boundary condition for the Earth to find consistent solutions to the thermal evolution of the planet and the mineralogy of the mantle.

Recently reported geoneutrino data are consistent with most existing Earth models, and now exclude, at the 67% confidence level, models that invoke a homogeneous, fully radiogenic Earth model. Stable (O, Ca, Ti, Cr, Ni, Mo) and radiogenic (142Nd, Sr, Hf) isotope data for chondrites provide a perspective and perhaps a constraint on which group of chondrites best fit the bulk Earth composition. Increasingly, these data find the greatest misfit between the composition of the Earth and that of carbonaeous chondrites, whereas better fits are observed for the Earth and enstatite and ordinary chondrites. Models that describe the planetary proportion of Fe, O, Si, Mg (>90% of the Earth's mass) define the mass of core and mineralogy of the mantle, with the latter potential describing a compositionally layered state. No chondritic material, present in our collections, are consistent with data for the Earth and demonstrate that adhoc adjustments are needed to describe the nature of the building blocks of the Earth. Matching compositional models of the primitive mantle with that for the continental crust constrains the family of permissible compositional and mineralogical models for the present day mantle and any potential stratification. Data and uncertainties will be presented for quantitative models that describe the concentration and distribution of elements, particularly the heat producing elements, in the present day mantle. Models invoking deep mantle reservoirs (BMOL, 142Nd-layer, primitive mantle regions, upper/lower boundaries) will be assessed quantitatively. All model predictions from the three approaches described above are presently permissible given uncertainties, however ever accumulating geoneutrino data sets will provide tighter bounds by which one can critically assess the viability of Earth model compositions.

Episodic, post-supereruption resurrection of the Peach Spring magmatic system (western Arizona, USA) over ~2 Ma

SUSANNE M. MCDOWELL[1*], CALVIN F. MILLER[1], CHARLES A. FERGUSON[2], AND JOE WOODEN[3]

[1]Vanderbilt University, Earth & Environmental Sciences, susanne.m.mcdowell@gmail.com (* presenting author)
[2]Arizona Geological Survey, caf@email.arizona.edu
[3]Stanford University, jwooden@standford.edu

The Silver Creek caldera (southern Black Mountains, western Arizona) is the source of the 18.8 Ma supereruption that produced the Peach Spring Tuff (PST), a ≥700 km^3 ignimbrite that crops out in northwestern Arizona, southern Nevada, and southeastern California [1, 2, 3]. Intruding the caldera's eastern margin is a ~30 km^2 epizonal, intermediate to felsic plutonic complex. The complex reveals a ~2 Ma history of episodic, post-PST magmatic recharge, suggesting that this magmatic system was periodically revitalized long after its colossal eruption.

Indications of magmatic rejuvenation are evident throughout the intrusive complex, which consists of two primary, texturally-diverse units: the coarse-grained Moss porphyry (~62-68 wt. % SiO_2) in the north, and the fine- to coarse-grained, commonly granophyric Times porphyry (>70 wt. % SiO_2) in the south. The Moss displays locally abundant, 2-10 cm rounded enclaves (59 wt. % SiO_2). Near the Moss/Times contact along Silver Creek, a crystal-rich Times matrix consisting of rounded feldspars set in a fine-grained groundmass hosts 0.5-2 m enclaves with intermediate compositions. Rapakivi feldspars appear in both units, and mafic, intermediate, and felsic porphyry dikes crosscut the entire complex.

U-Pb SHRIMP zircon ages and mineral geochemistry support field evidence for magmatic recharge. The Times, the Moss, and a distinctive porphyry similar to the Moss yield zircon age spectra of ~16.8-19 Ma (coeval with nearby volcanics), though PST-age zircons are notably scarce. Probability density analysis indicates two main age peaks at ~17.4 and ~18.2 Ma, with the Moss containing a larger population of older grains than the Times. Moss zircon and sphene record increasing concentrations of Ti and Zr, respectively, from core to rim, consistent with reheating.

A preliminary interpretation of the data is that the Moss was emplaced in the shallow crust at ~18 Ma and substantially reheated and reactivated at ~17.4 Ma, roughly coincident with emplacement of the Times. The wide zircon age spread may reflect other recharging events that are irresolvable via SHRIMP dating. Regardless, the shallow subvolcanic system appears to have been sporadically resurrected over one to two million years following the PST supereruption.

Lacustrine cave carbonates: novel, absolute-dated paleohydrologic archives in the Bonneville Basin (Utah, USA)

DAVID MCGEE[1,*], JAY QUADE[2], R. LAWRENCE EDWARDS[3], WALLACE S. BROECKER[4], HAI CHENG[3,5], AND ELENA STEPONAITIS[1]

[1]Massachusetts Institute of Technology, Cambridge, USA, davidmcg@mit.edu (* presenting author), estep@mit.edu
[2]Univ. of Arizona, Tucson, USA, quadej@email.arizona.edu
[3]Univ. of Minnesota, Minneapolis, USA, edwar001@umn.edu
[4]Columbia Univ., New York, USA, broecker@ldeo.columbia.edu
[5]Xi'an Jiaotong Univ., Xian, China, cheng021@umn.edu

Records of past changes in closed basin lake levels and lake water isotopic composition provide key insights into past variations in the hydrological cycle; however, these records are often limited by dating precision and temporal resolution. Here we present data from lacustrine cave carbonates, a novel class of carbonates that comprise a promising new archive of past hydrologic changes in the Bonneville Basin of the northeastern Great Basin (U.S.A.). These dense carbonates precipitated within caves, crevices and other protected spaces flooded by Lake Bonneville during its highstand in the last glacial period. We focus on deposits in Cathedral and Craners caves, located ~50 km apart at a similar elevations approximately 100 m above the modern Great Salt Lake and almost 200 m below Lake Bonneville's highstand shoreline. Carbonates from the two caves show similar chronologies, mineralogical transitions, isotopic compositions and trace element concentrations. These findings suggest that lacustrine cave carbonates record changes in lake level and in the isotopic composition and chemistry of lake water. Importantly, the deposits can be precisely dated by U-Th methods, providing the first high-precision, absolute-dated records of Lake Bonneville's water balance changes.

We use dates for the onset and cessation of lacustrine cave carbonate deposition to offer new constraints on past changes in lake level and the carbonate saturation state of lake water. We also present precisely dated, high-resolution oxygen and uranium isotope records from the deposits. Within a first phase of deposition reflecting the lake's transgression between 26 and 18 ka, our isotopic data suggest a large influx of freshwater during Heinrich Stadial 2. A hiatus in deposition beginning 18.2 ± 0.3 ka may be the result of freshening related to the lake's overflow. Calcite deposition resumes at Cathedral Cave at 16.4 ± 0.2 ka, suggesting that basin overflow had ceased by this time and that the lake re-entered calcite saturation; this interpretation implies that the lake's deglacial regression began well before the Bølling warming. Cessation of this second phase of deposition at 14.7 ± 0.2 ka may reflect the lake's drop below Cathedral Cave's elevation.

We have located similar deposits at over forty locations in the basin spanning almost the entire ~270 m elevation range between the modern Great Salt Lake and the highstand shoreline. We present data from several elevations that offer additional constraints on changes in lake level and lake chemistry during the last glacial period and deglaciation.

[3]Teal Exploration & Mining, Chingola, Zambia, toby@tealming.com
[4]School of Earth Sciences, University of Tasmania, donna.satterthwait@utas.edu.au

The supergiant Century sediment-hosted Zn-Pb-Ag deposit formed in an outer shelf setting [1] from a submarine hydrothermal vent system developed on, or very near, the seafloor[2]. The mine sequence comprises variably sulfidic (mainly sphalerite) and sideritic siltstones and carbonaceous shales [1,3]. It is somewhat (~1.5x) thicker than equivalent strata observed in a drill-core (MMG788) 5km to the west, suggesting sub-basin development at the site of ore deposition [3]. Unlike other northern Australia Proterozoic sedex Zn deposits, Century is relatively low in pyrite.

Sideritic siltstones in the mine sequence are characterised by crinkly and whispy carbonaceous, bedding-parallel seams, previously interpreted as stylolites. We have re-interpretted these features as microbialites. Their diversity and abundance in the mine sequence, compared to drill-core MMG788, is consistent with locally abundant biological activity at the site of ore formation.

Major element geochemical data and iron speciation measurements from samples from the mine and MMG788 indicate anoxic (ferruginous, *not* sulfidic) conditions mostly prevailed [3]. This is despite several hundred million tons of biogenically reduced S having been sequestered into the Century deposit.

We will present new Mo, P and organic C data from the mine sequence that speak to locally high primary organic productivity. Organic matter thus produced may have been fuel for biogenic sulfate reduction sufficient to form the Century Zn sulfide orebody.

Geologic Storage Mavericks: Insights and Promise from Laboratory and Field Pilot Studies in Flood Basalts

B. PETER MCGRAIL

Pacific Northwest National Laboratory, Richland, Washington, USA, pete.mcgrail@pnnl.gov

Abstract

"Maverick" according to the Merriam-Webster dictionary is defined as "One that refuses to abide by the dictates of or resists adherence to a group." Hence, "maverick" is apropos for anyone seriously studying flood basalts for sequestration of carbon dioxide. Continental flood basalts represent one of the largest geologic structures on earth but have received comparatively little attention for geologic storage of CO_2. In fact, flood basalts have flow tops that are porous, permeable, and have enormous capacity for storage of CO_2 or other gases of interest. In appropriate geologic settings, interbedded sediment layers and dense low-permeability basalt rock flow interior sections may act as effective containment for injected gases. For CO_2 sequestration purposes, containment is critical so that sufficient residence time is established for mineralization reactions to occur. Initial laboratory experiments conducted nearly a decade ago with $scCO_2$ showed rapid chemical reaction of CO_2-saturated pore water with basalts to form stable carbonate minerals. However, recent discoveries in laboratory tests with water-saturated supercritical CO_2 show that mineralization reactions occur directly in this phase as well, providing a second and potentially more important mineralization pathway than was previously understood. In fact, in deep geologic settings, mineralization by water-wet $scCO_2$ is the dominant mineralization pathway. But, despite many years of laboratory investigation, the remarkable 10 fold variability in reactivity of different basalts remains an unresolved scientific question, defying easy correlation to mineral makeup or chemical compositional differences in the basalts.

