High heat-producing granitic rocks (HHPGs) are characterised by abnormally enriched values of radiogenic U, Th and K above upper continental crustal averages. In recent years, HHPGs have received considerable attention as they can be targeted for enhanced geothermal systems (EGS). The Soultz-sous-Forêts monzogranite is a notable example. With the exception of K, U and Th commonly occur with rare earth elements and yttrium (REE and Y, REY) in primary accessory phases [1]. Upon interaction with hydrothermal fluids, accessory phases such as titanite, may destabilise and form polymineralic metasomatic assemblages. Analysis of these metasomatic minerals is integral for understanding not only the chemistry of the hydrothermal fluid, but also the mobility of elements previously held in primary accessory phases. As such, this study focuses on the comparative EPMA of primary and metasomatic accessory phases to further the understanding of REE, Y and Th mobility in the Soultz monzogranite.

Petrographic studies show primary REY and Th-bearing titanites have been altered to anatase + calcite + quartz + synchysite-(Ce) [(Ce,Ca,Th)$(CO_3)_2$F] ± bastnaesite-(Ce) [(Ce,Th)(CO_3)F] or monazite-(Ce) [(Ce,Th)PO_4] + xenotime-(Y) [(Y)PO_4] ± thorite [$ThSiO_4$]. These observations represent the first documented citing of synchysite-(Ce) formation through titanite destabilisation. The purely fluorocarbonate-bearing assemblage is restricted to samples exhibiting minor selective alteration. Phosphate-bearing assemblages are, however, found in pervasively altered samples where primary apatite was significantly affected. Comparative mass balance studies of titanite, synchysite-(Ce) and monazite-(Ce) found $HREE_2O_3$, Y_2O_3 and ThO_2 levels to be relatively depleted in fluorocarbonate-bearing samples. Although ThO_2 levels were maintained in monazite-(Ce) relative to parent titanite, $HREE_2O_3$ and Y_2O_3 appeared lower due to the presence of xenotime.

Following the experimental work of Hunt and Kerrick [2], the ingress of CO_2-rich fluid was integral for titanite destabilisation. On the other hand, fluorine in synchysite was most likely sourced from proximal chloritised biotite. Following synchysite formation, excess FCO_3^- or HCO_3^- anions may have remained in solution and led to the significant mobilisation of HREE, Y and Th through complexation. Our study provides evidence for not only differential REE and Y mobility in the Soultz monzogranite, but also that Th, conventionally considered an immobile element, is mobilised under certain hydrothermal conditions.

Modelling the vapour transport of Au, Ag, and Cu chlorides at high temperature based on new experimental data

ART. A. MIGDISOV[1*], N. HURTIG[1], AND A.E. WILLIAMS-JONES[1]

[1]McGill University, Earth & Planet. Sci., Montreal, QC, Canada (*correspondence: artas65@gmail.com)

The fact that water can significantly increase the gaseous transport of weakly volatile compounds has been long-known and is attributed to hydration, namely the formation of gaseous clusters involving H_2O molecules. However, laboratory experiments performed in simple H_2O-bearing systems have yielded concentrations of metals, e.g., Cu and Au, considerably lower than reported for vapour inclusions in many natural samples. Furthermore, calculations of the stability of known Cu- and Au-bearing gaseous clusters have shown that these clusters cannot explain the very high concentrations Cu and Au predicted for some vapour-dominated hydrothermal systems. Assuming that the source of this disagreement lies in the models that have been developed for the hydration process, we have re-visited the Au-HCl-H_2O, AgCl-HCl-H_2O, CuCl-HCl-H_2O, and $CuCl_2$-HCl-H_2O systems, and conducted additional experiments that allow us to more accurately determine the hydration numbers of metal-bearing gas clusters.

Our experiments involved determining the solubility of metal chlorides (or metals) in HCl-bearing water vapour at a variety of water vapour pressures and temperatures ranging from 300 to 450 °C. The experimental technique employed in this study is identical to that reported in our previous publications [1]. The data obtained from these experiments demonstrate that, in contrast to conclusions in our earlier publications, hydration numbers of metal-bearing clusters are not constant, but increase with increasing fugacity of water. This results in an exponential increase in the saturation concentrations of metals in water wapour at elevated pressures and temperatures.

We fitted our experimental data to a simplified model similar to that developed by Pitzer and Pabalan [2] for the solubility of NaCl in low-density fluids. The model accounts for a set of hydrated species of the common stoichiometry $MeCl(H_2O)_n$, where n ranges from 1 to 14. After independent treatment of each of the experimental isotherms, it was found that the Gibbs free energy of each of the modelled clusters varies linearly with the reciprocal absolute temperature (1/TK). This allows extrapolation of the data collected at 300 to 450 °C to much higher temperatures. The new model has been tested against the measurements of Simon et al. [3] for the solubility of Au and Ag at 1000 to 1400 bar and 800° and yield reasonable results. .In addition, the concentrations of Ag and Au (the experiments on Cu are still in progress) calculated for 500 °C show much closer approximation to those determined in natural fluid inclusions than in any previous models

The role of changing abstraction patterns in the contamination of a low-arsenic aquifer in Bangladesh

I. MIHAJLOV[1*], M. STUTE[1,2], B.C. BOSTICK[1], I. CHOUDHURY[3], K.M. AHMED[3] AND A. VAN GEEN[1]

[1]Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, USA, mihajlov@ldeo.columbia.edu (* presenting author)
[2]Barnard College, New York, USA
[3]Dhaka University, Dhaka, Bangladesh

The installation of deeper aquifer community wells has been one of the primary arsenic mitigation strategies in Bangladesh, a country where a large portion of shallow tubewell groundwaters exceed the WHO limit of 10 µg/L As. Shifting groundwater abstraction patterns, in particular the increased pumping from deeper aquifers, could potentially threaten this resource by vertical transport of As and organics between aquifers and across leaky confining units. While this scenario has been addressed by Bengal basin-wide models [1], hydrogeologic conditions across the basin are variable.

Our study focused on a site 25 km east of Dhaka where a community well was installed twice in a low-As aquifer separated from the shallow aquifer by >10m of silty clay, but As levels in both wells rose within <18 months. An increasing downward hydraulic gradient across clay units in the vicinity, as well as a lack of evidence of mechanical failures at the site, led us to suspect vertical leakage across the clay. Thus, a network of pumping and monitoring wells was established on the site to conduct pumping tests and continuously monitor hydraulic heads. Lithologs, sediment X-ray fluorescence (XRF) and chemical extraction profiles were collected during well installation, and groundwater was sampled for water chemistry, DIC ^{13}C and ^{14}C, ^{2}H, ^{18}O, ^{3}H, and noble gas analysis.

Lithologs and XRF profiles established that stratigraphy and sediment composition were laterally uniform. Pumping from long-screen wells in either aquifer did not induce measurable drawdown in the other, but the time plot of drawdown in the confined aquifer was characteristic of a leaky aquifer. Given the present downward hydraulic gradient of ~1m between the aquifers, continuous slow downward transport of As and/or organics across the clay may exist.

High-As groundwater is absent at the depth of the community well failures, but the upper ~10m of the aquifer (below the clay) is ^{3}H-dead and displayed high dissolved conc. of Fe, As, and NH_3. The well-advanced reduction in this stratum was accompanied by elevated Na, DOC, and DIC levels, and a lower pH. Depressed ^{14}C and heavy ^{13}C signature of the DIC there, along with low diss. [Ca], was characteristic of microbial consumption of old organic C (potentially leached from the clay with Na) and methanogenesis. Water level and ^{3}H data, however, also implied that a flow of recently recharged water exists below this upper portion of the aquifer, presumably due to pumping from a nearby factory. While the community wells probably failed due to vertical transport of As within the aquifer itself, it is presently unclear if the source of As and DOC in the upper part of the aquifer is from clay leakage or if that layer is a zone of low flow where resident organic C is currently consumed.

A stable isotopic aproach to surface uplift history of the S margin of the Central Anatolian Plateau (CAP), the second largest orogenic plateau in the Alpine-Himalayan belt, is the focus of this work. Extending at average elevations of 1 km and bordered by the 2-3 km-high Tauride Mts to the S, Mediterranean mantle dynamics have been instrumental in governing regional surface uplift [1], yet with detailed temporal and spatial patterns of surface uplift remaining conjectural. For the first time, we apply a paleoaltimetric approach to the CAP by (1) looking at stable hydrogen and oxygen isotope ratios of continental deposits (such as paleosol and lacustrine carbonates and hydrated volcanic glasses), taking advantage of their recent, precise age calibration based on chrono- and biostratigraphy, and (2) providing a robust template of stable hydrogen and oxygen isotopes from modern surface waters on the CAP and across the Tauride Mts, against which the continental proxy data can be validated. We show that integrity of the modern meteoric water data nicely images the present-day topographic structure of the CAP and the Tauride Mts. with ca. -24 ‰/km and -3 ‰/km isotopic lapse rates for δD and $\delta^{18}O$, respectively. We then compare two sets of $\delta^{18}O$ data of fossil meteoric waters as recorded in proxy minerals from Upper Miocene to Quaternary deposits in front of the growing Tauride Mts and in its N rainshadow. The data reveal fairly uniform isoscapes at the S plateau margin until 6.3 Ma, with a major isotopic shift occurring between 8.2 and 5.5 Ma, with a $\Delta(\delta^{18}O_{windward\text{-}leeward})$ of 3.4 to 5.6 ‰. This difference corresponds to ca. 50 to 75% of that of the present-day altitude effect on isotope fractionation across the Taurides. Combined with stratigraphic evidence from margin-capping shallow-marine deposits of 8.4 to 8.1 Ma age [1], and with basin subsidence history at the Tauride front revealing a major clastic influx at 5.5 Ma [2], we conclude that 1000 to 1500 m of surface uplift occurred in less than 2.7 Ma, pointing to notably high uplift rates of 0.4 to 0.6 mm/yr for the Taurides in the Tortonian to Messinian. Our data compare well to short-term Quaternary uplift rates on incised river terraces [3].

Evidence for distinct stages of magma evolution recorded in the composition of accessory phases and whole-rocks in silicic magmas

ANDREW MILES[1*], COLIN GRAHAM[1], MARTIN GILLESPIE[2], CHRIS HAWKESWORTH[3], RICHARD HINTON[1] AND EIMF[4]

[4]Edinburgh Ion Microprobe Facility, University of Edinburgh, Edinburgh, UK, ionprobe@ed.ac.uk

Accessory minerals may contain a detailed record of the evolution of silicic magmas. Different stages of magma evolution are preserved in the trace element compositions of apatite inclusions and their host rocks in the normally zoned Criffell pluton, southern Scotland. Apatites in metaluminous outer zones define a trend of variable La (277 to 2677 ppm) and less variable Y (0 to 662 ppm) (trend 1), and lie on the same trend as that defined by the whole-rocks (WR) throughout the pluton. By contrast, apatites from peraluminous inner zones show variable Y (276 to 2677 ppm) and low La (<1079 ppm) (trend 2). WR isotopic and elemental trends have previously been modelled by assimilation and fractional crystallization (AFC) [1]. Zircon $\delta^{18}O$ varies by more than 3‰ between zones, but zircons within individual zones (within which apatite is included) are mostly within analytical error (0.4‰ 2σ) and thus show limited evidence for assimilation during crystallization of apatite and zircon. Crucially, in each metaluminous zone only the most primitive (La-rich) apatites crystallized from melts that closely match its WR composition. Both the WR and the most primitive apatites in each metaluminous zone therefore preserve liquidus compositions, and little open system fractionation occurred throughout the crystallization of accessory phases in these zones. Trend 2 reflects the effects of monazite crystallization in peraluminous zones that led to depletion of La in accessory phases that crystallized after monazite saturation. However, no WR compositions lie on trend 2, indicating that they were not influenced by monazite fractionation. Variations in apatite trace element concentrations within each zone therefore reflect the effects of *in situ* crystallization of allanite in metaluminous zones and monazite in peraluminous zones. The independently determined compositions of WR and apatites support numerical models for the existence of crustal hot zones in the formation of silicic magmas [2]. WR compositions are determined at depth while textural maturity and the compositions of accessory minerals such as apatite and zircon are largely determined at shallower depths by the presence or absence of other accessory phases during *in situ* crystallization of small melt batches.