In this paper, we will also discuss an important leveraging application of the work on CO_2 sequestration in basalts for compressed air energy storage to help manage electric grid stability in the Pacific Northwest. Here, mineralization reactions need to be avoided to prevent reservoir permeability decline over the course of many air injection and extraction cycles. Oxygen depletion through reaction with Fe(II) in the basalts also might need mitigation if the extracted air is to be used directly in a combustion turbine.

Field testing of CO_2 storage in basalts is proceeding with drilling of the world's first supercritical CO_2 injection well in flood basalt being completed in May 2009 near the township of Wallula in Washington State and corresponding CO_2 injection permit granted by the State of Washington in March 2011. Injection is in the final planning stage. In Iceland, the CARBFIX project has drilled an injection well and several monitoring wells and plans to test injection of groundwater saturated with a CO_2-H_2S gas mixture obtained from a geothermal power plant. If proven viable by these field tests and others that are in progress or being planned, major flood basalts in the U.S., India, and perhaps Australia would provide additional CO_2 storage capacity and regional sequestration options in these countries where conventional storage is limited, and also provide tangible benefits for future applications in energy transmission and storage.

The role of surface charge and exchange cation speciation on the structure of interfacial water in nontronite suspensions

JUSTIN V.T. ROTH,[1] CHRISTOPHER A. HEIST,[1] AND MOLLY M. MCGUIRE[1*]

[1]Bucknell University, Department of Chemistry, Lewisburg, PA, U.S.A., mmcguire@bucknell.edu (* presenting author)

Attenuated total reflection infrared spectroscopy (ATR-FTIR) was used to investigate the structure of water at the surface of suspensions of the nontronites, NAu-1 and NAu-2. Raw ATR spectra were converted to absorption index (k) spectra via the Kramers-Kronig transform to allow direct comparison of samples with different indices of refraction. Difference spectra produced from these k spectra allowed subtle shifts in the O-H stretching region to be discerned, thereby providing information about differences in the degree of hydrogen bonding. Suspensions of both NAu-1 and NAu-2 exchanged with either Na+ or K+ exhibit increased hydrogen-bonding at the mineral/water interface as compared to bulk water. NAu-1, which has greater total and tetrahedral charge than NAu-2, shows no change in water structure upon reduction of structural Fe or the addition of a small excess of electrolyte. These observations suggest that the ordering of interfacial water in NAu-1 suspensions is dominated by the highly charged mineral surface. Reduction of structural Fe in NAu-2 results in changes to the interfacial water structure that are dependent on the exchange cation species. In this case, reduction produces a significant increase in tetrahedral charge, which alters the interactions of the exchange cations with the surface.

A Tertiary record of Australian plate motion from ages of diamondiferous alkalic intrusions

BRENT MCINNES[1*], NOREEN EVANS[1,2], FRED JOURDAN[1], BRAD MCDONALD[1,2], JOHN GORTER[3], CELIA MAYERS[1] AND SIMON WILDE[1]

[1] John De Laeter Centre for Isotope Research, Curtin University, Perth Australia, b.mcinnes@curtin.edu.au ([*] presenting author), f.jourdan@curtin.edu.au, Celia.Mayers@curtin.edu.au, s.wilde@curtin.edu.au

[2] CSIRO Earth Science and Resource Engineering, Perth, Australia, noreen.evans@csiro.au, brad.mcdonald@csiro.au

[3] Eni Australia Ltd, Perth, Australia, John.Gorter@eni.com

Multiple geo/thermochronometry datasets (zircon (U-Th)/He[1], phlogopite $^{40}Ar/^{39}Ar$ and wadeite $^{40}Ar/^{39}Ar$) have been acquired from four Western Australian kimberlite and lamproite localities distributed over 850 km. The linear orientation of the eruption centres (~015°), southwardly younging emplacement ages, and apparent co-linearity with modern geodetic measurements has implications for Australian plate geodynamics (Fig. 1).

The Fohn diatreme field consists of ~30 lamproite pipes discovered during oil exploration in the Timor Sea[2]. Phlogopite recovered from lamproite cuttings in an offshore exploration well (Fohn-1) returned a robust plateau $^{40}Ar/^{39}Ar$ age of 29.4 ± 0.7 Ma (P=0.99). A diamond pipe from the North Kimberley kimberlite field (Seppelt) yielded four zircon grains with thermally reset (U-Th)/He ages averaging 25 Ma. Diamondiferous pipes at Ellendale contain xenocrystic zircon grains with (U-Th)/He ages of 20.6 ± 2.8 Ma that were thermally reset by lamproitic intrusions. Other researchers[3] report K-Ar ages for the Noonkanbah lamproite field of ~19 Ma, whereas $^{40}Ar/^{39}Ar$ dating of wadeite from the Walgidee Hills lamproite yielded plateau ages of 17.46 ± 0.17 Ma (P=0.44).

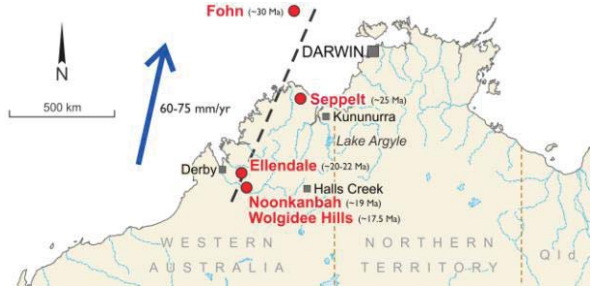

Figure 1: *Age-distance relationships of WA lamproites (red) and Australian plate motion as determined by GPS (blue arrow).*

Geodetic measurements indicate that the Australian plate is currently moving NNE at a rate of 60-75 mm/year relative to the Eurasian plate, whereas long period geospeedometry estimates range from 50-78 mm/year[4]. The age-distance relationship between the Fohn and Wolgidee Hills sites in this study are consistent with a plate motion of 70 mm/yr during the Tertiary.

Effects of polydispersity on natural organic matter fate and transport

DANIEL MCINNIS, LINDSAY SEDERS DIETRICH, DIOGO BOLSTER, AND PATRICIA MAURICE*

University of Notre Dame, Civil Engineering & Geological Sciences, 156 Fitzpatrick Hall, Notre Dame, IN 46556, USA dmcinnis@nd.edu, lseders@gmail.com, bolster@nd.edu, pmaurice@nd.edu (* presenting author)

Natural Organic Matter (NOM) is a polydisperse material whose components display a range of adsorption rates and affinities as determined largely by molecular weight (MW). In this study, the mobility of NOM was examined in sand columns at pH 5-8, in 0.001 to 0.1 M $NaClO_4$. Effluent data were modelled using the advection-dispersion equation (ADE). Greater overall mobility of NOM was observed at higher pH and lower ionic strength. High-pressure size exclusion chromatography (HPSEC) was used to monitor the MW distribution of column effluent; results were consistent with fractionation by preferential adsorption of intermediate to high MW components, as previously observed in many batch systems. Transport rates of different components were quantified by dividing the MW distribution into separate 'bins' and examining breakthrough curves for each bin. Heterogeneity in the retardation factor (*R)* led to heavy tailing of breakthrough curves as the experiments progressed. This non-Fickian transport behaviour was described using a continuous time random walk (CTRW) model designed to address variability in geochemical properties controlling sorption-desorption kinetics. Results of this study demonstrate that the effects of NOM compositional heterogeneity on transport can be addressed through a systematic coupling of geochemical and hydrologic approaches.

Origin, distribution and hydrogeochemical controls on methane occurences in shallow aquifers in southwestern Ontario

Abstract

Fractured organic-rich shales, such as the Marcellus, Antrim, and Utica are major targets for thermogenic and biogenic production in Michigan, New York, Pennsylvania, and Quebec. Age-equivalent shales extend into southwestern Ontario (Findlay Arch region), where there has been no shale gas production to date and little information exists on the origin and distribution of natural gas, despite historical accounts of gas in water supply wells screened in shales. To determine the origin and extent of natural gas, and investigate water quality associated with natural gas occurrences, 912 water supply wells were sampled for gas composition, isotopes, and water chemistry in Paleozoic bedrock and overburden formations throughout southwestern Ontario.

Methane concentrations, measured at the well head, ranged from <5 to 415% in-situ saturation (0 to ~251 ppm) with the highest concentrations in wells screened in the Georgian Bay, Dundee, Marcellus, Hamilton Group, and Kettle Point formations, and overlying glacial drift deposits. Carbon isotopes values of CH_4 (-89.9 to –52.3‰), the correlation of hydrogen isotopes of CH_4 and water, and the lack of higher chain hydrocarbons (C_2+<0.8 mole%), indicates the gas is biogenic in origin. Isotopic signatures of methane in overburden deposits were similar to gas accumulations in underlying bedrock formations, suggesting the gas migrated vertically into shallow aquifers, rather than being generated in-situ. Groundwater associated with methane accumulations are dominantly Na-HCO_3 type, with no dissolved oxygen, low Fe (<0.06 mM), low SO_4 (<0.44 mM), and low H_2S (<0.5 mM). Alkalinity concentrations ranged from 0.2 to 15.0 mM, and there was no correlation with CH_4 concentrations. High CH_4 concentrations were observed in groundwater with variable $\delta^{18}O$ values (-18.6 to –8.3‰), representing microbial methanogenesis associated with both modern and Late Pleistocene recharge. Results from this study provide important baseline data on dissolved gases and water quality in shallow aquifers overlying shales, in the case of future shale gas production, hydraulic fracturing and/or geologic sequestration of carbon dioxide to evaluate potential environmental impacts.

Anatexis and uranium protore in the Wollaston Domain, Saskatchewan

CHRISTINE L. MCKECHNIE [1,2*], IRVINE R. ANNESLEY [2,3], AND KEVIN M. ANSDELL[2]

[1] CanAlaska Uranium Ltd., Saskatoon, caustman@canalaska.com (* presenting author)

[2] Department of Geological Sciences, University of Saskatchewan, Saskatoon, Canada, kevin.ansdell@usask.ca

[3] JNR Resources Inc.., Saskatoon, Canada, jnrirvine@sasktel.net

The Fraser Lakes Zone B U-Th-REE-bearing granitic pegmatites are located within the Wollaston Domain of northern Saskatchewan, Canada. The mineralized zone lies circa 25 km from the southeastern edge of the highly prolific Athabasca Basin; home to some of the world's highest grade uranium deposits.

The granitic pegmatites intruded into a NNE-plunging regional fold structure at/near the highly deformed contact between Archean orthogneisses and overlying Paleoproterozoic metasedimentary rocks of the Wollaston Group.[1,2,3] Their intrusive contacts suggest the pegmatites formed during the later stages of the ca. 1.8 Ga Trans-Hudson Orogeny.[1,2,3] This agrees with CHIME dating of uraninite in the uranium-rich pegmatites (a cluster of ages between 1.85 and 1.80 Ga). A primary magmatic age has yet to be determined for the Th-LREE-rich pegmatites, which have contact relationships similar to the strongly U-rich pegmatites. High-grade metamorphism and migmatization occurred concurrently with pegmatite intrusion, at peak temperatures of up to T ca. 850°C at P ca. 9 kbar (i.e. lower granulite facies) followed by retrograde amphibolite-facies metamorphism.

A combination of partial melting of a metasedimentary-dominated source at depth, accessory mineral entrainment, and assimilation-fractional crystallization processes during ascent and emplacement is thought to be responsible for U, Th, and REE enrichment of the granitic pegmatites.

These pegmatites show similarities to the alaskite-hosted uranium deposits at Rossing (Namibia) and to uraniferous pegmatites in the Grenville Province (Canada).[1] Similar pegmatites have also been found in the proximity of some of the Athabasca Basin basement-hosted unconformity-type uranium deposits, including Moore Lakes, Eagle Point, and Millennium. Hence, it has been proposed [4,5,6,7] that such pegmatites are protore for the formation of these uranium deposits in the Athabasca Basin. Hydrothermal alteration (i.e. chlorite, hematite, and clay minerals) similar to that in the alteration halos around some of the Athabasca deposits is also found at Fraser Lakes Zone B [1,2,3,7], indicating that fluids of similar composition may have passed through the pegmatites.[7] The presence of younger, secondary, hydrothermal U mineralization within fractures cutting the pegmatites also supports this hypothesis.

Mineral and element vectoring in the Pilley's Island VMS district, Newfoundland Appalachians, Canada

C.P. MCKINLEY [1*], S.J. PIERCEY[1], L. WINTER[2], AND J.G. THURLOW[3]

[1]Department of Earth Sciences, Memorial University of Newfoundland, St. John's, Canada, cmckinley@mun.ca (*presenting author), spiercey@mun.ca

[2]Altius Minerals Corporation, St. John's, Canada, lawrence@altiusminerals.com

[3]Corner Brook, Canada, geoffthurlow@gmail.com

A major challenge in ancient volcanogenic massive sulfide (VMS) districts is that many have been strongly affected by metamorphism and deformation, resulting in mineralization being hosted within imbricated, thrust-faulted terranes, with abundant stratigraphic offset and juxtaposition. In such environments, barren volcanic units are often juxtaposed next to those that may be VMS-bearing, causing difficulty in stratigraphic reconstruction and in the discrimination of prospective from less prospective stratigraphy. These stratigraphic and structural uncertainties result in the requirement for the integration of lithogeochemistry and detailed mineralogy with traditional mapping, to vector towards mineralization at the prospect and regional scale. Pilley's Island, Newfoundland is an ideal location to demonstrate this vectoring because it hosts several VMS deposits in a small area (10 km^2), it is heavily faulted with barren mafic volcanics thrust between VMS-bearing felsic volcanic panels, and has excellent surface exposure and archived drill core for detailed geological and geochemical visualization.

Results from mapping, lithogeochemistry, and shortwave infrared-near infrared (SWIR-NIR) spectroscopy have identified alteration haloes around the VMS deposits of Pilley's Island. The distribution of AlOH, FeOH, and MgOH hull absorption values from SWIR-NIR spectra defines, from proximal to distal to mineralization, haloes of illitic phengite, phengite, illitic muscovite, muscovite, and Fe- to Fe-Mg- to Mg-chlorite. Surface and 3D gridding of lithogeochemical data have also identified prospective zones for mineralization. In particular, useful vectors include Na, K, and alteration indices. For example, zones with highest Na depletion, with K addition and associated with illitic phengite alteration are most prospective for sulfide mineralization.

Despite this VMS district being intensely imbricated, the integration of mapping, drill core reconstructions, lithogeochemistry, and SWIR-NIR spectroscopy readily distinguishes the mineralization-related thrust faulted panels from those that are barren of mineralization. The integration of both geochemical and mineralogical vectoring methods exemplified at Pilley's Island, can be useful in the exploration and delineation of VMS and other hydrothermal deposits elsewhere in the Appalachians and in other heavily faulted collision zones worldwide.

Carbon Dioxide Groundwater Mixing and Mineralization Reactions with Reservoir Rocks at a Natural Analogue Site, Soda Springs, Idaho, USA

TRAVIS L. MCLING[1]*, ROBERT W. SMITH[2], AND WILLIAM SMITH[3],

[1] Idaho National Laboratory-Center For Advanced Energy Studies, Idaho Falls, ID, USA, travis.mcling@inl.gov*.

[2] University of Idaho-Center for Advanced Energy Studies, Idaho Falls, ID, USA, smithbob@uidaho.edu

[3]Idaho State University, Pocatello, Idaho, USA, smitwill@isu.edu

Analogue sites are particularly relevant and useful to the study geologic carbon dioxide sequestration for a number of reasons, particularly because they offer the opportunity to examine a system that has operated on a time scale (centuries to eons) that laboratory and field experimentation (days to decades) cannot compare. One such example of a mafic rock CO2 analogue is the Soda Springs site located in Caribou County of Southeastern Idaho, USA. At this site, CO2 and formation fluids generated by the dissolution of Paleozoic carbonates at depth are migrating and reacting with a series of shallower thoelitic basalt flows that host a fresh water aquifer. We believe that the layered basalt flows are acting as a reactive barrier to the vertical migration of the deep CO2 charged fluids. However, in several cases the CO2 charged reservoir fluids make it to the surface and are expressed as either carbonated springs, or as cold-water geysers caused by wells that encounter the system at depth. Analysis of these sources of water shows a steady evolution of groundwater from unaffected by the basalt (deep wells) to more fully reacted (springs).

Data from this system makes a compelling argument for the ability of basalt flows to maintain containment for CCS applications. Our study has shown that CO2 charged fluids migrating upwards are being neutralized by mineral dissolution and precipitation within the basalt flows. These neutralization reactions have resulted in a specific chemical signature being imparted to the formation fluid that can be used to determine which minerals are dissolving and precipitating. Through and integrated study of this natural analogue site including field and laboratory experiments, the relative roles of mineral dissolution and precipitation and phase assemblage are being characterized for this basalt-hosted system.

The benefit of studying this natural analogue is that it has been active for many 1000's of years and depending on sample location and depth, the resulting fluid chemistry carries the chemical signature (tracer) indicative of the degree of reaction within the basalt formation. Additionally, the study of this system is helping define the appropriate laboratory scale experiments that will be needed to accomplish the larger objective of the project, understanding changes in aqueous geochemistry associated with progressing CO2-water-interactions.

Reconstructing the large-scale deep and intermediate ocean circulation in the North Atlantic during the LGM and last deglaciation

The large-scale subsurface circulation of the ocean is an important component of the Earth's climate system, and contributes to the global and regional transport of heat and mass. More than two decades ago, geochemical analyses of deep-sea sediments in the Atlantic Ocean revealed that the distribution of water masses and their characteristics were significantly different at the LGM and other times in the past when compared to modern observations. Although some of the paleodata have been reproduced and shown to be robust, there has been continued debate about the implications of these results for the dynamics of the large-scale circulation and the consequences for the storage and transport of heat, freshwater, nutrients and carbon in the past. There is also no consensus on the variations in water mass and dynamics that occurred between the LGM and the establishment of the modern Atlantic circulation despite the development of time series and maps of more than a half dozen paleo proxies for various aspects of the circulation.

Here we present a discussion of new and previously published Pa/Th, $\delta^{13}C$, SS, εNd, $\Delta^{14}C$, Cd/Ca, B/Ca, Zn/Ca and other data. We consider which aspects of past circulation during the LGM and deglaciation are robustly established and which remain open to competing interpretations. These results combine to confirm that the Atlantic circulation was different both in terms of water masses and their fluxes. The LGM Atlantic was characterized by rapidly overturning intermediate waters, consisting of more than one water mass, most likely of northern origin, and southern-sourced deeper waters with a longer residence time in the basin. Early in the deglaciation, during the H1 iceberg discharge and ensuing stadial, the boundary between intermediate and deep water masses shoaled, although a shallower overturning cell persisted throughout. We seek to reconcile apparently conflicting new and existing proxy evidence regarding any substantial change in the rate of deep water production and residence time during H1. Shortly after 15 ka, nearly all proxies indicate a rejuvenation of deep overturning, followed by a reduction during the Younger Dryas event (12.7 – 11.5 ka), and the subsequent development of the modern Atlantic circulation in the Holocene.