Picrite-driven cratonization: a perspective from the NeoArchean Ungava craton

DEJAN MILIDRAGOVIC[1]*, DON FRANCIS[1], AND DOMINIQUE WEIS[2]

[1]McGill University, Earth and Planetary Sciences, Montreal QC
dejan.milidragovic@mail.mcgill.ca (*presenting author)
don.francis@mcgill.ca

[2]Univ. British Columbia, EOS, PCIGR, Vancouver BC
dweis@eos.ubc.ca

Zoned ultramafic/mafic plutonic rocks emplaced at mid-crustal depths occur scattered across the disparate terranes of the Ungava craton of the Archean Superior Province. These Qullinaaraaluk (Q-suite) intrusions are coeval with the ca. 2.74-2.72 Ga pyroxene-bearing granitoids and high-K granitoids that dominate the Ungava craton [1], and their wide spread distribution suggests that mantle-derived magma may have played a key role in cratonization of the northern Superior province at the end of Archean. The Q-suite intrusions are small, irregularly-zoned cumulate bodies that include a spectrum of lithologies, ranging from olivine-dominated adcumulate-mesocumulate cores to more evolved gabbro(norites). Their parental magmas appear to have been H_2O-rich as indicated by the abundance of oikocrystic amphibole in the mesocumulate rocks. Electron microprobe analyses of olivine (Fo_{max} = 85) from peridotitic cores across the peninsula, suggest that the parental magmas were enriched in Fe relative to present day picritic magmas. Although the Q-suite intrusions intrude a number of isotopically distinct terranes (Boily et al. 2009), their trace element signatures are strikingly similar across the entire 300$^+$ km width of the Ungava Craton. Despite the Fe-rich composition of their parental magmas, Q-suite rocks are characterized by "calc-alkaline" trace element signatures, with relatively flat $(MREE/HREE)_{PM}$, elevated $(LREE/MREE)_{PM}$, and strong depletions in the HFSE, in particular Nb and Ta (Fig. 1). Furthermore, the pyroxene-bearing granitoids have compositions that span the gap between the coeval Q-suite and high-K grantoids, indicating intimate interaction between mantle-derived magmas and crustal melts. Geochemical, mineralogical and field data thus suggest that the craton-wide emplacement of Fe-rich picritic magma with "calc-alkaline" trace element affinities may have been responsible for the crustal melting episode that stabilized the Ungava craton at the end of the Archean.

Recent literature suggests Li isotopic fractionation can occur during weathering, hydrothermal alteration, igneous and metamorphic processes [1], while the B isotopic signature preserved in refractory minerals, such as tourmaline, can aid in determining the source of fluids and P-T conditions during crystallization [2]. The objectives of this research are to determine the δ^7Li and δ^{11}B of relatively fresh to strongly altered basement lithologies in the vicinity of uranium mineralization in the Athabasca Basin (SK, Canada) and to evaluate if bulk isotopic analysis of Li and B can provide insight into the fluids that precipitated this mineralization with implications as a possible vectoring tool.

The largest high grade uranium deposits in the world are found within the Athabasca Basin of northern Saskatchewan, although the source of the uranium and the ultimate depositional mechanism are still highly debated. A suite of samples from the Dawn Lake area (12.9 M lbs @ 1.69% U_3O_8) include fresh to strongly altered graphitic pelitic gneiss and granitic pegmatites. Li concentrations from bulk chemical analysis range between 76 and 369 ppm, whereas B concentrations vary between 62 and 915 ppm. The elevated concentrations of Li and B are related to the presence of hydrothermal clay minerals and tourmaline, while the latter is also present as earlier formed magmatic and/or metamorphic minerals. The significant concentrations of Li and B were more then adequate for isotopic analysis, δ^7Li measured by MC-ICP-MS relative to L-SVEC display values between +4‰ and +13‰ for pelitic and graphitic pelitic gneiss and +6.2 to +18.6‰ for granitic pegmatites. The δ^{11}B measured by HR-ICP-MS relative to NBS951 was determined for granitic pegmatites to be in the range from -5.3 to 1.6 ‰, whereas the δ^{11}B for metasediments range from -0.8 to 3.5 ‰. There is no correlation between the elemental concentration of Li and B and the isotopic composition, but large variations in δ^7Li and δ^{11}B may be due to mixing of magmatic/metamorphic and hydrothermal components (eg., [3]) in these bulk samples. Further work will aim to unravel the cause of the isotopic variability and determine whether δ^7Li and δ^{11}B of bulk samples can aid in vectoring towards U mineralization.

Iodide and iodate interactions with clay minerals

ANDREW MILLER[1*], JESSICA KRUICHAK[1], HERNESTO TELLEZ[1], YIFENG WANG[1]

[1]Sandia National Laboratories, Albuquerque, USA, andmill@sandia.gov (* presenting author)

Abstract

Clay minerals are likely candidates to aid in waste isolation due to their low permeability, favorable swelling properties, and high cation sorption capacities. Iodine-129 is often the major driver of exposure risk from nuclear waste repositories at timescales >10,000 years. Therefore, understanding the geochemical cycling of iodine in clays is critical in developing defensible quantitative descriptions of nuclear waste disposal.

Anions are not typically considered to interact with most clays as it is assumed that the fixed negative charge of clays actively repels the dissoloved anion. This is corroborated by many batch studies, but diffusion experiments in compacted clays have shown iodide retardation relative to chloride. The reasons for this are unknown; however, several possible hypotheses include: redox transformation controls on sorption behavior, complex surface charge environments due to overlapping charge domains, and sorption to ancillary minerals or weathering products.

A series of clay minerals have been examined using several techniques to chracterize the surface charge environment of the clays, as well as to discern the potential for redox transformation and variable sorption behavior of different iodine oxidation states. Surface charge environments were examined through surface titrations and cation exchange capacity determination with methylene blue. Batch sorption experiments were completed with illite and palygorskite samples with both iodide and iodate. The batch experiments were completed at a range of pH values from 4-10, and at a constant ionic strength of 0.1M NaCl. Sorption experiments were performed at 20g/L solid:solution ratios to exacerbate sorption properties. The results show a range of sorption behaviors based on the clay mineral involved, as well as chemical conditions such as pH. Palygorskite has a higher sorption affinity for iodide compared to illite. There is evidence for some anion exhchange capacity on palygorskite; iodide sorption led to fluoride release. While not typically considered as a disposal medium, this result points to the use of alternative clay minerals to further isolate anionic components in nuclear waste.

Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corperation, for the U.S. Department of Energy's Nation Nuclear Security Administration under contract DE-AC04-94AL85000.

Peach Spring Tuff, Arizona-California-Nevada, USA: Generating an isolated supereruption

C.F. MILLER[1*], A.S. PAMUKCU[1], C.A. FERGUSON,[2] , T.L. CARLEY[1], G.A.R. GUALDA[1], J.L. WOODEN[3], W.C. MCINTOSH[4], M. LIDZBARSKI[5], J.S. MILLER[5], AND S.M. MCDOWELL[1]

[1]Vanderbilt Univ, Earth & Env Sciences, Nashville USA, calvin.miller@vanderbilt.edu (* presenting author)
[2]Arizona Geological Survey, Tucson USA, caf@email.arizona.edu

[5]San Jose State Univ, Geology, marshalidz@aol.com

The >700 km^3 Peach Spring Tuff (PST) is exposed through much of the western Colorado Plateau and the extended terrane of southern Nevada, SE California, and NW Arizona. Voluminous early volcanism and plutonism characterized the early Miocene history of this region, but large ignimbrites were rare and PST was almost an order of magnitude larger than any other erupted deposit.

Discovery of the source of PST (Silver Creek caldera, southern Black Mtns, AZ [Ferguson 2008]), a refined $^{40}Ar/^{39}Ar$ sanidine age (18.78±0.02 Ma, intracaldera & outflow [Ferguson et al in rev]), and detailed studies of pumice [Pamukcu et al in revision] shed light on the eruption and magma chamber evolution that preceded it. Phenocryst assemblages are consistently san>plag+bio+ hbl>qtz+px, +prominent sphene+zrc+all/chev. However, intracaldera pumice is distinct from distal outflow: richer in phenocrysts (~30-40%, showing strong resorption textures, vs ≤10%, mostly euhedral), trachyte rather than rhyolite (66-69 wt% SiO_2 vs 74-76 wt%). Thick proximal sections have common high-Si pumice, but in their upper parts crystal-rich, low-Si rhyolite-trachyte pumice is present. Core-rim zoning in zrc and sph in lower-Si pumice have compositions suggesting late growth from hotter less evolved melt (e.g. zrc rims to 50 ppm Ti: T >~900 C), in contrast to normally-zoned counterparts in high-Si pumice. Crystal size distributions and resorption textures also point to late heating in low-Si but not high-Si pumice.

We propose that trachyte in the caldera and proximal outflow represents basal cumulate mush within a zoned magma body, and that Si-rich outflow pumice was derived from higher levels. Only the lower portion was affected intensely by a pre-eruption heating event. Rhyolite-MELTS simulations suggest that the trachyte was melt-poor and ineruptible prior to reheating. The most plausible mechanism for heating and destabilizing of the mush, and perhaps for triggering eruption as well, is basal injection of hot, more mafic magma. Mafic injection is consistent with presence of sparse andesite magmatic enclaves within the ignimbrite and of a near-caldera basaltic andesite lava that was was emplaced just prior to the PST supereruption.

Regional uniqueness of the PST poses a conundrum: either super-quantities of eruptible magma or triggers to destabilize them must have been generally lacking, yet regional magma flux was high and interaction between felsic and mafic magma was ubiquitous.

Identification of the geographical origin of exotic wood species using $^{87}Sr/^{86}Sr$ isotope amount ratios

KERRI MILLER[1*], TYLER COPLEN[2], AND MICHAEL WIESER[1]

[1]Department of Physics and Astronomy, University of Calgary, 2500 University Drive NW, Calgary, AB, T2N 1N4, Canada, kamiller@ucalgary.ca (*presenting author)

[2]US Geological Survey, 12201 Sunrise Valley Drive, Reston, VA, 20192, USA

Rosewood species constitute only a small amount of the Dalbergia genus, however this wood is highly sought after for use in expensive cabinetry, flooring, musical instruments, and decorative objects. As a result, rosewood is an over-exploited resource and three species of the Dalbergia genus are currently controlled by the Convention on International Trade in Endangered Species of Wild Flora and Fauna (CITES). Because some rosewood species are threatened with extinction, trade for commercial purpose is illegal. Despite the efforts of international trade officials to prevent illegal export of this wood species, it is still common to hear about new investigations taking place. The goal of this study is to use strontium isotopic composition to aid in the determination of the geographical origin of wood samples in an effort to prevent the illegal trade of exotic timber.

The $^{87}Sr/^{86}Sr$ isotope amount ratios in 120 wood samples were analyzed by thermal ionization mass spectrometery. Samples were identified by species and country of origin. Isotope amount ratios varied from 0.704174 to 0.790101 with external repeatabilities typically on the order of 20 ppm (2s). Many regions exhibited a distinct isotopic fingerprint.

Magma dynamics beneath the ancient Mt. Etna: Clinopyroxene isotopic and thermobarometric constraints

S.A. MILLER[1*], M. MYERS[1], J.G. BRYCE[1], J. BLICHERT-TOFT[2]

[1]University of New Hampshire Earth Sciences, Durham, NH USA (*smiller@alumni.caltech.edu, correspondance)

[2]Ecole Normale Supérieure de Lyon, Lyon, France

Early stages of volcanism associated with Mount Etna, Europe's largest and most active volcano, began at ~0.5 Ma [1] and are now preserved around the perimeter of the modern-day edifice [2]. Magmatic products of these early centers, including those of ancient alkali centers active between ~200 and ~100 ka, generally have mantle-derived isotopic signatures consistent with contributions from both enriched and depleted source components. More recent Etna volcanics exhibit tell-tale signs of assimilation, but the degree to which this affected the early products is debated. Here we use an approach combining clinopyroxene (cpx) thermobarometry with an investigation of Pb, Hf and Nd mineral-whole rock isotopic (dis)equilibrium to constrain the depths at which magmas crystallized beneath these alkali centers and to gain insight into the nature of the source of ancient Etna lava isotopic signatures. The advantage of using these three isotopic systems together lies in coupling two slowly diffusing elements (Hf and Nd) with a more rapidly diffusing one (Pb), thereby providing the potential to infer any links between the timing of magma mixing (or assimilation) and eruption [cf. 3].

We have applied detailed single-cpx and cpx-liquid thermobarometric modeling based on back-calculated liquids from whole rock compositions [4] and the models of Putirka [5]. Crystals from two mafic flows from ancient alkali centers yield temperatures of 1140-1180 °C and 1090-1130 °C. Calculated initial crystallization depths lie at or below the Moho [6], consistent with polybaric fractionation and shoaling crystallization depths over time. Hf-Pb-Nd isotopic data from cpx phenocryst separates of ancient alkali lavas indicate no difference between whole rock and cpx values. Accordingly, we infer that the isotopic signatures of these magmas were locked in at pressures, at minimum, corresponding to early cpx crystallization. The lack of isotopic disequilibrium also suggests that the magmas were relatively well-mixed by the time they ascended to the depths at which cpx crystallization began.

Taken together, our results support the interpretation that observed isotopic systematicatics in ancient Etna lavas result from mixing between MORB-like and enriched mantle sources, with volatile-bearing peridotite and pyroxenite components preferentially melting to generate ancient alkaline volcanism. Shallower crystallization depths recorded in some phenocrysts correspond to the current location of a high-velocity body in the upper crystalline basement [7], indicating that this may be a long-lived feature.

Solubility of fish-produced high magnesium calcite

FRANK J. MILLERO[1]* AND RYAN WOOSLEY[1]

[1]Rosenstiel School of Marine and Atmospheric Science,University of Miami, Miami, FL 33149, USA, fmillero@rsmas.miami.edu (* presenting author)
rwoosley@rsmas.miami.edu

It has been suggested that the fish produced high 10 to 48% magnesium calcite can contribute to the input of calcite to the oceans. Fish produce this material as part of the physiological mechanisms for maintaining salt and water balance. In this paper, we report on the first measurements of the solubility of this high magnesium calcite in seawater. The solubility ($pK^*_{sp} = 5.89 \pm 0.09$) of this material is approximately two times higher than aragonite ($pK^*_{sp} = pK^*_{sp} = 6.18$) and similar to the high magnesium calcite generated on the Bahamas Banks ($pK^*_{sp} = 5.90$). The dissolution of this fish-produced $CaCO_3$ input to the oceans will be discussed. The higher solubility of this fish-produced carbonate to surface ocean waters may partially explain the increase in total alkalinity above the aragonite saturation horizon in the oceans. More recent work has shown that the production of this high-magnesium calcite may affect the total alkalinity of coral reefs.

Ultra-high precision Fe isotope analysis of eucrites and diogenites - Fe stable isotope fractionation during planetary differentiation?

M.-A. MILLET[1,*], J.A. BAKER[1], M. SCHILLER[2], J. CREECH[1], J. DALLAS[1], M. BIZZARRO[2]

The redox state of mantle sources, fractional crystallization of minerals with varying Fe^{3+}/Fe^{2+} ratios, diffusion processes and high pressure silicate-metal segregation have been identified as the main causes of Fe stable isotope variations in terrestrial magmatic rocks [1-4]. However, samples from smaller reduced planetary bodies show limited Fe stable isotope variations similar to chondritic values, which may indicate that Fe isotopes are not fractionated by any other processes during planetary formation and differentiation [1,5]. However, the limited number of samples measured and the precision of the available data preclude this as a definitive interpretation.

Diogenites and eucrites originate from the HED parent body, thought to be the asteroid 4-Vesta, and may have been generated during the crystallization of a nearly complete magma ocean within a few millions years of Solar System formation [6]. As such, they offer a unique opportunity to investigate the fractionation of Fe stable isotopes during planetary formation and differentiation, provided suitable analytical precision can be attained.

Here we present ultra-high precision Fe stable isotope measurements on a suite of diogenites and eucrites obtained by high-resolution MC-ICP-MS using a ^{57}Fe-^{58}Fe double spike to correct for instrumental mass bias (2 sd = 0.02‰, [7]) along with major and trace element concentrations and $\mu^{26}Mg^*$ values (for diogenites only, [6]). This dataset will allow us to investigate in detail the processes occuring during the development of planetary embryos and if Fe stable isotope fractionation occurred during differentiation of the HED parent body.

U-Th-Pb geochronology of meta-carbonatites and meta-alkaline rocks

LEO J. MILLONIG[1*], AXEL GERDES[2], LEE A. GROAT[1]

[1]Department of Earth and Ocean Sciences, University of British Columbia, Vancouver, Canada, lmillonig@eos.ubc.ca (*presenting author), lgroat@eos.ubc.ca
[2]Institut fuer Geowissenschaften, Goethe University Frankfurt, Germany, gerdes@em.uni-frankfurt.de

U-Pb and Th-Pb ages of zircons from eight meta-carbonatite and four meta-alkaline rock samples provide evidence for three distinct episodes of carbonatite and alkaline magmatism in the southern Canadian Cordillera spanning a period of ~460 Ma. The earliest (Neoproterozoic) event occurred at ~800-700 Ma and coincides with the postulated initial break-up of Rodinia. The second, previously undocumented, event of carbonatitic magmatism is constrained to the Late Cambrian to Early Ordovician at ~500-490 Ma and corresponds to a period of extensional tectonics that affected the western continental margin of North America from the Canadian Cordillera to the southwestern United States. The youngest and most prevalent period of alkaline igneous activity occurred in Late Devonian to Early Carboniferous times at ~360-340 Ma and also resulted from extensional tectonics. In addition, different episodes of amphibolites facies metamorphism subsequently affected the igneous rocks between ~170-50 Ma.

The magmatic emplacement ages, as well as the time of subsequent metamorphism, were further confirmed and constrained by U-Th-Pb dating of the accessory minerals baddeleyite, titanite, monazite, allanite, pyrochlore, and apatite (Figure 1).

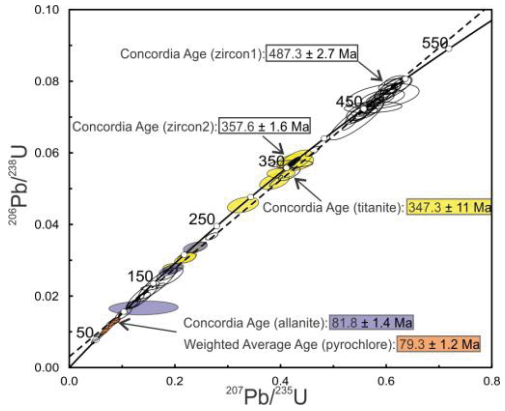

Figure 1: Concordia diagram of zircon, titanite, allanite and pyrochlore analyses from a meta-carbonatite sample (HwCr-001) defining a linear array with upper and lower intercepts of 436 and 71 Ma. However, this 'simple' linear array obscures the complex behavior of different isotope systems in the accessory phases and the complex geological history that led to the above pattern.

In combination, these datasets put new constraints on the timing of carbonatite and alkaline igneous activity and the evolution of (ancestral) North America's western continental margin from Neoproterozoic to Carboniferous times, and elucidate the applicability of different geochronometers and their sensitivity to amphibolites facies metamorphism in this set of unusual high-alkaline rocks.

Lithium isotopes systematics in Geothermal systems

ROMAIN MILLOT[1*], PHILIPPE NÉGREL[2], AND BERNARD SANJUAN[3]

[1]BRGM, Metrology Monitoring Analysis Department, Orléans, France, r.millot@brgm.fr (* presenting author)
[2] BRGM, Metrology Monitoring Analysis Department, Orléans, France, p.negrel@brgm.fr
[3] BRGM, Department of Geothermal Energy, Orléans, France, b.sanjuan@brgm.fr

Assessing the origin and behaviour of lithium and the distribution of Li isotopes in geothermal systems is of major importance in order to increase our knowledge of the lithium cycling in the Earth's crust. Lithium is a fluid-mobile element and due to the large relative mass difference between its two stable isotopes, it is subject to significant low and high temperature mass fractionation which provides key information on the nature of water/rock interaction processes. The main objective of the present work is to constrain the behaviour of Li and its isotopes in geothermal systems both for geothermal water samples representing deep circulation in the crust and by using an experimental approach.

The behaviour of Li and its isotopes (δ^7Li) have been characterized in geothermal systems located in volcanic island arc areas: Guadeloupe, Martinique islands [1] and in New Zealand [2]. Moreover, one particularly important aspect of this work was to establish the nature, extent and mechanism of Li isotope fractionation as a function of temperature during water/rock interaction.
And, we also report results of Li isotope exchange experiments during seawater/basalt interaction (from 25 to 250°C). These results confirm that Li isotopic exchange is strongly temperature dependent, and demonstrate the importance of Li isotopic fractionation during the formation of Li-bearing secondary minerals and allow us to determine the following empirical relationship between isotopic fractionation and temperature: $\Delta_{solution - solid} = 7847 / T - 8.093$.

This work shows that the fractionation of Li isotopes is dependent upon the extent of water/rock interaction in terms of intensity (i.e. temperature that control primary mineral dissolution and secondary mineral formation in geothermal systems). Altogether, this study highlights that the use of Li isotopic systematics is a powerful tool for characterizing the origin of geothermal waters as well as the nature of their reservoir rocks.

t.m.lenton@exeter.ac.uk

Current zero-dimensional carbon and sulphur cycle models provide estimates of O_2 and CO_2 concentration over the Phanerozoic eon, and show a reasonable correlation with available proxys [1][2].

In this work we attempt to further extend these techniques to address conditions throughout the Proterozoic. As well as the controlling processes in the Phanerozoic, this model must include the interaction of the surface system with the mantle, the steady accumilation of carbon in the crust and the change in removal pathways as the continental area expands – processes which have been addressed individually in previous work [3][4][5].

Initial results show that the accumilation of crustal carbon in the combined model agrees well with previous modelling, and the predicted surface temperature and isotopic fractionation fall within reasonable limits. However, the baseline model does not predict the expected low oxygen concentration throughout the Proterozoic, instead predicting a stable concentration of around 0.2-0.5 PAL (present atmospheric level). The conclusion is that important processes may be missing.

Thankfully there are many candidates for the missing process (e.g. reduced organic burial due to limited nutrient delievey [6]), and we therefore use our model framework as an assesment tool: for each possibility, model predictions for O_2, CO_2, temperature and the isotopic fractionation of carbon and sulphur are compared to all available geochamical proxies, allowing the evaluation of these mechanisms, and hopefully the beginnings of a combined model for Earth evolution.

Concentration and transport of solutes drive by transpiration at the edge of a Prairie Pothole wetland

CHRISTOPHER T. MILLS*, MARTIN B. GOLDHABER, CRAIG A. STRICKER

United States Geological Survey, Denver, CO, 80225, USA
*presenting author (cmills@usgs.gov)

The Prairie Potholes region (~715,000 km^2) extends from Alberta, Canada to Iowa, USA. Retreat of Pleistocene glaciers left millions of pothole-like depressions that are internally drained. Topographically low, groundwater discharge wetlands tend to be saline (often Ca-Mg-SO_4-HCO_3) due to reaction of groundwater with glacial till rich in pyrite, gypsum, and calcite. However, several other processes influence discharge wetland chemistry, including plant transpiration at the wetland edge. This process can concentrate solutes and change hydrologic gradients at the wetland margin causing it to alternate between a source and sink of water and solutes to the wetland. We used $\delta^{18}O_{H2O}$, $\delta^{2}H_{H2O}$, and $\delta^{34}S_{SO4}$ values of groundwater and wetland water to investigate this process at the edge of wetland P1 in the Cottonwood Lake study area near Jamestown, North Dakota (USA).

Solutes (including SO_4) were least concentrated in wetland P1 water and deep (several meters below ground surface) groundwater upgradient of P1. Solutes were more concentrated in mid-depth (150 cm) to shallow (60 to 90 cm) groundwater at the edge of the wetland due to plant transpiration. Transpiration did not affect $\delta^{18}O_{H2O}$/ $\delta^{2}H_{H2O}$ values of mid-depth groundwater samples which were similar to deep, upgradient groundwater and fell on the meteoric water line ($\delta^{18}O_{H2O}$ from -14.6 to -12.0‰). Deep and mid-depth groundwater samples also shared similar $\delta^{34}S_{SO4}$ values (-18.2 to -15.1‰). Water from P1 fell below the meteoric water line ($\delta^{18}O_{H2O}$=-4.6‰) and had more positive $\delta^{34}S_{SO4}$ values (-4.2‰).

Shallow groundwater from the wetland edge had $\delta^{18}O_{H2O}$/ $\delta^{2}H_{H2O}$ and $\delta^{34}S_{SO4}$ values that were intermediate between deeper groundwater and wetland water. A plot of $\delta^{34}S_{SO4}$ versus the deuterium offset showed shallow groundwater to be a mixture of deeper groundwater and wetland water. Samples taken at different times of day located differently along the mixing line indicating dynamic mixing. Samples collected earlier in the day showed a smaller contribution of wetland water than samples collected later in the day. This may be a result of a diurnal cycle of the hydrological gradient at the wetland edge due to plant transpiration. This study clearly demonstrated the use of natural abundance isotope systems for investigating this hydrochemical process and the potential impact of plant physiology on wetland geochemistry.