From Rhizosphere To Ecosystem: Heavy Metals and Plant Defense

David H. McNear Jr. [1*]

[1]Unvieristy of Kentucky, Lexington, U.S.A., dave.mcnear@uky.edu

Human use and manipulation of our natural resources, especially since the industrial revolution, has accelerated the introduction of HM's into soils resulting in a dramatic increase in their concentration in many soils of the United States (and beyond). Many of these HM's even at very low concentrations are toxic and reside in sites that are close to large and often socially downtrodden populations, and hence, pose a significant threat to both human health and the environment. Few remediation technologies have been effective at treating HM enriched soils *in-situ*. Phytoextraction, the use of specialized metal hyperaccumulating plants to remove metals from soils has been growing in popularity because it overcomes many of the limitations of conventional remediation methods. address the ecological implications that could arise from planting non-native plants capable of transferring metals from the soil to the shoots of the plant where they can then be introduced into the food chain, and/or have undesirable effects on ecosystem structure and function.

Elucidating how metals in specialized metal hyperaccumulating plant tissues influence plant physiology and insect feeding behavior is fundamental to understanding the evolution of this unique trait and the influence these plants may have on ecosystem structure and function. The elemental defense hypothesis (EDH) states that metals taken up and stored are effective at protecting plants from insect herbivores because of the inherent toxicity or unpalatability of the metals. A concomitant hypothesis, known as the trade-off hypothesis, states that plants will trade more physiologically costly chemical defenses (e.g. glucosinolates (GL's)) for less costly metal defenses. The objectives of this study were to investigate these hypotheses by examining the spatial and temporal relationship between Zn and GL concentration and speciation in leaves of the model Zn hyperaccumulator *Noccaea caerulescens* (formerly *Thlaspi caerulescense*) and assess how these patterns influence insect feeding behavior. A six week greenhouse study was conducted with *N. caerulescens* grown in soil receiving 250, 500 and 1000 uM Zn treatments. At the end of the experiment whole plant metal concentrations were determined in addition to the analysis of young, medium and old leaves for total metal content (ICP-MS), total GL's (as glucose) and GL species (HPLC). Metal distribution was also determined in young, medium and old leaves using synchrotron based x-ray fluorescence (SXRF) mapping and scanning electron microscopy (SEM-EDX), and the spatial distribution of specific GL's determined using matrix assisted laser desorption time of flight mass spectrometry (MALDI TOF/TOF MS) chemical mapping. The influence of these patterns on insect feeding behavior was assessed using the generalist herbivore *Trichoplusia ni* (Cabbage looper) in choice and no-choice feeding experiments. Preliminary results show that the concentration and distribution of Zn in young, medium and old leaves is inversely proportional to that of GL's with the younger leaves having a higher GL content than older leaves. Feeding patterns are alterned in response ot Zn concentrationa and distribution in the leaves providing evidence for the trade-off hypothesis.

Siqueiros Transform MORB; characteristics of a S-saturated suite

Andrew McNeill[1], Leonid Danyushevsky[1*], Kevin Klimm[2], Alexei Ariskin[3], Mike Perfit[4]

[1]CODES, University of Tasmania, Hobart, Australia, Leonid.danyushevsky@utas.edu.au (* presenting author)

[2]Johann Wolfgang Goethe University, Frankfurt, Germany, klimm@em.uni-frankfurt.de

[3]Vernadsky Intstitute, Moscow, Russia, ariskin@geokhi.ru

[4]University of Florida, Gainesville, USA, perfit@geology.ufl.edu

Geochemically diverse mid-ocean ridge basalts, with a significant range of major and trace element contents in pillow-rim glasses, were recovered from the Siqueiros Transform Fault, in the East Pacific Ocean. All these glasses were S-saturated at eruption, on the basis of the presence of immiscible sulfide globules (Fig. 1A). Based on the compositions of silicate melt inclusions in early-crystallised olivine phenocrysts, previous workers [1] have interpreted the early Siqueiros liquids, which were less fractionated than the pillow-rim glasses, to be S-undersaturated. However, since we have observed numerous inclusions of immiscible sulfides in the same early olivine phenocrysts, we interpret that most of Siqueiros parental liquids were S-saturated early in their fractionation history. The compositions of these immiscible sulfide liquid inclusions in olivine are consistent with those from other MORB suites [2] and estimates of sulfide liquid compositions from mantle rocks (e.g., [3]). In the Siqueiros samples S-Saturation appears to be largely independent of liquid composition over a wide compositional range, and is only controlled by total Fe content (Fig. 1B).

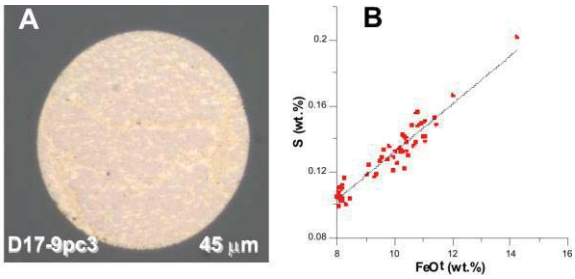

Figure 1: A; reflected light image of a 'quenched' immiscible sulfide globule in pillow-rim glass. B; relationship between FeO^t (all Fe as FeO) and S for Siqueiros Transform Fault pillow-rim glasses. The strong correlation indicates S-saturation (see [4]).

Laser Raman analyses, using the method of [5], of primitive and evolved pillow-rim glasses indicate that all S is present at S^{2-} and that the maximum fO_2 is therefore close to QFM. Mössbauer analyses are being completed to confirm the fO_2 of the pillow rim glasses.

Our data from the erupted basalts and inclusions provides a well constrained natural dataset that has been combined with experimental data to produce a new sulfur saturation model [6] and can be used to test the results of this and other models.

A Microbial Fuel Cell enhances Bioremediation of Gasworks Contaminated Groundwater

B. MC POLIN[1*], R. DOHERTY[1], M.J. LARKIN[2]

[1] Environmental Engineering Research Centre, SPACE, Queen's University Belfast (*correspondence: bmcpolin03@qub.ac.uk), (r.doherty@qub.ac.uk)
[2] School of Biological Sciences, Medical Biology Centre, Queen's University Belfast (M.Larkin@qub.ac.uk)

Microbial Fuel Cell (MFC) technology has been applied to many different remedial technologies, including bioremediation of contaminated groundwater. As of yet full scale implementation of the technology in relation to remediation projects has not been proven. In regards to groundwater bioremediation a MFC consists of bacteria oxidising contaminants such as organic pollutants within an anaerobic area of a plume (the anode) and the transfer of electrons through a circuit to a cathode where terminal electron acceptors are reduced. This results in the generation of a low current and the depletion of contaminants.

From geophysical analysis a large MFC (50+mV) was observed to be functioning at a gasworks site containing high levels of organic and ammonium contamination in groundwater. The aim of this research is to investigate what parameters play a role or drive the MFC and can it be utilised as a sustainable remediation tool.

Experiments involve constructing a MFC with graphite electrodes connected by wire that provides a direct circuit from high contamination (the anode) to an area of bioelectric activity (the cathode). A variable resistor and datalogger are used to monitor current production. Comparison of water samples using chemical analysis (monitoring levels of TOC, Ammonium, Nitrate & Nitrite) and molecular microbiology techniques (characterising the microbial population at the anode and cathode using PCR, DGGE, and metagenomics approaches) before and after electrode operation would indicate whether the MFC has enhanced bioremediation. Initial results indicate considerable microbial diversity between the anode and cathode on site and a large Self-Potential (electrical) difference. There is also evidence of microbial utilisation of ammonium.

Genetic analysis of the shift in microbial population before and after MFC installation would highlight the involvement of microbes in the bioremedial process. Characterising the microbial biofilm formed at the anode and cathode would give a better understanding of the role the active microbial communities play in electrical conductivity and ultimately a better understanding of the potential bioremedial/ bioelectric potential of the native microbial consortia which can be exploited for bioremediation.

Comparing the soil solution chemistry of soils amended with nano-sized copper oxide, micron-sized copper oxide, and with a copper salt.

HEATHER MCSHANE[1,*], JOANN K WHALEN[1], GEOFFREY SUNAHARA[2], WILLIAM HENDERSHOT[1]

[1]University of McGill Dept. of Natural Resource Sciences, Ste Anne de Bellevue, Quebec, Canada, Heather.Mcshane@mail.mcgill.ca (* presenting author)
2: National Research Council Canada - Biotechnology Research Institute, Montreal, Quebec, Canada, geoffrey.sunahara@cnrc-nrc.gc.ca

Engineered copper oxide nanoparticles (nano-CuO) are likely to be used in agriculture in the future but little is known about their effects on soil biota. As nano-CuO particles dissolve, they release Cu^{2+}, which can be measured as Cu activity, and which is thought to be the main form of bioavailable Cu in soils. Copper bioavailability may change over time as the Cu redistributes between soil solid and solution phases. Soluble Cu salts have been used to evaluate Cu^{2+} transformations but they can reduce soil pH and increase the concentration of dissolved cations in the soil solution, and they may overestimate bioavailable Cu. In this study, we amended two natural soils with 500 mg Cu / kg soil as nano-sized or micron-sized CuO, or as Cu nitrate, and measured the change in Cu activity, pH, and concentrations of dissolved Ca, Mg, and Zn in the amended soils over a period of 56 d. The initially low Cu activity in the oxide-amended soils increased over the course of the experiment, whereas the initially high Cu activity in the salt-amended soil declined. Soil pH was lower and dissolved cation concentrations were higher in the salt-amended soils than in the oxide-amended soils for the duration of the experiment. We conclude that amending soils with Cu nitrate does not accurately reflect Cu^{2+} transformations in soils amended with nano- and micron-sized CuO.

Understanding partial melting of ancient gneiss terranes is crucial when considering crustal contamination in volcanic systems, for example, as these rocks are unlikely to melt completely at magmatic temperatures (900-1200 °C) and crustal pressures (<500 MPa). Variations in the bulk composition of the protolith, magma temperature, pressure (depth), the composition and abundance of any fluids present will produce a variety of melt compositions. This may range from partial melts enriched in incompatible elements to more complete melts, nearing the bulk chemistry of the parent gneiss.

We have used piston cylinder experiments to simulate partial melting in a suite of 10 gneisses from NW Scotland and Eastern Greenland at magma chamber temperatures and pressures (P = 200 MPa, T = 975 °C). These gneisses form the basement to much of the North Atlantic Igneous Province, where crustal contamination is frequently identified. However, the actual compositions of the crustal partial melts are poorly constrained. Partial melts were produced in all 10 experiments. The experimental charges were quenched so that partial melts were preserved as glass, making them suitable for in-situ microanalysis. Electron microprobe spot analyses of the glasses indicate they are compositionally heterogeneous and are significantly different to the bulk chemistry of the parent gneisses. The samples were mapped using energy-dispersive x-ray spectroscopy (EDX), which deciphered the spatial variation in melt chemistry and revealed evidence of intense mixing and mingling processes. Individual melt domains were microdrilled for Sr and Pb isotope ratios.

This novel petrological, experimental and in-situ geochemical approach allows quantification of partial melting in a volcanic context, providing accurate geochemical end-members for modelling crustal contamination processes.

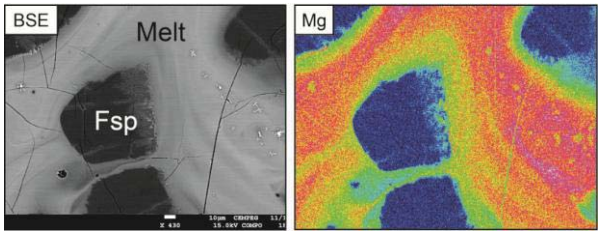

Figure 1: BSE image and EDX map of a partial melting experiment showing heterogeneous composition and mixing/mingling textures. Images and analyses were collected using the FE-EPMA facility at Uppsala University (http://www.geo.uu.se/mpt).

Pumping away: Impact of benthic macrofauna on flow, redox dynamics and sediment N cycling

C. MEILE[1,*], T. DORNHOFFER[1], S. KAZA[2], N. VOLKENBORN[3] AND G.G. WALDBUSSER[4]

Burrowing organisms have long been recognized to play a major role in biogeochemical cycling in aquatic sediments. However, only recently have advances in sensor developments and computational capabilities provided the opportunity to detail the flow dynamics and oscillatory redox conditions driven by the pumping activity of benthic infauna. Here we present a coupled flow-reaction model analysis linked to observations in experimental microcosms.

While volumetric pumping rates are fairly well known and experimentally accessible, flow patterns in the subsurface are not. However, they are important to quantify location and extent of oxic-anoxic interfaces which are critical in determining the biogeochemical cycling of redox sensitive elements. We present the determination of such velocity fields using optical flow anlysis of fluorescent dye tracers in antfarm experiments.

Our work then focuses on the role of burrowing organisms on O_2 dynamics and nitrogen cycling in coastal sediment. We will present model analyses of the impacts of burrowing depth, irrigation intensity and activity patterns. Our results show a distinct role for all these factors on denitrification. Model simulations show a significant impact of volumetric water exchange on areal denitrifaction; notably, they also predict a different trajectory of total denitrification with increasing burrow depth for continuous vs. episodic biologically induced flow.

Our findings have significant implications for removal of N from shallow water environments, and the controls thereof. Initial results suggest that nitrate removal is controlled not only by spatial structuring of the sediment (e.g. concentration gradients), but also by temporal dynamics (duration and frequency) of anoxic conditions forming in the sediment domain. Our findings also suggest that bioirrigation models which depict organism activity as an averaged continuous, unidirectional process miss the temporally dynamic character of biologically active sediments that may profoundly affect sediment nitrogen cycling.

Behavior of uranium isotopes in shallow aquifers of southern Québec, Canada

PAULINE MÉJEAN[1], GENÈVIEVE VAUTOUR[3], DANIELE L. PINTI[4], BASSAM GHALEB[2], MARIE LAROCQUE[5]

[1,2,3,4]GEOTOP-UQAM, Montréal, QC, Canada

[5]Département des Sciences de la Terre et de l'Atmosphère, UQAM, Montréal, QC, Canada
[5] larocque.marie@uqam.ca

A multi-isotopic study was initiated in order to quantify the groundwater resources available in a shallow aquifer of southern Québec. Uranium content and its isotopes ^{234}U and ^{238}U, which are partially dependent of redox conditions and physical/lithological characteristics of the aquifers and their recharge were measured. In specific cases, $^{234}U/^{238}U$ activity ratios can give information on the residence time of groundwater, a fundamental piece of information for a correct estimation of groundwater sustainability.

The target area is the lower portion of the Bécancour River watershed located between Montréal and Québec. Groundwater flows in shallow sands intercalated with clays of the Champlain Sea (Holocene age) and deeper fractured carbonates of Ordovician age of the St. Lawrence Lowlands. Water chemistry is dominantly bicarbonate.

Two transects (15 wells) were preliminary selected. The first follows the main flow path from the Appalachian Mts. (the main recharge area) downstream to the St. Lawrence River. The second transect is perpendicular to the first one and contains more mineralized waters. Along the flow path, there is a clear decreasing trend of the $^{234}U/^{238}U$ activity ratio, from a maximum of 3.12 measured close to the recharge to a value of 1.14, on the plain next to the St. Lawrence River.

During decay of ^{238}U to ^{234}Th, an α particle is emitted. The recoil energy is sufficiently important for the mineral to eject ^{234}Th to groundwater or to weak mineral sites were ^{234}U will be produced, making it easily leachable. Consequently, recharging groundwater would be enriched in ^{234}U when compared to ^{238}U and this mechanism might explain the high $^{234}U/^{238}U$ activity ratios observed close to the recharge areas.

The observed decrease of the $^{234}U/^{238}U$ ratio along the flow path could be interpreted by the radioactive decay of the excess of ^{234}U compared to that of ^{238}U at the ^{234}U time scale (10^6 yrs). However, a recent noble gas survey shows clearly that groundwater in the recharge area contains tritiogenic ^3He with ages younger than 20 years. A different process should be evoked to explain the isotopic fractionation of $^{234}U/^{238}U$. There is a clear relation between the alkalinity of waters (and the HCO_3^- content) and the $^{234}U/^{238}U$ activity ratio. This relation suggests that the mobility of uranium might be related to HCO_3^- and CO_3^{2-} ions complex. It is known that carbonates and hydroxyls could be efficient agents of complexation inducing higher mobility of ^{234}U after the "recoil". Thus the high activity ratios observed could be related to the enhanced mobility of ^{234}U in bicarbonate waters.

Low energy absorption edges of NS3 glass, albite and silicon investigated using x-ray Raman scattering

X-ray Raman Scattering (XRS)

The investigation of processes of geological relevance is directly connected to environments of extreme conditions, e.g., high pressure and high temperature. For in situ studies of materials under such conditions one needs to use special sample chambers with highly absorbing sample environments such as diamond anvil cells, which prevent the use of electron or soft x-ray techniques like EELS or XANES, combined with laser or resistive heating.

XRS is a non resonant inelastic photon-in-photon-out scattering process. The incoming high energy photons are scattered by core-hole electrons, exciting them to unoccupied states by transferring a relatively small amount of energy [1]. The application of hard x-rays makes x-ray Raman scattering a unique tool to investigate low energy absorption edges for binding energies between 10 eV and 2 keV of low Z elements like silicon, sodium, iron or oxygen under geologically relevant conditions.

XRS is very sensitive to changes of the electronic and local atomic structure, e.g., the oxidation or spin state of the studied atom. It provides the similar information as soft x-ray absorption and electron energy loss spectroscopy.

NS3 glass, albite and silicon

Silicon is the subject of many current studies. These include silicate melts and glasses due to their geological relevance, as well as pure silicon [2,3]. We present first results of an XRS study of the sodium K-edge of dry and water bearing NS3 glass ($Na_2Si_3O_7$) and albite ($NaAlSi_3O_8$) as well as results on the aluminum L-edge of albite. Furthermore we show recent in situ measurements of pure silicon at the Si L-edge at pressures up to 20 GPa.

Greener and leaner soil and sediment remediation: an overview of *in-situ*

CHARLES MENZIE [1]

[1]Exponent Inc., Alexandria VA, USA, camenzie@exponent.com

Abstract

Over the past decade there has been heightened interest in using in-situ remediation for contaminated sediments and in-situ technologies for soils have been underway for the past few decades. Such technologies include methods for degrading the contaminants in place or arresting or blocking exposures through the use of various barriers and amendments. These approaches appeal to common sense as they can be less costly to implement, can be less disturbing to the environment, and may pose lower risks to humans. But often the arguments regarding pros and cons of in-situ vs. removal technologies focus on specific aspects of the remedial process. What can be lost in narrow arguments is the fuller understanding of the life cycle of the various technologies with respect to overall economic, environmental, and human health benfits.

The economic benefits aspects are often the easiest to grasp and to compare among removal and in-situ remedial technologies. Less obvious are overall ecological benefits. Understanding relative ecological benefits typically requires a broad understanding of the ecological risks/impacts that contaminants are having within the system, the degree to which these risks will be reduced in the short and long-term by the remedial technologies, and the short and long-term impacts of the remediation.

A variety of methodologies have arisen to capture the relative environmental risks and benefits of alternative technologies. These include Net Environmental Benefits Analysis (NEBA), Integrated Environmental Benefits Analysis (IEBA), and Relative Risk Methods (RRM). Implementation of these methods requires knowledge of the various ecological systems and associated ecological srvices.

Relative human health risks and benefits involve a comparison of technologies in the short and long-term for the full range of remedial elements. Particular attention has been given to the life-cycle aspects that influence site-related risk reduction, potential risks associated with remediation, and even risks to remedial workers. While the last has gotten much discussion, it is important to note that “risk acceptability” is itself a variable that is not constant over all populations.

This talk will weave together the above aspects into a consideration of the “greener” and “leaner” nature of in-situ remediation and the efforts that are needed to make that case.