Current Status of Phosphate (U-Th)/He Thermochronology of Meteorites

KYOUNGWON MIN[1*], SEUNG RYEOL LEE[2]

[1]University of Florida, Department of Geological Sciences, Gainesville, USA, kmin@ufl.edu (* presenting author)
[2]Korea Institute of Geoscience & Mineral Resources, Daejeon, Korea, leesr@kigam.re.kr

Traditional whole-rock (U-Th)/He methods applied to meteorites commonly yield apparently younger ages than expected from other thermochronologic tools, suggesting that (U-Th)/He systems are disturbed by thermal event(s) after the primary cooling. However, recent investigations applied to phosphates at a grain scale have revealed that some of the phosphate (merrillite, apatite) grains retain their pristine (U-Th)/He ages, allowing for determination of the temporal and temperature conditions that their parent bodies experienced during the primary cooling or shock events. In this contribution, we aim to explain the current status of the (U-Th)/He methods applied to extraterrestrial phosphates.

For unshocked meteorites, the single-grain (U-Th)/He methods provide a unique way to determine absolute ages when the meteorites have passed through temperatures below ~200 °C. Recent stepped heating experiments indicate that the closure temperatures of merrillite and chlorapatite are generally in the range of 85-145 °C and 7-108 °C, respectively, for a wide range of cooling rates (0.1– 100 °C/Ma) and at a diffusion domain radius of 50 μm. Two examples of the single-grain (U-Th)/He thermochronometry used to constrain low T thermal histories are for the Acapulco and St. Séverin meteorites whose pristine ages are well consistent with the medium-to-high T cooling curves. For shocked meteorites, the phosphate (U-Th)/He ages can provide crucial information regarding shock temperature conditions. Due to the high He diffusivity in phosphates, the transient shock event causes significant fractional loss of He (f_{He}), which can be utilized for thermal modeling and peak T estimation. Because most of the phosphate crystals are severely fractured, most likely during the shock event, diffusion domains are smaller than crystals; therefore, requiring detailed petrographic examination and image analysis of phosphate grains for modeling. This approach has been applied to the Los Angeles, ALHA84001, Zagami and EETA79001 Martian meteorites. Some of the results from this approach indicate bias from the peak T estimated from traditional shock recovery experiments. (U-Th)/He study of Zagami indicates relatively high peak T (> 400 °C); whereas, shock recovery experiments yield minor shock conditions (post-shock T ~ 60 °C). It is unclear what causes such a large discrepancy. In order to improve phosphate (U-Th)/He methods, the following issues need to be thoroughly addressed. First, because the morphology-based α recoil correction is essentially impossible for meteoritic samples, an alternative way of avoiding this correction has been suggested. Although there is a tendency that large grains with other phases attached yield more pristine ages without α recoil correction, there are some exceptional cases that are not fully understood. Second, the He diffusion properties in meteoritic apatite seem to show relatively large sample-to-sample variations, rendering additional efforts to constrain the diffusion properties for various meteoritic phosphates.

The evolution of clay minerals and rift structure in Zhanhua Depression, China

Zhao Ming[1*], Ji Junfeng[2], Chen Xiaoming[3], Wu Changzhi[4], Wu Bing[5] and Pan Yuguan[6]

[6]Nanjing University, China, Earth Sciences and Engineering, yuguan.pan@gmail.com

Introduction, Results and Conclusion

Zhanhua Depression is located in Bohai Bay Basin, China. The depression has an area of about 3800km^2. It is a major oil and gas exploring district in the basin.

The study on diagenesis of clay minerals in Zhanhua Depression shows that the disordered mixed-illite/smectite (R_0I/S) and kaolinite in the Neogene were formed at the burial depths <2000m during the post-rift in Zhanhua Depression, while the appearance of the ordered mixed-illite/smectite ($R_{\geq 1}$I/S) in the Paleogene at the burial depths >2000m and the disappearance of kaolinite at the same depths were symbolized as the syn-rift in the depression. This regularity is referred to the burial depths, which are controlled by the paleotemperatures in the evolution of the clay minerals.

By using the chlorite geothermometer [1, 2, 3], the forming temperature of chlorites during the rift period in the Paleogene is calculated as 135-180℃ in Zhanhua Depression. The relationship between the chlorite diagenetic temperature and its burial depth indicates that the paleogeothermal gradient is about 38℃/km in the Paleogene in Zhanhua Depression. It is higher than the present geotemperature (34.5-32℃/km [4]). This phenomenon was attributed to the evolution of the structural dynamics in the rifted basin [5, 6].

Hydrocarbon adsorption on Carbonate and Silica surfaces: a First Principles study with van der Waals interactions

VAGNER A. RIGO[1] AND CAETANO R. MIRANDA[1*],

[1]Universidade Federal do ABC (UFABC), Santo Andre-SP, Brazil, caetano.miranda@ufabc.edu.br (* presenting author)

We study the adsorption of hydrocarbon molecules on carbonate minerals and silica surfaces by means of first-principles calculations based on Density Functional Theory (DFT) with and without van der Waals (vdW) corrections. The inclusion of vdW corrections in ab-initio methods can improve the description of these systems particularly, the long range weak dipole-dipole interaction as well as provide a fully electronic description for the interface of hydrocarbon molecules and mineral surfaces. To take into account the vdW dispersion forces, we used the DFT with the Dispersion-Corrected Atom-Centered Potentials model (DCACP) [1] Energetic, electronic, structural and kinetic properties have been determined for the adsorption of the representative hydrocarbons (benzene, anthracene, naphthalene, toluene, heptane and hexane) on calcite ($CaCO_3$) and dolomite [$CaMg(CO_3)_2$] (10-14) and quartz (SiO_2) surfaces. Our results suggest that Ca sites are the most energetically favorable for hydrocarbon adsorption on both carbonate systems. The calculations also indicate a weak interaction between the hydrocarbon with the bare silica surface for all hydrocarbons studied. The vdW corrections strengthen the hydrocarbon-surface bond with a corresponding reduction in the bond distance between the benzene and the surfaces. The inclusion of London dispersion forces to benzene results in an increase of 70% in the surface-molecule energy interaction. The energy barrier, for the displacement of the hydrocarbons along the calcite and quartz SiO_2 surfaces were determined using the Nudged Elastic Band method, and adsorption energies for the most stable sites show the same order of magnitude. The highest energy barriers associated with the hydrocarbon displacements on the surfaces are of the same order of the adsorption energies for the most stable sites. By taking into account the vdW interactions within the energy barriers in complement to adsorption energies in a model for hydrocarbons/mineral-rocks interaction can give us a more realistic description to the hydrocarbon carbonate/silicate interactions.

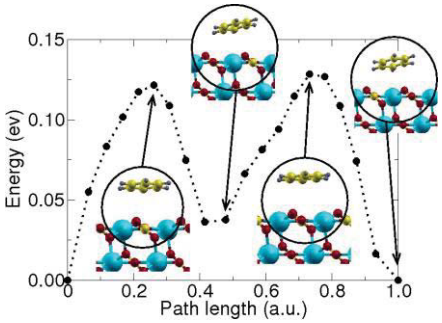

Figure1 - Energy barriers for benzene displacement along [48-1] direction for calcite (10-14) surface

Litho-, chrono- and S-MIF-chemo-stratigraphy of late Archean Dharwar Supergroup, south India

KAORU MISHIMA[1]*, RIE YAMAZAKI[2], M. SATISH-KUMAR[2], TOMOKAZU HOKADA[3], YUICHIRO UENO[1]

[1]Department of Earth & Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan. mishima.k.ab@m.titech.ac.jp
[2]Institute of Geosciences, Shizuoka University, Shizuoka, Japan
[3]National Institute of Polar Research, Tachikawa, Tokyo, Japan

Earth's tectonic and climatic systems may have fundamentaly changed through the late Archean period, which is characterized by major deposition of banded iron formation (BIF) and appearance of stromatolite reef along continental margins. Also, mass-independent fractionation of sulfur isotopes (S-MIF) demonstrated that Earth's atmosphere and ocean were virtually oxygen-free before 2.3 Ga [1]. In the late Archean, the S-MIF signature changed dramatically: minimam $\Delta^{33}S$ at around 2.9 Ga, subsequent large $\Delta^{33}S$ variation culminated at 2.5 Ga and its sudden drop at the end of Archean. These changes may reflect perturbation of atmospheric chemistry. However, almost the S-MIF record so far came from Pilbara and Kaapvaal cratons, that may have been a single continent (Vaalbara) at that time [2], and thus the observed S-MIF may possibly reflect local environment. It is important to test the "globalism" of the S-MIF signature for tracing the atmospheric evolution.

We studied late Archean volcano-sedimentary sequence of the Dharwar Supergroup, distributed in the Chitradurga schist belt, western Dharwar craton. Our new field mapping and zircon U-Pb dating allows us to reconstruct detailed lithostratigraphy. The lower unit (post-3.0 Ga) consists of basal conglomerate, stromatolitic carbonate, silici-clastics with diamictite, chert/BIF and pillowed basalt in assending order, all of which are older than 2676 Ma magmatic zircon ages from dacite dyke intruded into the topmost pillowed basalt. The upper unit unconformably overlies the pillow lava, and consists of conglomerate/sandstone with ~ 2600 Ma detrital zircons, komatiite lava, BIF and silici-clastic sequence with mafic volcanics. Sulfur isotope analysis of extracted sulfide of these sedimentary rocks show a clear $\Delta^{33}S$-$\Delta^{36}S$ correlation with a $\Delta^{36}S/\Delta^{33}S$ slope of -0.98. This trend is similar to those reported from Pilbara-Kaapvaal equivalents, thus could be a global signature, whereas $\delta^{34}S$-$\Delta^{33}S$ relation from each stratigraphic level shows somewhat different trend, possibly reflecting local environment and/or postdepositional overprint.

Global oxygen isotope survey of lithospheric mantle: Implications for the evolution of cratonic roots

A. MIŠKOVIĆ[1]*, R.B. ICKERT[2], D.G. PEARSON[2], R. A. STERN[2], M. KOPYLOVA[3] AND B. KJARSGAARD[4]

[1]Northwest Territories Geoscience Office, Yellowknife, Canada, amiskovic@eos.ubc.ca (* presenting author)
[2]CCIM - Earth & Atmospheric Sciences, University of Alberta, Edmonton, Canada
[3]Earth & Ocean Sciences, University of British Columbia, Vancouver, Canada
[4]Geological Survey of Canada, Ottawa, Canada

The sub-continental lithospheric mantle (SCLM) forms the roots to the earliest crust and represents the most ancient mantle domain on Earth. Hundreds of oxygen isotope data have been reported for various mantle domains in the past three decades, yet the full geodynamic significance of these data is largely unappreciated. When coupled to the major element systematics, oxygen isotopes have the potential to illuminate the longstanding conundrum of the origin of highly depleted lithospheric roots beneath the Archean crust given that the current debate on their genesis is centred on quantifying the relative contributions of mantle plumes (asthenospheric source) and subduction zone processes (lithospheric source).

We present isotope analyses for 61 grains of olivines extracted from peridotite xenoliths entrained by kimberlites and pericratonic basalts worldwide; the most extensive high-precision *in situ* $\delta^{18}O$ database to date. Olivines analysed by multi-collector SIMS in this study were collected at: Paleogene to Jurassic Diavik and Jericho kimberlites (Slave Province), Cretaceous Somerset Island kimberlites (Rae Craton), Late Neoproterozoic kimberlites of Western Greenland (North American Craton), Middle Cretaceous to Late Mesoproterozoic Kimberly, Finsch, Letseng-la-Terae and Premier kimberlites (Kaapvaal Craton), Early Carboniferous Udachnaya pipe (Siberian Platform), and Miocene Vitim alkaline basalts.

The SCLM $\delta^{18}O$ data are normally distributed about the mean value of 5.30 ‰ (±0.22; 2σ) and largely corroborate previous upper mantle compilations [1]. There is no correlation between $\delta^{18}O$ and major or trace element chemistry, rhenium-depletion ages or equilibrium pressure-temperature conditions from which the mantle xenoliths were derived. Based on the new data we find no statistical difference between the oxygen isotope composition of cratonic peridotites and modern MORB-source mantle. These observations rule out an origin for SCLM via subcretion of serpentinised oceanic lithosphere [2]. However, we cannot discriminate between the subduction of relatively unaltered oceanic lithospheric mantle versus a plume origin. Furthermore, the overlap of the SCLM data with the mean global δ18O value of MORBs of 5.17‰ (±0.21; 2σ) has important implications for the long-term relationship between the convecting asthenospheric mantle and refractory cratonic roots.

Improved Analytical Method for Determination of B Isotopes by Magnetic Sector ICP-MS

SAMBUDDHA MISRA[1*], JOANNA KERR[1], MERVYN GREAVES[1], HENRY ELDERFIELD[1]

[1]University of Cambridge; Dept. of Earth Sciences; Cambridge, UK (*presenting author: sm929@cam.ac.uk)

The boron isotopic composition of seawater, as recorded by foraminifera, can be used as a tracer of past variations in atmospheric pCO_2 [1, 2]. However, widespread application of B isotopes in geochemical studies is limited by the large relative mass requirement for high precision measurements, large memory effect, high procedural blanks, artificial fractionation induced by matrix purification methods, and low matrix tolerance [3]. We present an improved method for B istope ratio ($\delta^{11}B$) determination with low mass consumption (5 to 10 ng-B per quintuplicate analyses), high precision (± 0.5‰, 2σ), low blanks (< 9 pg-B/ml), and high matrix tolerance using Element XR® Single Collector ICP-MS (***figure)***. The present ICP-MS method is optimised for analysis of < 0.5 mg foraminifera samples.

Preliminary analyses of B standards following standard – sample bracketing technique gave external precision (quintuplicate) of ± 0.50‰ independent of analyte concentration (4 ppb – 10 ppb). Moreover, this new ICP-MS method has relatively large tolerance for Na, Mg, and Ca – the dominant matrix elements in foraminiferal calcite and provides an improved methodology to investigate B isotopic variations of planktonic and benthic foraminifera samples over geologic timescales.

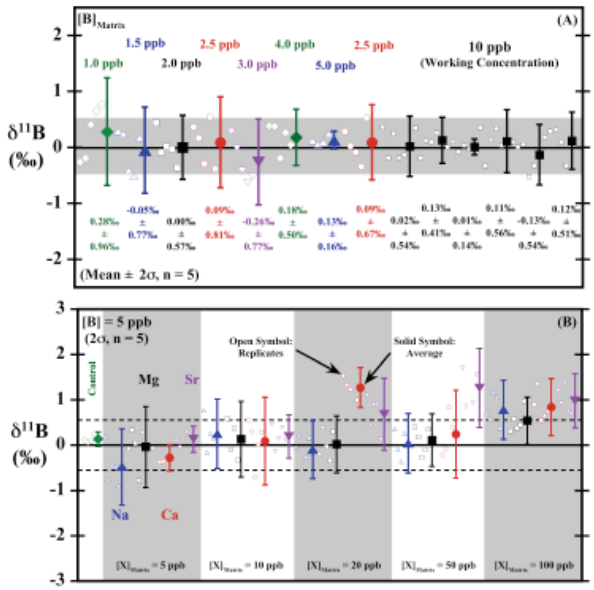

Figure: Results of **(A)** Boron concentration experiment, and **(B)** matrix experiment. All samples analysed following standard – sample bracketing technique. Analyses of sample in quintuplicates.

During the operation of Geologic Carbon Capture and Storage (CCS) and the injection of supercritical CO_2 into underground formations, microbe-rock-fluid interactions occur. These interactions may be important for controlling the ultimate fate of the injected CO_2, and may also be manipulated to enhance the storage of the CO_2, via mineral-trapping, solubility trapping, formation trapping, and leakage reduction.

We have demonstrated that engineered microbial biofilms are capable of enhancing formation, mineral, and solubility trapping in carbon sequestration-relevant formation materials. Batch and flow experiments at atmospheric and high pressures (> 74 bar) have shown the ability of microbial biofilms to decrease the permeability of natural and artificial porous media [1], survive the exposure to $scCO_2$ [2], and facilitate the conversion of gaseous and supercritical CO_2 into long-term stable carbonate phases as well as increase the solubility of CO_2 in brines [3].

Ongoing microscopy and modelling studies aim to understand these processes at both the pore- and core-scale in order to facilitate larger scale understanding and potential manipulation for biologically based CCS engineering [4,5]. Successful development of these biologically-based mineralisation concepts could result in microbially enhanced carbon sequestration strategies as well as CO_2 leakage mitigation technologies, which can be applied either before CO_2 injection or as a remedial measure around injection wells.

Sorption and abiotic reduction are important processes influencing the mobility and cycling of Se in natural environments. Although these processes have received increasing attention in recent years, the associated isotopic fractionations are poorly known [1, 2]. In this study we determined the rates of reaction and isotopic fractionations of Se(IV) and Se(VI) during sorption to iron oxides (2-line ferrihydrite, hematite and goethite) and iron sulfides (FeS and FeS_2) in batch reactor experiments. No change in Se oxidation state was observed when Se(IV) and Se(VI) sorbed to iron oxides. In contrast, XANES spectra showed evidence of reduction on the iron sulfides. Reaction rates were obtained using inverse modeling of dissolved Se concentration time series, following the mixed-reaction modeling approach of [3]. Sorption rates were highest in the Se(IV)-goethite system, while Se(VI) sorbed slowly on 2-line ferrihydrite and not at all on hematite and goethite. Reduction was fastest in the Se(IV)-FeS system and slowest for Se(VI)-FeS_2. Changes in the isotopic composition of aqueous Se were monitored as a function of time. The results revealed the absence of measurable equilibrium isotope fractionation for all systems studied. Kinetic fractionation was observed in the case of Se(IV) sorbing to 2-line ferrihydrite and Se(IV) being reduced by FeS_2. Figure 1 illustrates the $\delta^{82/76}$Se trends of aqueous and solid-bound Se(IV) sorbing to 2-line ferrihydrite. The data follow the standard Rayleigh fractionation model, except for the last two time points, as the system approaches equilibrium.

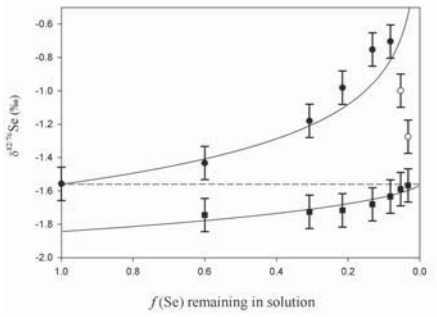

Figure 1: Se(IV) sorption to 2-line ferrihydrite. Circles show measured $\delta^{82/76}$Se of the remaining Se(IV) in solution, squares the calculated $\delta^{82/76}$Se of Se(IV) sorbed to 2-line ferrihydrite. The open symbols correspond to the two last samples collected, whose data were excluded when fitting the data with the Rayleigh fractionation model. Error bars indicate the precision of $\delta^{82/76}$Se measurements.

Dislocation microstructures of ferropericlase at high pressures.

NOBUYOSHI MIYAJIMA[1*] AND TETSUO IRIFUNE[2]

[1]Bayerisches Geoinstitute, Bayreuth Universität, Bayreuth, Germany, nobuyoshi.miyajima@uni-bayreuth.de

Introduction

The rheological behavior of magnesium silicate perovskite (MgPv) and ferropericlase (Fp) at high pressure and temperature is indispensable for discussing dynamics of the Earth's lower mantle. Deformation of plastically weaker Fp than coexisting MgPv is likely to be responsible for bulk strain of the rock, if it develops a sufficient grain connectivity in a fabric development at high temperature. Particularly, lattice preferred orientations (LPO) of the polycrystalline Fp can be important to explain observed seismic anisotropies in the bottom of Earth's lower mantle, so called "D'' layer". For understanding deformation mechanisms to create a LPO pattern, dislocation microstructures of Fp under lower mantle conditions are very important, because dislocation creep mechanisms could become one of dominant mechanisms in the D'' layer. To discuss the influence of pressure on the active slip system in Fp, we report dislocation microstructures of Fp in a pyrolite mineral assemblages synthesized at 44 GPa and 2073 K [1], in comparion to those of lower pressure samples, by using TEM.

Results and Conclusion

In the pyrolite mineral assemblage, MgPv contained a few dislocations and Fp displayed a high density of dislocations (Figure 1). In a Fp grain, straight long screw dislocations with $\boldsymbol{b}$ = 1/2[1-10] were nucleated on the (110) and/or (11-1) planes (Figure 1a) and the other dislocations with $\boldsymbol{b}$ = 1/2[01-1] was also along the (011) plane (Figure 1b) in the same grain.

Dislocation microstructures of Fp synthesized at high temperatures and different pressures from 0 to 44 GPa were compared in the TEM images. The highest pressure sample indicate that an active slip system of 1/2<110>{110} in Fp, consistent with previous experimental studies at lower pressures. The characteristic textures of straight screw dislocations along a specific crystal orientation strongly imply that the Peierls friction for movement of 1/2<110> dislocations in Fp increases with increasing pressure. The dislocation microtextures are compared with a current theoritical study of dislocation mobilities in MgO [2].

Local structure of Al in Al-Zn hydroxide coprecipitates

AKANE MIYAZAKI[1*], KAORI ETOU[1], MAYUMI ETOU[2], KOTARO YONEZU[3], IOAN BALINT[4], AND TAKUSHI YOKOYAMA[5]

Al-Zn hydroxide coprecipitate

Zn^{2+} adsorption onto alumina, which represents the behavior of heavy metal ions in soil systems, can be devided into three processes; adsorption due to formation of inner-sphere complex, desorption of Zn^{2+} accompanied with dissolution of Al^{3+}, and then re-adsorption of Zn^{2+} [1]. Recently, the final product of the above three processes was found to have AlO_4 species in its structure [2]. The formation of AlO_4 was induced by Zn^{2+} adsorption and it relats deeply to the dissolution and re-adsorption of Al^{3+}. There are two possible assignement for the AlO_4 species; one is Keggin-like structure, and the other is substitution of Zn^{2+} by Al^{3+} in the structure of zinc aluminate, $ZnAl_2O_4$. Because the adsorption experiments were performed at constant pH of 6.5, where Keggin is not stable, the formation of Keggin-like structure seems to be unlikely. On the other hand, $ZnAl_2O_4$ is a member of the spinel family and Al^{3+} can substitute four coordinated Zn^{2+} in its structure. Zinc aluminate is known to be prepared by calcining Al-Zn hydroxide coprecipitates [3]. In the process of Zn^{2+} adsorption onto alumina, it is possible that the desorbed Zn^{2+} and dissolved Al^{3+} coprecipitate to form zinc aluminate-like structure as the final products of adsorption. In order to examine this possibility, Zn-Al hydroxide coprecipitates having various Zn/Al ratios were prepared and chemical states of Al was compared to the final product of adsorption using ^{27}Al MAS NMR.

^{27}Al MAS NMR spectra of the coprecipitates

Figure 1 shows the ^{27}Al MAS NMR spectra of coprecipitates prepared by hydrolysis of mixed solution of zinc and aluminum nitrates. Peaks at around 60 ppm, which correspond to AlO_4 species, increased by decrease of Zn/Al ratios. Fig. 1 shows that the AlO_4 species can be formed by coprecipitation of Al and Zn, without calcination. AlO_4 species increased by lowering Zn/Al ratios. Therefore, less Zn^{2+} seems to cause more isomorphic subsbitution by Al^{3+}. The shape of ^{27}Al MAS NMR spectra of the coprecipitate with low Zn/Al ratio is almost identical to that of the final product of Zn^{2+} adsorption onto alumina. Therefore, it is highly possible that Zn^{2+} adsorption onto alumina induced the formation of Zn-Al hydroxide coprecipitate having zinc aluminate-like structure.

Carbon is the fourth most cosmic abundant element in the solar system. It has a key role in the melting phase relations of mantle rocks and can move within mantle as carbonate rich melts [1]. Additionally, carbon is deposited in the ocean floor as carbonate minerals and organic matter, and is recycled into the mantle during subduction. Carbon isotopic composition serves as an efficient tool to understand the carbon cycle, both in the shallow and deep Earth environments. Recently, the presence of low $\delta^{13}C$ diamonds was considered to provide evidence for deep cycling of surface carbon of the organic matter origin [2], however recent experimental results in the Fe-C system suggests an alternate possibility of light carbon in the core [3]. Therefore, it is essential to understand the carbon isotope fractionation at mantle *P-T* conditions. Here, we present results on experimental determination of partitioning of carbon isotopes at high-pressure and high-temperature conditions, analogous to melting of carbonated mantle in the presence of graphite/diamond, and discuss the carbon movement in the mantle.