Origin of uranium deposits revealed by their rare earth element signature

JULIEN MERCADIER*, MICHEL CUNEY, PHILIPPE LACH, MARIE-CHRISTINE BOIRON, JESSICA BONHOURE, ANTONIN RICHARD

G2R, Université de Lorraine, CNRS, CREGU, 54506 Vandoeuvre-lès-Nancy, France (*julien.mercadier@g2r.uhp-nancy.fr)

Uranium deposits have formed in a wide range of geological settings including deep metamorphic/magmatic to surficial conditions and range in age from Archean to recent time. These temporal and spatial variations have given rise to an extreme diversity of deposits [1]. However, understanding their genesis and exploring for uranium deposits have remained challenging. In particular, very limited link between trace element or isotopic composition of uranium oxide and the conditions for their accumulation to economic grades have been clearly established.

Here we report REE abundances in uranium oxides, measured by microbeam methods (SIMS and LA-ICP-MS), for a series of 20 worldwide uranium occurrences from six of the major uranium deposit types. This study demonstrates that the REE contents of uranium oxides are very specific to each deposit type, regardless of the age or variations in local geological settings. Thus, REE abundances reflect directly the mineralising processes specific to each deposit type. We propose an evaluation of the first order parameters (T, REE sources and fluid composition) controlling the REE behaviour in each mineralized system. When applied to giant unconformity-related deposits, REE abundances enable to better understand their formation. Our results demonstrate that the REE patterns of uranium oxides are powerful tools for refining metallogenic models, and a key for the definition of the genetic model of new uranium discoveries [2].

Pre-eruptive conditions of ore-forming magma that produced the Henderson molybdenite deposit, CO: Insights from melt inclusions and mineral thermobarometry

CELESTINE N. MERCER[1*], ALBERT H. HOFSTRA[1], TODOR I. TODOROV[1], AND ERIN E. MARSH[1]

[1]USGS, Denver, USA, cmercer@usgs.gov (* presenting author)

The Henderson ore body is a Climax-type porphyry molybdenum deposit related to Oligocene high-silica rhyolite intrusions of the Red Mountain Complex near Empire, Colorado [1, 2]. The Hideaway Park rhyolite ashflow tuff outcrops 17 km NE of the Henderson deposit, and is thought to be a co-genetic extrusive expression of the intrusive complex that formed the Henderson deposit [3, 4]. We use quartz-hosted melt inclusions and phenocryst mineral chemistry to place constraints on the pre-eruptive magmatic conditions (P, T, f_{O2}, f_{S2}), volatile contents (H_2O, CO_2, F, Cl, S), and metal concentrations to better understand the process of metal segregation within Climax-type ore-forming stocks.

Melt inclusions in the Hideaway Park rhyolite are comprised of glass, devitrified glass, crystals, and vapor. Crystals typically include quartz, alkali feldspar, magnetite, fluorite, zircon, and monazite. No molybdenite crystals have yet been identified within the crystallized inclusions, however some inclusions likely contain them because preliminary trace element analysis by LA-ICP-MS reveals several inclusions with anomalously high Mo concentrations (15-115 ppm) compared to the modal Mo concentration (10 ppm).

Accessory minerals in the Hideaway Park rhyolite include magnetite, ilmenite, biotite, zircon, and monazite. Preliminary magnetite-ilmenite pairs indicate crystallization at an f_{O2} of NNO+1.7 and an a_{TiO2} of 0.4 [6].

SEM-CL images of quartz phenocrysts show alternating bright-to-dark euhedral growth rims and resorbed zones. Ti concentrations in quartz measured by electron microprobe range from 39 to 66 ppm corresponding to crystallization temperatures [7] between 720-790°C (assuming a_{TiO2} = 0.4 and a preliminary pressure estimate of 2 kbar, equivalent to a shallow crustal magma reservoir at ~6 km depth). Quartz phenocrysts contain zircon inclusions, but pyrrhotite and molybdenite inclusions have not yet been found in any phenocrysts. Given that the Henderson deposit was formed in an extensional tectonic regime, carries a deep crustal/upper mantle signature (Mo/Rb = 0.013-0.040), and is only moderately oxidized, the magma is likely to be saturated with both molybdenite and pyrrhotite [5]. Assuming pyrrhotite and magnetite saturation at 750°C and an f_{O2} of NNO+1.7, the Hideaway Park rhyolite should saturate with molybdenite with 8 ppm Mo in the melt [5]. The modal Mo value of 10 ppm may be indicative of a slightly higher average crystallization temperature (+10-20°C) or a slightly higher prevailing f_{O2} of NNO+2.

Experimental solubility of silica in nano-pores

LIONEL MERCURY[1,*], MAJDA BOUZID[2,3], JEAN-MICHEL MATRAY[3]

[1] Institut des Sciences de la Terre d'Orléans, UMR 7327 Université d'Orléans/CNRS/BRGM, 1A rue de la Férollerie, 45071 Orléans Cedex, France. (* presenting author)

[2] IDES, UMR 8148 CNRS/Université Paris-Sud, bâtiment 504, 91405 Orsay cedex, France

[3] IRSN, DEI/SARG/LETS, BP 17, 92262 Fontenay-aux-Roses cedex, France

We used a pressure membrane extractor (Model 1020, Soil Moisture Equipment Corp.) to study the silica content at equilibrium with the decreasing pore sizes of amorphous silica. The principle is to extract the aqueous solution through a sequential process from the larger (micrometric) pores to the thinner (some nm) pores. Each extraction step is followed by an equilibration period.

The measurements confirmed earlier observations [1,2] that the concentration in dissolved silica decreases when the extraction pressure increases. The direct conclusion is that the silica solubility is pore-size dependent. These results are interpreted with the Young-Laplace relationship, at constant silica-solution surface tension, which means to attribute an elasto-capillary pressure to the solid.

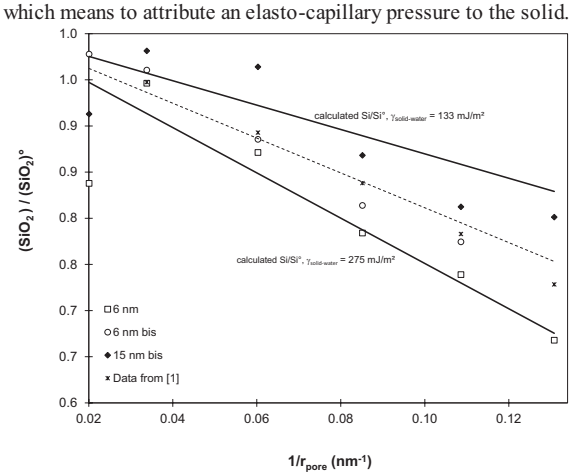

Figure 1: Decreasing silica solubility extracted from pores having decreasing radii.

The geological implication can be illustrated using a simple scheme (e.g. [3]), wherein aquifer compartments with changing pore sizes are successively put along a flowing line (in series). Depending on the modeling assumption (pore sizes, succession type, equilibrium state of the solution), this process can result in a preferential cementation of the thin or the large pores.

Our experiments demonstrate that the negative curvature of the solids has a geochemical feed-back on the solid-solution interactions, with a threshold size at around 0.1 µm.

Carbon isotope diffusion in quartz & apatite and its relationship to biosignatures

SEBASTIAN T. MERGELSBERG[1,2]*, DANIELE J. CHERNIAK[1] AND E. BRUCE WATSON[1,2]

[1]Department of Earth & Environmental Sciences, Rensselaer Polytechnic Institute, Troy, NY 12180, USA (*correspondence: merges@rpi.edu)
[2]New York Center for Astrobiology, Rensselaer Polytechnic Institute, Troy, NY 12180, USA

While organisms live, their enzymatic reactions tend to accumulate certain isotopes of particular elements more than others. The most abundant element in any organism – carbon – is no exception and its lighter isotope is preferentially accumulated and incorporated, leading to a general $\delta^{13}C$ of around -40.00‰ to -10.00‰. When an organism dies, its remains may be taken up by a growing host mineral, such as quartz or apatite. This inclusion would "freeze" the ratio, creating a biosignature that is thought to be stable over time. Most of the evidence for the earliest life forms on Earth is found in the form of isotopic biosignatures. Durable and inert minerals such as apatite and quartz are potential hosts for these isotopic anomalies, but their ability to accommodate carbon is uncertain, especially in the case of quartz. Recently, the origin and validity of biosignatures have been questioned, suggesting abiotic origins of lower $\delta^{13}C$ isotope ratios [1] rather than being strictly derived from enzymatic action.

To investigate the potential of apatite and quartz to record and retain biosignatures, the solubility and diffusion of different carbon species in these minerals were investigated. Carbon is detectable in both apatite and quartz treated at high temperature and pressure in the presence of graphite, CO, CO_2, and CO_3^{2-}. Regardless of primary carbon species, however, the diffusion rates remained more or less constant. In addition, the values seemed to line up quite well with oxygen isotope diffusion data in quartz, when the diffusing species was CO_2 [2]. Based on these findings, it seems possible that the primary diffusion of carbon in these minerals depends greatly on the production of CO/CO_2 and thus the oxygen fugacity in the system.

Recent studies of isotope fractionation in the production of these gases from carbon indicate that CO production may lead to great distortion of the isotope ratio in the parent material. Evidence of such mechanisms would be suggesting a certain fallibility in interpretating isotopic ratios as biosignatures and recognizing proof of early life on earth.

The use of trace elements in Fe-oxides in deducing the fractionation history of a silicate magma: A LA-ICP-MS study

J. MERIC[1*], S.A.S.DARE[1], S.-J. BARNES[1] AND G. BEAUDOIN[2]

[1]Université du Québec à Chicoutimi, Québec, Canada, G7H 2B1
[2]Université Laval, Québec City, Québec, Canada, G1V 0A6

Knowledge of the trace element compositions of Fe-oxides will help to develop indicator minerals for exploration in addition to improving our understanding of the petrogenesis of the deposit. This study has characterized Fe-oxides, using laser ablation ICP-MS, from the upper part of Sept-Îles layered intrusion (Québec, Canada), which hosts an Fe-Ti-P deposit, rich in magnetite, ilmenite and apatite. The Fe-oxides record a sequence of fractional crystallization that evolves from the bottom to the top of the deposit. Trace elements in both magnetite and ilmenite vary as a function of their stratigraphic position (Fig. 1). Aluminium, Co, Cr, Mg and V decrease in the Fe-oxides up sequence whereas Ga, Ge, Hf, Mn, Mo, Nb, W, Sc, Sn, Ta, Zr and Zn increase. These geochemical variations appear to be controlled by the partition coefficients of compatible (e.g., V) and incompatible (e.g., Mo) elements into the co-crystallizing phases (olivine, plagioclase, magnetite, ilmenite and apatite) and in the magma during fractional crystallization of the silicate magma. Although magnetite and ilmenite show similar variations (Fig. 1), elements partition differently between the two. For example, Hf, Mg, Nb, Sc, Ta, Ti, W, and Zr are more abundant in ilmenite whereas Al, Co, Cr, Ga, Ge, Mo, Ni, Pb, Sn and V are more abundant in magnetite.