High-pressure experiments were performed in the Mg-Si-C-O system using a Kawai type multi-anvil high-pressure apparatus at the Institute for Study of the Earth's Interior, Okayama University, Misasa, Japan. Starting materials comprise of natural enstatite, synthetic magnesite ($\delta^{13}C$ = -32.8‰), San Carlos olivine and pure graphite ($\delta^{13}C$ = -16‰), that were mixed in the molar ratio 3:2:1:1 or 3:2:1:3. This mixture is assumed as simplified carbonated harzburgite in a upper mantle. Experiments were carried out at pressures of 5 and 10 GPa at varying temperature conditions between 1100 ºC and 1800 ºC. Retrieved samples from HPHT experimental runs were mounted in epoxy and cut into two halves and polished. One half was used for petrographic observations and chemical analysis using an electron microprobe and the other half for carbon isotope measurements. Run products were mechanically and/or chemically separated and carbon isotope measurements were carried out using a conventional gas source isotope ratio mass spectrometer (IRMS).

Preliminary results indicate that runs at 5 GPa and above 1500 ºC have melted and the chemical composition of the melt varied widely, such as C-rich melt or Si-rich melt. Carbon isotope results show considerable partitioning between graphite/diamond and carbonate melt at temperatures and pressures corresponding to upper mantle conditions. We discuss the carbon isotope systematics during melting of carbonated mantle and implications for deep carbon cycle based on our experimental results.

There is broad consensus that the main mechanism for the mobilization of arsenic (As) in reducing groundwater is the microbial reductive dissolution of iron (Fe) oxyhydroxides driven by the oxidation of labile organic matter (Figure 1). There is increasing evidence that the chemical quality of dissolved organic matter (DOM) may have an additional influence on arsenic (As) mobilization in reducing groundwater. [1] For example, humic substances, a major part of the DOM pool, are known electron shuttles that may also be involved in metal complexation (Figure 1). We used UV-vis absorbance and novel fluorescence techniques to characterize DOM in groundwater with dissolved As concentrations ranging from 2 to >400 µg/L and spanning a wide spatial extent in Araihazar, Bangladesh. For a subset of wells, we also determined % fulvic acid and performed elemental and ^{13}C-NMR analyses on fulvic acid isolates.

Our results consistently showed that terrestrially-derived aromatic organic compounds with low protein-like character were found where dissolved As concentrations are elevated. Moreover, the lowest As concentrations were found in village wells that had sewage pollution-derived DOM signatures. Together with highly significant relationships between arsenic and aromaticity and fluorescence of the fulvic acid isolates, our results provide strong evidence that humic substances have an important role in arsenic mobilization and potentially its maintenance in solution (Figure 1).

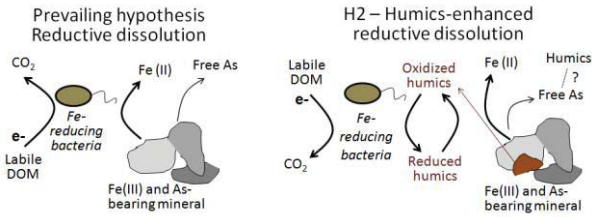

Figure 1: Conceptual diagram showing the "reductive dissolution" hypothesis (left) and an expanded "humics-enhanced reductive dissolution" hypothesis (H2; right) in which labile DOM and reactive DOM (including humic quinones) serve to donate and shuttle electrons, and are involved in complexation reactions. Sedimentary organic matter sources of labile and reactive DOM shown in brown.

Petrography and composition of iron formation from the ca. 3.8 Ga Nulliak Supracrustal Association (northern Labrador, Canada)

ALEKSANDRA M. MLOSZEWSKA[*1]; RASMUS HAUGAARD[1]; KURT O. KONHAUSER[1]

[1]Earth and Atmospheric Sciences, University of Alberta, Edmonton, Canada, mloszews@ualberta.ca (*corresponding author)

Banded iron formations (BIFs) are important sources of information on the composition of ancient seawater [1,2]. Eoarchean BIFs in particular may disclose information on the nutrient levels bracketing the evolution of early microbial metallo-enzymes. Only a limited amount of pre-3.6 Ga year old BIFs are know, and chemical sediments from the ca. 3.8 Ga year old Nulliak Supracrustal Association of northern Labrador (Canada) [3] offer an exciting opportunity to expand our data base.

We present new petrographic and geochemical data on these Fe- and Si-facies iron formations, by integrating geochemical relationships observed between minerals in thin section and whole rock chemistry. This approach provides an important framework for studying the chemical variations in these sediments, on several scales. Preliminary results show that the Nulliak sediments are relatively aluminous (Al_2O_3>1 wt%), with correspondingly high abundances of Zr (up to 20 ppm) and other high-field strenght elements (e.g., Nb, Hf), suggesting a non-trivial detrital component. These chemical sediments contain noteworthy abundances of Cr, Ni, Zn, Sr, and Ba, while other elements tend to be <25 ppm. The high Ni and Zn abundances correlate well with previous studies on Eoarchean-aged iron formations, suggesting that these metals were found globally in high concentrations during the Eoarchean [3,4]. Rare earth element and yttrium profiles tend to show seawater-like anomalies (LREE<MREE<HREE; positive La and Eu anomalies, and superchondritic Y/Ho ratios) despite granulite-facies metamorphic overprinting. Collectively, these findings indicate that at least some of the original seawater signature has been preserved. Neverthless, these sediments may not be an accurate seawater proxy, as detrital material tends to obscure seawater signals. Instead, they may provide a measure of balanace between hydrothermal- and terrestrial inputs affecting the composition of Eoarchean seawater composition as reflected in BIFs.

GOLIATH: A systems biology, geochemical and physiological approach to discern microbial transformations of Mercury and Methylmercury.

JAMES G. MOBERLY[1], CARRIE L. MILLER[1], RICHARD A. HURT, JR, STEVEN D. BROWN[1], SCOTT C. BROOKS[1], CRAIG C. BRANDT[1], MIRCEA PODAR[1], ANTHONY V. PALUMBO[1], DWAYNE A. ELIAS[1*]

[1]Oak Ridge National Laboratory, Oak Ridge, USA, eliasda@ornl.gov (* presenting author)

BACKGROUND: Mercury (Hg) contamination is a global concern. Hg methylation is an important biogeochemical process, which generates the potent neurotoxin monomethylmercury (MeHg). Net MeHg production in aquatic ecosystems is linked to environmental and geochemical parameters along with electron donor and acceptor availability. Recently we found that methylating communities contained high populations of Desulfobulbus and Geobacter spp. To gain a deeper understanding of the microbial community populations invlolved in, and geochemical influences on, Hg methylation, physiological and meta-omic analyses were performed. **METHODS**: Intact sediment cores from two methylating sites (NOAA, upstream; New Horizon, downstream) and a background site were collected and used to construct sediment microcosms from different depths with 6 different carbon/electron sources. All microcosms were spiked with Hg stable isotope tracers to enable quantification of both Hg methylation and MeHg demethylation and incubated under anaerobic conditions in the dark for 48 hours at room temperature. DNA from the original core material and incubations were hybridized to functional gene arrays and sequenced via 454 16S rRNA gene pyrosequencing. **RESULTS**: Functional gene array results revealed a greater relative abundance of Hg(II)-reduction genes at NOAA while actual methylation was higher downstream at New Horizon. Each of the latter two sites displayed ~15X more methylation than the background site. Upstream at NOAA, methylation was moderately stimulated by methanol and ethanol but not by acetate, lactate, propionate or cellobiose, while downstream at New Horizon cellobiose stimulated methylation relative to unamended controls. Meta -genomic, -transcriptomic, and -proteomic analyses as well as 454 pyrosequencing are currently underway. **CONCLUSIONS**: The multidisciplinary combination of the above approaches are being employed together for the first time in order to more comprehensively ascertain the influence of geochemistry on the microorganisms, genes, and gene products that are differentially present, abundant and expressed in active MeHg generating ecosystems.

The magmatic and metasomatic formation of zircon in the Nechalacho deposit at Thor Lake, Northwest Territories, Canada

VOLKER MÖLLER[1*], ANTHONY E. WILLIAMS-JONES[1]

[1]McGill University, Earth and Planetary Sciences, Montreal, Canada, volker.moeller@mail.mcgill.ca (* presenting author)

The Nechalacho Rare Metal Deposit represents a world-class resource of REE, Y, Nb, Ta, Zr and Ga. Two densely mineralized horizons are hosted in intensely altered rocks of the upper part of the Nechalacho Layered Syenite Suite. These evolved, fluorine-rich peralkaline rocks are dominated by acmite, annite, sodalite, nepheline and feldspars. Primary REE- and HFSE-minerals include eudialyte, zircon, pyrochlore, britholite and Na-zircono-silicates. During alteration, eudialyte syenites were converted to an assemblage of zircon, quartz, magnetite and phlogopite. Secondary REE- and HFSE-bearing phases in the two REE-mineralized horizons comprise zircon, fergusonite, allanite-(Ce), bastnäsite-(Ce), synchisite-(Ce), parisite-(Ce), monazite and columbite[1].

The average whole rock content of ZrO_2 ranges from 2 to 3 wt. % and locally exceeds 10 wt. % in the deposit, making zircon an important rock-forming mineral. Three textural types of this mineral have been recognized: 1. rare magmatic phenocrysts in fresh or partially altered syenite; 2. quartz-hosted euhedral zoned crystals in the upper mineralized zone; 3. unzoned subhedral crystals intergrown with quartz in pseudomorphs after eudialyte in the lower mineralized zone.

Based on new Laser ICP-MS and electron microprobe data, magmatic zircon has a low trace element content (e.g., 80 to 6500 ppm REE) and displays heavy REE-enriched, near-linear chondrite-normalized profiles with strong positive Ce and negative Eu anomalies (avg. Ce/Ce*=3.4, avg. Eu/Eu*=0.44). Secondary type 2 and 3 zircon varies widely in composition, is strongly enriched in REE, Y, Nb and F, has elevated P and displays non-linear chondrite-normalized REE profiles with weak or absent Ce anomalies and strong Eu anomalies. Type 2 zircon has an average content of 2.3 wt. % REE, 1.1 wt. % Y and 1.3 wt. % Nb, has light and heavy REE enriched rims and cores respectively and contains significant fluorine. Relict magmatic cores and rims in the upper zone are distinguished by their low REE-contents and positive Ce anomalies which are comparable to type 1 zircon. Secondary zircon in the lower zone (Type 3) is strongly enriched in heavy REE and contains 2.8 wt. % REE, 1.7 wt. % Y and 1.6 wt. % Nb on average.

The HFSE mineralogy suggests that miaskitic and agpaitic rocks occurred in close spatial association. Metasomatic-hydrothermal replacement of both magmatic zircon and zircono-silicates was important for the formation of REE-enriched varieties of zircon. A possible mechanisms for the incorporation of such high levels of the REE is the formation of hydrated varieties at the alteration stage.

Deglacial forcing of rapid deoxygenation and seafloor ecological change, Santa Barbara Basin, CA

SARAH E. MOFFITT[1*], TESSA M. HILL[2]

[1]University of California at Davis, Bodega Marine Laboratory, Bodega, smyhre@ucdavis.edu (* presenting author)

[2]University of California at Davis, Bodega Marine Laboratory, Bodega, tmhill@ucdavis.edu

Background

Deglacial sediment from Santa Barbara Basin (SBB) are high-resolution records of regional climate, intermediate and surface water processes, and benthic ecology. Patterns of bottom water oxygenation in sediment records, and thus the presence of Oxygen Minimum Zones (OMZs), can be reconstructed by proxy using the oxygenation and environmental tolerances of modern taxa. We construct a record of deglacial community ecology, intermediate water oxygenation and coastal oceanography for SBB (34° 15'N, 119° 45'W) using a core from the northwestern basin slope at 418 m water depth (MV0811-15JC).

Results

The 9.2m core, which spans 4-16ky, is completely bioturbated. Significant faunal community deoxygenation horizons are evident at deglacial Termination 1A (~14.5 ky) and 1B (~10.9 ky), demarcated by the loss of ostracod, mollusc and brittle star fossils. The faunal record has high-resolution structure across taxa groups, indicating that stressful hypoxic events occur very rapidly at this depth. Results indicate the capacity for both rapid and sustained expansion of OMZs, the gradation of biological responses, and the spatial oceanographic processes that impact oxygenation across the coastal basin feature through the deglaciation.

Figure 1: Spetangoid heart urchin fossills in deglacial marine sediment, Santa Barbara Basin, CA. Note the biological orientation of the respiratory structures, indicating preservation at the time of death.

Assessing the role of Holocene sapropels on the Black Sea methane cycle

JOSÉ M. MOGOLLÓN [1*], SABINE KASTEN[1]

[1]Alfred Wegener Institute for Polar and Marine Research, Jose.Mogollon@awi.de (* presenting author) Sabine.Kasten@awi.de

Sapropels, sedimentary intervals rich in organic matter, represent a substantial carbon source which directly affects the sedimentary redox conditions in marine sediments. While recently-deposited sapropels produce a shoaling of the redox zonation, the long term effect of sapropelic sediments once these become buried over several millennia and lose their most labile carbon fraction requires further addressing. In the northern Black Sea, the changing limnic to marine conditions due to the flooding of the Bosphorous straight and subsequent connection with the Mediterranean Sea circa 9.5 kyr before present (BP), led to local geochemical conditions which favored ocean stratification and an increase in the amount of organic matter reaching the sediment between 8.0 and 3.5 kyr BP. Through reactive transport models which focus on the methane cycle, we track the geochemical effects of the sapropel since its initial deposition up to present time. Our results reveal that, from the onset of their deposition, sapropels heavily influence the methane cycle by controlling the position of the sulfate-methane transition (SMT) through organoclastic sulfate reduction. Nevertheless, the influence of the sapropels on methanogenesis will ultimately depend on the time required for the sapropel to be buried below the SMT. Consequently, methane formation will be favored in locations with high sedimentation rates, or locations receiving turbidites and slumps, such that the sapropel can be quickly buried into the methanogenic zone.

Determining thiotungstate stability constants for low temperature, low ionic strength aqueous solutions

T. J. Mohajerin[1*] & K. H. Johannesson[2]

[1] Tulane University, New Orleans, USA, thaug@tulane.edu (* presenting author)

[2] Tulane University, New Orleans, USA, kjohanne@tulane.edu

Abstract

Due to recent findings that suggest childhood leukemia may be linked to exposure to tungsten in drinking water, a need has arisen to better understand geochemical reactions affecting W concentrations and speciation in groundwater flow systems. Preliminary data show that W has a strong and statistically significant positive correlation ($p \leq 0.001$) with dissolved sulfide [i.e., S (-II)] concentration ($r = 0.95$) in the Carrizo Sand aquifer where groundwaters become anoxic. We hypothesize that like Mo [1], W may form thiotungstate complexes in sulfidic groundwaters. In sulfidic waters the general form of the thiotungstate forming reaction is:

$$WO_xS_{4-x}^{2-} + H_2S \leftrightarrow WO_{x-1}S_{5-x}^{2-} + H_2O$$

where x is 0 – 4, and the concentration product, Q, which is used to obtain the conditional equilibrium constants, is given as:

$$Q = [WO_{x-1}S_{5-x}^{2-}]/\{[WO_xS_{4-x}^{2-}][H_2S]\}.$$

To better understand the geochemical behavior of thiotungstates, we are measuring the stability constants for these species in dilute, aqueous solutions. As the thiotungstate forming reaction occurs, sulfur replaces oxygen in the tungstate oxyanion. Changes in solution composition are measured by periodic scanning of the absorption spectrum (200 nm $\leq \lambda \leq$ 450 nm) by UV/Vis spectrophotometry. As shown in Figure 1, the wavelegth pattern changes with time as different thiotungstate species are produced. Using the absorbsion coefficients and absorption at the maximum spectra for each thiotungstate species, Beer's Law is employed to calculate the concentration of each thiotungstate species, from which Q for each reaction can be determined. The stability constants are then calculated from Q using a modified Debye-Hükel equation. Determination of the stability constants of each of thiotungstate species is then used in a geochemical model to predict their importance in groundwater systems. Preliminary data are presented for the stability constants of the thiotungstate complexes in dilute aqueous solutions.

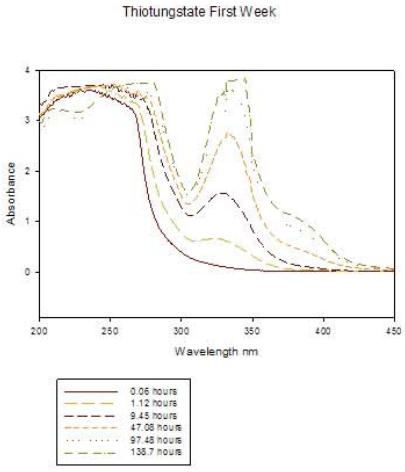

Figure 1: Spectral changes occurring during the time interval when WO_4^{2-} changes to WO_3S^{2-}, and is beginning to form $WO_2S_2^{2-}$

Investigating geochemistry and the stable isotope ($\delta^{18}O$ & $\delta^{2}H$) composition of Karde Carbonate lake water (NE Iran)

MOHAMMADZADEH HOSSEIN [1], MOJTABA HEYDARIZAD[2]

[1] Groundwater Research Center (GRC), Ferdowsi University of Mashhad, Mashhad, Iran, mohammadzadeh@um.ac.ir (* presenting author)

[2] Ferdowsi University of Mashhad, Department of geology, amour_elle_86@yahoo.com

Introduction

Karde dam's lake is a carbonate-precipitating and diamictic lake, which supplies irrigation and potable water for more than 4 million inhabitant of Mashhad city (NE Iran). In the following survey, Vertical (five depths 1, 5, 10, 15, 20) and temporal distribution of major cations and anions (especially nitrogen) in lakes water are investigated during 15 months (Jan 2010 to June 2011).

Results

The Calcite, Dolomite and Aragonite saturation index of lakes water and evaluation of Na, Mg, Ca concentration in lake, local ground water and rock samples in ternary diagram indicate that Na, Ca and Mg concentrations are mainly governed by incongruent dissolution of local carbonate (Mozdooran formation) and silicate (Neogen red formation).

Identification of dissolved minerals with ion activity (a) and $Log(aCa^{2+}/a(H^{+})^{2})$ versus $Log(aMg^{2+}/a(H^{+})^{2})$ graph for Carbonate minerals and $Log(aMg^{2+}/a(H^{+})^{2})$ and $Log(aCa^{2+}/a(H^{+})^{2})$ versus $Log(aNa^{+}/a(H^{+})^{2})$ for silicate minerals show that carbonate minerals "Calcite and Dolomite" and silicate minerals "Kaolinite, Laumontite and Clinochlore" are the dominate dissolved minerals within dam lake water. Vertical distribution of N in lake water shows significant increasing in NH_4^+ and NO_2^- concentrations with depth when the NO_3^- concentration decreases. Principal Component Analysis (PCA) of hydrochemical analyses revealed 3 components which explain 67% of the variance observed. In the first component, strong relationship between EC, TDS, Mg^{2+}, HCO_3^- and hardness reflect carbonate weathering. The variables in the second component are NH_3, NH_4^+, dissolved oxygen and depth. All the variables are directly related except dissolved oxygen which has inverse relationship with this component. This factor represents high Organic production in Karde dams' lake water. The third component shows relationships in the concentrations of Na^+, Ca^{2+}, SO_4^{2-} indicating the weathering of evaporative minerals especially gypsum ($CaSO_4$) and Glabuer's salt (Na_2SO_4) in the upper hand basin.

In the classical plot of $\delta^{18}O$ vs $\delta^{2}H$, the isotopic signature of lake water samples (-6.82‰, -48.3‰) plot further to (LMWL) comparing to the local ground water (-8.21‰, -57.5‰) and upstream river (-8.7‰,-61.8‰) which appear to be controlled by evaporation loss of the lake water.

With a view toward establishing a deep geological repository for low- and intermediate-level radioactive waste, a geoscientific site characterization program has been conducted on the eastern margin of the Michigan Basin at the Bruce nuclear site. Drilling and collection of cores within an ~ 860 m near-horizontally layered Paleozoic sedimentary sequence, resting atop the Precambrian basement, has provided an opportunity for porewater and groundwater sampling and analysis with an unprecedented level of detail. This abstract presents a methodology for estimating diffusion coefficients for He in low permeability sedimentary rocks obtained from the drilling.

Drill core samples (76 mm diameter) of Ordovician shale and limestone were preserved in the field inside N_2-purged and vacuum-sealed bags; first polyethylene and then aluminized polyethylene. The samples were transported to the University of Ottawa where a sub core (6 mm diameter and ~ 20 mm long) was removed from the centre of the larger core and encapsulated in a stainless steel container at 1×10^{-2} Torr. Gas accumulating in the head space by room temperature (20 °C) diffusion was periodically sampled for He and Ne isotopic measurements using a MAP L 215-50 Noble Gas Mass Spectrometer. A typical experiment involved 5 gas measurements over a period of 24 hr. The measured He was corrected for air contamination using accompanying ^{20}Ne data. The time-series of He concentrations in the head space are treated as an out-diffusion experiment and numerical simulations were conducted to estimate the He diffusion coefficients by matching simulated out-diffusion profiles to the measured data. Simulations were conducted by running the reactive transport model MIN3P under the control of the parameter estimation code, PEST.

In general, there is a good match between the measured He data and the simulations (Fig. 1); D_p values ranging from 1 to 4 × 10^{-11} m^2/s. However, samples from a 70 m interval that straddles the Blue Mountain Formation shale and the underlying Cobourg Formation limestone are an exception. This is a zone with high organic carbon content and the He release profiles suggest a delayed release of He – perhaps due to out gassing from an organic or petroleum phase.

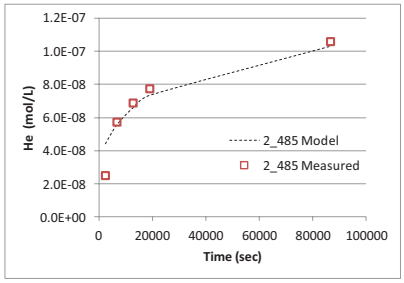

Figure 1. Example of He out diffusion showing measured He concentrations in the stainless steel container head space (open squares) and simulated out-diffusion profile indicating $D_p = 3.2 \times 10^{-11}$ m^2/s.

Paleo-environmental reconstruction of mercury and terrigenous organic matter dynamics in large Northern Quebec boreal lakes: an assessment of anthropogenic activities occuring in their watersheds

MATTHIEU MOINGT[1]*, MARC LUCOTTE[1], SERGE PAQUET[1], AND BASSAM GHALEB[1]

[1]GEOTOP-UQAM, Montréal, H3C 3P8, Canada
matthieumoingt@yahoo.fr (* presenting author)
lucotte.marc_michel@uqam.ca
paquet.serge@uqam.ca
ghaleb.bassam@uqam.ca

Mercury dynamics in boreal lakes is of special concern as human populations may be exposed to the contaminant through fish consumption.To evaluate the impact of watershed pertubations on the mercury dynamics in boreal aquatic systems, we studied sediment cores retrieved in six large boreal lakes of Québec (Canada) with watersheds disturbed by anthropogenic activities such as logging or mining activities, and in two undisturbed lakes chosen as reference lakes. Sediment rates were estimated by ^{210}Pb dating and range from 0.03 to 0.33 cm/yr. Total mercury (THg) contents and lignin biomarkers (refering to both quantity and quality of terrestrial organic matter (TOM)) were measured in all eight cores whereas watershed modifications over a 30 year period were determined by analysis of remotely sensed images using GIS. In all cores, THg concentrations significantly increased over recent years with maximum values comprised between 70 and 370 ng/g, the lowest THg contents being observed in reference lake cores. Anthropogenic Sedimentary Enrichment Factor (ASEF) is comprised between 2 and 15 and surprisingly, not all the lakes with disturbed watersheds present an ASEF superior to the value of 3.5 usually reported in the literature [1]. Our results allowed us to emphasize the importance of mean slope inclination, repartition of slopes in classes and vegetation cover in the drainage area on Hg fluxes reaching lake sediments. Results from this study suggest that in large boreal lakes ecosystems, the size and the characteristics (e.g. nature of the vegetation cover, mean slope) can promote the uptake of atmospheric Hg leading to enahanced presence of THg in sediments. Then, supplementary Hg transfers from the watershed to the aquatic systems due to anthropogenic activities (e.g. logging and mining activities) can be masked in sedimentary profiles. This study also underlines the importance of TOM as vector of Hg since sedimentary Hg enrichment appears proportional to the amount of TOM coming from the watershed.