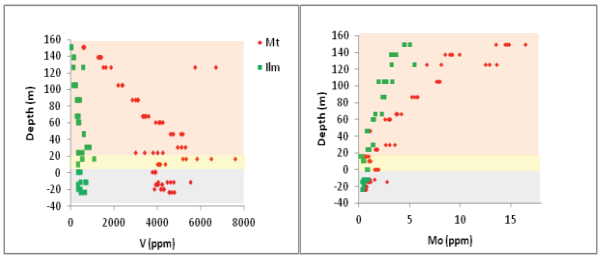

Figure 1: Variation of V and Mo in magnetite (Mt) and ilmenite (Ilm) as a function of depth in the Fe-Ti-P deposit of Sept-Îles. The layered sequence comprises, from bottom to top: magnetitite (grey), nelsonite (yellow) and nelsonitic-gabbro (orange).

This study shows that the chemical composition of Fe-oxides varies over a wide range within a single Fe-Ti-P deposit as a result of fractional crystallization. Thus it is necessary to understand the processes that control the chemical variability of the Fe-oxides in any given deposit in order to develop an effective exploration tool for the mining industry.

Improved representation of dust-nutrient deposition to the ocean for the Earth System Models

MESKHIDZE*, N. AND M. S. JOHNSON

North Carolina State University, Raleigh, USA,
*nmeskhidze@ncsu.edu, msjohns2@ncsu.edu

With the development of comprehensive Earth System Models (coupled climate-carbon models with land and ocean biogeochemistry) there is an increased need for improved representation of atmospheric fluxes of essential nutrients, i.e. iron (Fe), phosphorus (P), and nitrogen (N) to the surface oceans. These micronutrients have a controlling effect on marine ecosystem productivity and therefore can influence the global carbon cycle and climate. Today it is well established that models that consider interactive representation of aerosol-climate-carbon cycle do better job in predicting future climate. Since Fe at the dust source regions is thought to be primarily in an insoluble form with increasing bioavailability through the interaction of mineral particles with acidic trace gases, it is believed that anthropogenic activities may exert sizable influence on micronutrient fluxes to the ocean.

In this study the state-of-the-art dust-nutrient dissolution scheme has been implemented in the global 3-D chemistry transport model GEOS-Chem. The Fe-dissolution module of Meskhidze et al. (2005) [1] was updated to consider dust-mineralogy in different desert regions, Fe-organic acid (oxalate) interaction, the photoreductive dissolution of Fe containing minerals (hematite, goethite and aluminosilicates), and the redox cycling between relatively more soluble ferrous, Fe(II) and highly insoluble ferric, Fe(III) forms of iron. Dissolution of P containing minerals is carried out using acid-based chemistry [2], while nitrate production occurs through the deposition of gas phase nitric acid on mineral dust. Our calculations using dust-nutrient dissolution scheme show high temporal and spatial variability in nutrient deposition fluxes over the ocean. Preliminary results indicate (see Fig. 1) that simplified Fe dissolution schemes, with the prescribed amounts of soluble iron, are unable to capture the complex nature of micronutrient deposition to the surface ocean. Our study reveals that in order to properly account for the effects of anthropogenic activities on ocean biogeochemical cycles, next generation Earth System Models should consider implementation of more comprehensive modules for nutrient mobilization from mineral dust.

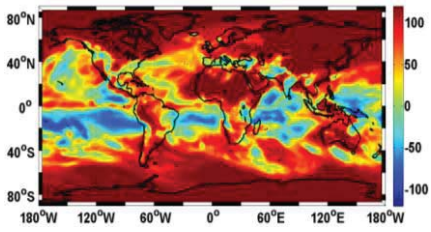

Figure 1: Percent difference (1% - model)/model in soluble Fe deposition during January 2009.

Influence of zostera meadows on geochemistry and meiofauna of the sediment of a tidal lagoon (Arcachon Basin): new technical approaches

EDOUARD METZGER[1*], DIDIER JEZEQUEL[2], EMMANUELLE GESLIN[1], FLORIAN CESBRON[1], LAURIE CHARRIEAU[1], MARIE-LISE DELGARD[3], BRUNO DEFLANDRE[3], FRANS JORISSEN[1], AND PIERRE ANSCHUTZ[3]

[1]Univ. Angers, LPGN-BIAF, OSUNA, Angers, France,
edouard.metzger@univ-angers.fr (* presenting author)
[2]Univ. Paris Diderot, Sorbonne Paris Cité, IPGP, France
[3] Univ. Bordeaux, EPOC, UMR 5805, Talence, France

Tidal lagoons are by definition very dynamic environments. Sediments from such environments are very heterogeneous especially because of direct action of living organisms (i.e. bioturbation). The intertidal flats of Arcachon basin are highly covered by seagrass meadows of *Zostera noltii*. The seasonnal dynamics of these meadows enhance the lateral heterogeneity of the sediment by influencing sedimentation and organic matter accumulation. The present study shows preliminary results from very new techniques which were applied to understand the relationship between the root system of seagrass and meiofauna such as foraminifera. Those are able to respire oxygen and nitrate as well as bacteria. Our hypothesis is that roots bring oxygen to the anoxic sediment maybe generating nitrate-rich microenvironments. Since foraminifera are able to denitrify, we suppose that some specialized taxa can gather in such environments.

Methodologically, our goals are: i) to document at a submillimetric scale and in 2 dimensions relevant redox species (e.g. H_2S, Fe(II), PO_4, NO_3) in the pore waters using combined DGT-DET gels and in the solid phase by X microflurescence; ii) to describe foraminiferal species related to documented microenvironments using a highly discriminant staining technique for living specimen (i.e. CTG fluorogenic probe). The metabolism of anoxia tolerant taxa is quantified using microchambers equiped with microsensors.

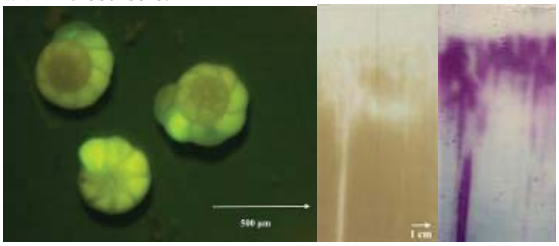

Figure 1: CTG Fluorescent foraminifera observed using an epifluorescence binocular (left) and 2D DET images (right): H_2S in brown, Fe(II) in pink and PO_4 in blue

2D DET gels show very heterogeneous redox layers which are very influenced by burrowing organisms and seagrass root webs. The first results seem to show that foraminferal densities are also influenced by the root web related to sedimentary redox interfaces. Anoxic sediment is dominated by *Eggerella* sp. which ability to denitrify is presently being assessed in the laboratory.

The source of Si in terrestrial plants: amorphous silica vs clay minerals

JEAN-DOMINIQUE MEUNIER*, MUHAMMAD RISWAN, JING SHA AND CATHERINE KELLER

Aix-Marseille Université, CNRS, CEREGE, Europôle Méditerranéen de l'Arbois, 13540 Aix-en-Provence, France, meunier@cerege.fr

Although Si is generally not considered as a nutrient for terrestrial plant, there are increasing evidences showing a beneficial effect of Si particularly under environmental stresses. Recent studies have suggested that land use and particularly agriculture can modify the Si cycle through a depletion of soil available Si. The extent of the perturbation, its impact on the plant cycle and food production is challenging and requires a better assessment of the biogeochemical acquisition of Si by plant. Si accumulated in plants originates from the dissolution of soil silicates. In soil solutions, Si is mostly present as the neutral molecule $Si(OH)_4$ (silicic acid). $Si(OH)_4$ is absorbed by the roots by a mechanism that is not fully understood. Both active and passive uptakes have been evidenced. In shoots, $Si(OH)_4$ is polymerized through the elimination of water by evaporation and, eventually, phytoliths (amorphous opaline silica particles) form. Steady state models show that plants absorb a significant fraction of dissolved Si that originates from litterfall decomposition i.e phytolith dissolution. Laboratory experiments show that phytoliths are a source of silica amongst the most soluble of the soil minerals at slightly acid to neutral pH. However, because the concentration of phytoliths in soil is generally low (below 10 mg/g), the contribution of clay minerals as a source of bioavailable silica is poorly documented but could be crucial in nutrient-limited soils where highly soluble primary silicates have been exhausted. A pot experiment using Durum wheat was conducted to assess the capacity of different silicate sources to release bioavailable silicon. For this purpose we used three types of sources: quartz (Q), clay (C, vermiculite) and amorphous silica (D, diatomite, as an analogue for phytoliths). Mixtures (Q + C and Q + D) were prepared in different proportions. Wheat plants were grown for 60 days in these mixtures. We found that the plants grown in the Q + D mixtures accumulated in their shoots about twice more silica (16-22 g kg^{-1}) than those grown in the Q + C mixtures (7-13 g kg^{-1}). These results show that, although soil amorphous silica (phytoliths) constitutes the most bioavailable Si pool for plants, the contribution of clay minerals should be more fully evaluated.

Nucleosynthesis and Isotopic Anomalies in FUN CAIs

BRADLEY S. MEYER[1*]

[1]Department of Physics and Astronomy, Clemson University, Clemson, SC, 29634-0978, USA, mbradle@clemson.edu (* presenting author)

Introduction

Millions of stars working over Galactic history generated the mix of isotopes present in the interstellar medium 4.6 billion years ago. Importantly, each of the roughly 280 different naturally-occurring isotopes in the Solar System had a different production route during this history, and present Solar System objects may contain a chemical memory of these varying histories [1]. Isotopes of Ca, Ti, Cr, Mo, and Ba in particular show anomalies in primitive Solar System samples, which thus give evidence of such chemical memory (e.g., [2]-[4]), and a key goal of isotope cosmochemistry in the coming years will be to understand what these anomalies are telling us about nucleosynthesis, Galactic chemical evolution, and Solar System formation.

Neutron-Rich Iron-Group Isotopes and FUN CAIs

The anomalies in the neutron-rich iron-group isotopes found in FUN (fractionation and unknown nuclear effects) CAIs (calcium-aluminum-rich inclusions) present a long-standing example of a likely cosmic-chemical memory effect [2]. FUN CAIs show correlated excesses and deficits in the isotopes ^{48}Ca, ^{50}Ti, and ^{54}Cr. All three of these isotopes have substantial production in a low-entropy environment [5], most likely the thermonuclear disruption of a dense white dwarf star [6]. At the same time, ^{50}Ti and ^{54}Cr, but not ^{48}Ca, have substantial production in massive stars (e.g., [7]). It is likely that the dust in the interstellar medium is highly anomalous. When this dust is incorporated into the Solar cloud, the Solar System will inherit these anomalies, and processing within the protoplanetary disk incorporates those anomalies in the FUN CAIs. In order to understand all of this history, we are making estimates of the siting of these isotopes in the interstellar dust along with their expected isotopic anomalies.

Tools for Understanding Nucleosynthesis and Galactic Chemical Evolution

Nucleosynthesis and chemical evolution are complex subjects that researchers best understand by running their own calculations. All of the computational tools we are developing to understand chemical memory in Solar System samples are open source and available for download (e.g., [8]), and we hope these tools will help others gain a better appreciation for nucleosynthesis and Solar System isotopic anomalies.

Fractionation of highly siderophile elements in the lower oceanic crust at ODP Site 735b, SW Indian Ridge

C. MEYER[1]*, H. BECKER[1]

[1]Freie Universität Berlin, Institut für Geologische Wissenschaften, chmeyer@zedat.fu-berlin.de

Compared to the mantle, abundances of some HSE in gabbroic oceanic crust and ocean ridge basalts are lower by a factor of 1000 or more, with Re, Au and Pd being more abundant than Os, Ir, Ru, or Rh. It has been suggested that the highly variable abundances may reflect sulfide fractionation processes in the deeper oceanic crust [1]. Samples from ODP site 735b, legs 118 and 176, a 1500 section of tectonically exhumed middle to lower oceanic crust were analyzed for abundances of HSE and Os isotopic composition. For reconnaissance study, 30 samples characterized by little alteration were selected to cover a range of lithologies, including olivine gabbro, gabbro, troctolitic gabbro, troctolite and disseminated oxide gabbro and oxide gabbro. 2.5 g of powder was digested in inverse aqua regia in a high pressure asher at 320°C. HSE separation and analyses methods follow those established in our lab. In a Re-Os isochron diagram, the most radiogenic samples (with large errors) plot along a 11 Ma reference line, in good agreement to the crustal age of site 735b [2]. Two troctolitic gabbros and 3 olivine gabbros with $^{187}Os/^{188}Os$ of 0.14 - 0.24 display a different linear trend that yields an apparent age of 244 ± 77 Ma with an initial $^{187}Os/^{188}Os$ of 0.126 ± 0.022. CI-chondrite normalized abundances of HSE in the lower crustal rocks cover a wide range (at the most extreme 10^{-3} to 10^{-7} x CI chondrite for Os), with relatively high abundances of all HSE in some troctolitic gabbros to more fractionated HSE patterns and much lower abundances of Os, Ir, Ru, Rh and Pt in other lithologies. Re is the least variable, with typical abundances in gabbros of 0.2 – 0.5 ppb, considerably lower than in most MORB. Au concentrations in most analyzed samples are typically <0.1 ppb. Au is more strongly depleted than Re compared to MORB [3] and most mantle rocks. This would imply that Au is more incompatible than Re during fractional crystallization, at least in this section of oceanic crust. From HSE abundance and ratio data, it appears that olivine gabbros behave as a coherent group, whereas troctolitic gabbros may reflect other processes. HSE abundances, Au/Ir, Pd/Ir and Os/Ir in "primitive" olivine gabbros reach values >100 and decrease substantially with decreasing Mg#, Cr, Ni and MgO. The progressive depletion of HSE in olivine gabbros may be related to fractional crystallization from progressively evolved basic melts. This process appears to result in a strong increase in Re/Os from olivine gabbro via gabbro to leuco gabbro and in a decrease of Au/Ir, Pd/Ir and Os/Ir. Consequently, while Re/Os in melts increase during fractional crystallization, Au/Ir, Pd/Ir and Os/Ir decrease. The evolution of troctolitic gabbros, increasing Au/Ir and Pd/Ir with decreasing Mg# and Cr, follows different trajectories and implies more complicated processes, presumably, hybridization of ultramafic cumulates or mantle tectonites by basic melts..

Lau Basin magmas show how magma ascent, crystallization and degassing can lead to either enrichment or depletion of Cu (and other chalcophile elements) in differentiated magmas. In these magmas, S degassing is correlated with H_2O degassing. Dissolved S occurs almost entirely as sulfide (S^{2-}) in analyzed glasses.

Glasses from the northern part of Eastern Lau Spreading Center (ELSC), located in the backarc, far from the active Tofua arc, are similar to MORB. They have not degassed H_2O, and their dissolved S contents are high and correlated with Fe. They have not degassed much S but have segregated immiscible sulfide liquids which leads to a MORB-like trend of decreasing Cu with decreasing MgO. Further south, ELSC (and its continuation, Valu Fa Ridge:VFR) is shallower and only 35-60 km from Tofua arc. Its magmas include a greater subduction component, especially H_2O which has degassed. Low S contents show that they have also degassed variable amounts of S. Cu contents are slightly elevated compared to northern ELSC and MORB, and Cu decreases with decreasing MgO.

In contrast, the small seamounts located a few km from the ELSC-VFR axis have Cu contents that *increase* with decreasing MgO, and reach much higher values than ELSC-VFR. They have degassed large amounts of H_2O and almost all of their Sulfur. Most seamounts are more primitive than the nearby spreading axis. A few analyzed glasses from the nearby Tofua volcanic arc are similar to the seamounts in their behavior of S and Cu.

We propose that Cu contents in differentiated magmas are controlled by immiscible sulfide liquid segregation and S degassing. Like MORB, glasses from northern ELSC undergo sulfide segregation that depletes Cu from residual liquids, while very little S is lost by degassing. Magmas from southern ELSC and VFR start crystallizing at moderate depths (6-8 km) where they segregate some sulfide liquid, and lose Cu. They also undergo degassing of H_2O and S as they crystallize and ascend to shallower levels, limiting the amount of formation of sulfide liquids and its consequent Cu depletion. In contrast, seamount (and arc) magmas ascend rapidly to shallow levels and degas H_2O and S before they have a chance to segregate immiscible sulfide liquid. Cu remains in the silicate liquid and its concentration increases in differentiated magmas.

An alternative mechanism to account for high Cu in some magmas is that during larger extents of partial melting beneath the arc and seamounts (caused by high H_2O in the source), sulfide in the mantle source is exhausted, releasing all Cu into the melt. However, low Cu in primitive seamounts suggests elevated Cu results from differentiation, not melting.

Potentially hazardous trace elements in biomass burned in power plants

MAREK MICHALIK[1], RENATA GASEK[2], WANDA WILCZYŃSKA-MICHALIK[2]

[1]Institute of Geological Sciences, Jagiellonian University, Kraków, Poland, marek.michalik@uj.edu.pl (* presenting author)

[2] Institute of Geography, Pedagogical University, Kraków, Poland, rgasek@ap.krakow.pl, wmichali@up.krakow.pl

The study is based on eight samples of biomass (OTR- corn bran; SLON-1 and SLON-2 – sunflower; TRO – sawdust; OLI – olive residue; SLOM - straw; BUK – beech bark; PAL – palm kernels) used in power plants in southern Poland and ashes obtained in relatively low temperature (475°C). Results are compared with average trace element contents in coal and coal ash [1].

Fourteen elements were selected as components of major environmental concern (As, Cd, Co, Cr, Cu, Hg, Mn, Mo, Ni, Pb, Sb, Se, V, Zn). Average values for hard coal are exceeded in biomass only for four elements (Table 1). The concentration of trace elements in biomass ash can be very high and for eight elements significantly exceed average values determined for coal ash (Table 2). The results indicate that concentration of several trace elements in biomass used as fuel and in biomass ash could be dangerous for environment.

Element	Average for hard coal	Highest values for studied biomass samples
Cd	0.2	0.31(TRO)
Cu	16	25 (OLI); 23 (PAL)
Mn	71	333 (PAL); 126 (OTR); 88 (BUK)
Zn	28	79 (OTR); 46 (PAL)

Table 1. Highest values of trace elements in biomass samples exceeding average value for hard coal (in ppm)

Element	Average for coal ash	Highest values for studied biomass ash samples
Ag	590	5319 (TRO)
Cd	1.2	71 (TRO); 2.1 (OTR); 1.66 (SLON-2)
Cu	110	587 (TRO); 509 (PAL); 266 (SLON-2); 255 (SLON-1); 178 (OTR); 169 (OLI)
Mn	430	>10 000 (TRO); 7373 (PAL); 2148 (OTR); 1507 (BUK); 444 (SLOM)
Mo	14	14.7 (OTR)
Ni	37	49 (PAL); 38 (OLI)
Pb	55	69 (TRO)
Zn	170	1923 (TRO); 1485 (OTR); 1051 (PAL); 428 (BUK); 399 (SLON-2); 321(SLON-1)

Table 2. Highest values of trace elements in biomass ash samples exceeding average value for hard coal ash (in ppm)