Introduction

Cave sediments preserve the geological and paleoenvironmental past as well as biological and anthropological information, important for the terrestrial continental history, where correlative sediments are mostly missing [1]. Our studies are first attempts to use fossil invertebrates from cave sediments as proxy in paleoclimate studies. Microbiological studies have been added to explain the processes of preservation.

Results

Six caves (S-E Europe) provided fossil invertebrates, mostly mites, springtails and ostracods, originating from the surface environments. All these groups are excellent as paleoecological bioindicators and were identified in Pliocene-Pleistocene sediments (Fig. 1). Their presence has been correlated with other proxies and provided reliable information about the type of vegetation on the surface and the deposition condition inside caves. Microorganisms isolated from the sediments were extremely scarce, with differences in the amount of bacteria or fungi.

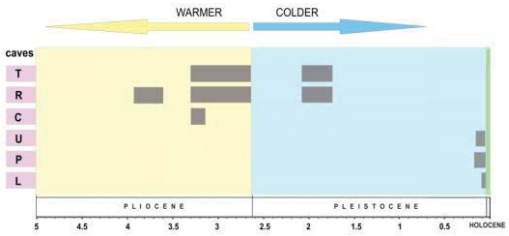

Figure 1: Invertebrate fossils found in the studied caves.

Conclusion

The depositional mechanisms and the low intensity of biochemical processes can explain the relatively good state of preservation of old invertebrate remains both in the cave sediments and Arctic lake sediments [2]. Considering the age of sediments, the state of preservation is relatively good. This may suggests a combination of: (1) a relatively short and slow transport to the site of deposition, (2) a rapid burial, i.e. a high sedimentation rate, and (3) subdued microbial and biochemical processes that could have altered the entire organisms. The difference we found in the concentration of bacteria or fungi, at different sediment levels, can also be correlated with dry/wet periods [3] and the work is still in progress.

Investigation of coupled flow and geochemical reactions at the pore scale by direct numerical simulation

S. MOLINS [1*], C. SHEN[2], D. SILIN[1], C.I. STEEFEL[1] AND D. TREBOTICH[2]

[1]Lawrence Berkeley National Laboratory, Earth Sciences Division, Berkeley, USA, SMolins@lbl.gov (* presenting author)

Prediction of chemical fate and transport in subsurface environments often relies on reaction rate constants applicable to each grid block of continuum-scale numerical models. Typically, laboratory-determined reaction rates are applicable to a scale smaller than that resolved by the continuum-scale models. Upscaling of these rates to a grid block is possible under certain conditions; otherwise, microscopic and macroscopic scales need be considered simultaneously (e.g. [1], [2]). This is often the case in carbon sequestration or remediation applications where the subsurface geochemical system is driven to far-from-equilibrium conditions in relatively short time scales, which result in short characteristic length scales. In addition, induced geochemical reactions such as mineral precipitation and dissolution can modify the geometry and structure of porous media, which further affects the macroscopic reactions rates.

Direct numerical simulation techniques in which the Navier-Stokes or Stokes equations are solved using conventional methods (e.g. finite volume, differences) allow for incorporation of complex multicomponent reaction networks into pore scale models. We employ pore scale modeling based on direct numerical simulation of flow and multicomponent reactive transport to investigate the two-way coupling between precipitation-dissolution reactions and flow. We focus on calcite dissolution-precipitation as system of environmental relevance. We observe that non-uniformity in the flow field at the pore scale decreases the overall reactivity of the system in equivalent continuum-scale systems. The effect becomes more pronounced as the heterogeneity of the reactive grain packing increases, particularly where the flow slows sufficiently such that the solution approaches equilibrium locally and the average rate becomes transport-limited.

Simulations show that dissolution and precipitation reactions affect the pore space non-uniformly. As a result, a simple porosity-permeability correlation may be insufficient to describe the complexity of the reaction-induced pore space evolution. The relative magnitude of the reaction rate constants affects the evolution of the permeability-porosity relationship. In dissolution simulations, fast reactions result in localized effects and further evolution of permeability is relatively unaffected by subsequent porosity increase. In contrast, slow reactions cause a less localized dissolution, with the result that the permeability increase is consistent with the porosity increment.

The most well-established organic-geochemical SST proxy index $U^{K'}_{37}$ based on haptophyte produced long-chain ketones (alkenones) has been shown to yield robust estimates of annual mean SSTs but may be more problematic in high productivity eastern boundary upwelling areas. In the last decade, two types of new organic geochemical SST proxies, i.e., the TEX_{86} index based on archaeal glycerol dialcyl glycerol tetraether (GDGTs) and two indices based on long-chain diols derived from diatoms (DCI) and eustigmatophytes (LDI) have been proposed. Those proxies have been suggested to be applicable in settings where the alkenones are less reliable or absent. On the other hand, each of the new indices has its own caveats. These include, but are not limited to: 1) the fact that GDGT producing archaea thrive throughout the water column and perhaps also in the sediment; 2) limited understanding of the physiological role of the respective lipids in their precursor organisms; 3) incomplete understanding of the export mechanismns responsible for the transport of lipids from the depth of production to the sediments; 4) concerns regarding differential degradation of individual lipids.

Here we address several of these questions using sediment trap samples collected at 1-2 week intervals between June 2003 and March 2007. The trap was moored off Cape Blanc in an area strongly influenced by seasonal coastal upwelling. We measured $U^{K'}_{37}$, TEX_{86}, and the diol indices as well as concentrations and fluxes of the respective lipids. The results are compared with total, carbonate, opal and organic matter fluxes as well as diatom abundances. For all indices, we observe pronounced seasonal cycles, while flux-weighted averages agree well with values measured in underlying surface sediments. Reconstructed SSTs based on $U^{K'}_{37}$ and TEX_{86} correspond generally well with satellite measured SSTs but reveal that $U^{K'}_{37}$ is more uncertain during periods of highest productivity. The DCI shows a well pronounced but reverse relationship with SST than originally proposed. Fluxes of all lipids are closely tied to total fluxes, implying that ballasting is an important mechanism. Delays between observed and reconstructed SST maxima are within the expected range for alkenones and larger but similar for GDGTs and diols, implying that these lipids are predominantly exported as diatom-rich aggregates known to sink at lower velocities than carbonate containing aggregates. We find no evidence for substantial sub-surface export of GDGTs.

Investigating Silver Nanoparticle Transport in Soil via Synchrotron X-Ray Microtomography

IAN L. MOLNAR[1*], DENIS M. O'CARROLL[1], JASON I. GERHARD[1] AND CLINTON S. WILLSON[2]

[1]University of Western Ontario, London, Canada, imolnar@uwo.ca (*presenting author)

[2] Louisiana State University, Baton Rouge, U.S.A., cwillson@lsu.edu

The rapidly increasing production and use of nanoparticles carries with it a risk of their release into the subsurface environment, contaminating aquifers that are either used for municipal drinking water or discharge into surface water bodies. To consider their risk, it is necessary to understand nanoparticles' fate in the subsurface. However, nanoparticle transport in the subsurface environment remains poorly understood and developed relationships are specific to the imposed experimental conditions and particle type. This research aims to improve our ability to non-destructively measure pore-level concentrations and distribution of nanoparticles in an effort to better understand the soil - nanoparticle interactions and role of pore geometry.

Synchrotron x-ray computed microtomography (SXCMT) is widely used for imaging soil and rock cores and fluids occupying their pore space. The high resolution, three-dimensional, quasi-real time datasets output by SXCMT are capable of accurately quantifying silver nanoparticle concentrations within a porous media. These datasets can provide valuable information about silver nanoparticle distribution throughout the pore-network and even within each individual pore. This presentation will: outline an SXCMT method for imaging and quantifying aqueous silver nanoparticle solutions in porous media, present and analyze and number of time-lapse images of silver nanoparticles invading and evacuating a variety of water saturated soil types and examine the role of intra and inter-pore geometry on nanoparticle transport and deposition.

Targeting sites for exploration for precious metal mineralization in the Guanajuato district, Mexico using petrography and fluid inclusions

D. MONCADA* AND R.J. BODNAR

Department of Geosciences, Virginia Tech, Blacksburg, VA 24061 USA, moncada@vt.edu (*presenting author)

The search for mineral deposits is a time consuming, risky and very expensive process. Any technique that can help the explorationist to quickly and inexpensively discriminate between areas with high potential for economic mineralization and those with lower potential provides a competitive advantage to those applying the technology. In this study, we describe a technique based on petrography of gangue minerals and fluid inclusion characteristics that may be applied in exploration for precious metal deposits to identify targets from surface, drill holes and underground workings.

The Guanajuato mining district in Mexico was discovered 1548. This initial discovery was in the la Luz area with major northwest trending vein systems. The mining in the area has been continuous and recent exploration programs to search for new targets have been successful. Mineralization in veins show variability, from gold-rich to silver-rich, in going from west to east. Ore textures also vary and include void space that formed during multiple fissuring events, banded quartz veins, vuggy quartz, lattice bladed calcite, lattice bladed calcite replaced by quartz, massive quartz veins and stockworks with adularia and sericite/illite. More than 200 samples from nine veins representing all different styles of mineralization were collected from the La Luz system, and the mineral textures and fluid inclusion characteristics of each sample have been defined. In addition, each sample was assayed for Au, Ag, Cu, Pb, Zn, As and Sb. Some drill holes were assayed for 34 elements.

Samples from the La Luz system show a wide range in silica textures. The veins that have been studied show a range in textures, including colloform, plumose and jigsaw texture, quartz that are all indicative of rapid precipitation, such as occurs when fluids boil. Other mineral phases, including illite, adularia and bladed calcite are also indicative of rapid growth in a hydrothermal system and are characteristic of boiling systems. Because boiling is an effective mechanism for precipitating gold and silver from hydrothermal fluids, the presence of mineral textures indicative of boiling is a desirable feature in exploration. In many samples, textural evidence for boiling is supported by coexisting liquid-rich and vapor-rich fluid inclusions, or Fluid Inclusion Assemblages consisting of only vapor-rich inclusions, suggesting "flashing" of the hydrothermal fluids. Several traverses along outcrop on the surface and perpendicular to the veins show that samples collected from within 25 m of the main veins show increasing precious metal abundances that correlate with an increase in features that indicate boiling. Drill core samples show the same behavior, with evidence of boiling increasing within 0 to 5 m of where precious metal abundances increase. This approach helps to establish new targets for detail exploration. Importantly, textural and fluid inclusion evidence for boiling has been observed in the deepest levels of the La Luz system, suggesting that additional precious metal resources may occur beneath these levels.

Mineralogical and geochemical processes occurring in sulfide-rich tailings after 60 years of subaqueous storage

[3]Present Address: Earth and Ocean Sciences, University of British Columbia, Vancouver, BC, Canada mlindsay@eos.ubc.ca

The oxidation of sulfide minerals in subaerial tailings deposits generates acid and releases sulfate and metals to pore water. Subaqueous disposal of tailings is a common method for limiting sulfide-mineral oxidation. Numerous short-term studies have demonstrated that shallow water covers are effective at limiting oxygen diffusion to submerged tailings; however, long-term studies are lacking. The former Sherritt-Gordon Zn-Cu mine, located in Sherridon, Manitoba, Canada, deposited sulfide-rich tailings into Fox Lake during 1951. The tailings formed a number of small exposed islands with the majority of material submerged underwater, extending outward into the Lake. Exposed tailings were visually oxidized and submerged tailings commonly were overlain by naturally-established vegetation. Surface water, porewater and core samples were collected in 2001 and 2009 to examine long-term biogeochemistry of land-deposited tailings and the submerged tailings under approximately 1 m of water.

Mineralogical examination of the land-deposited tailings showed a well-defined, ochreous oxidation zone that extended from surface to about 40 cm depth. The interval from 40 to 60 cm was a transitional or intermediate zone of much weaker oxidation, and at depths >60 cm sulfide minerals in the tailings were not altered. In contrast to the thickness of the oxidation zone in the land-based tailings, the equivalent zone in the submerged tailings extended <6 cm below the water-solids interface. Porewater collected from the land-based tailings was characterized by low pH, depleted alkalinity and elevated concentrations of dissolved sulfate and metals. Microbial communities within these tailings were dominated by neutrophilic sulfur oxidizing bacteria. Conversely, the natural colonization of vegetation over the subaqueous tailings resulted in the development of strong reducing conditions evident from circumneutral pH conditions, low concentrations of dissolved sulfate and metals, H_2S production and strong $\delta^{34}S_{SO4}$ and $\delta^{13}S_{DIC}$ fractionation indicating microbially-mediated (dissimilatory) sulfate reduction. Within the submerged tailings, secondary marcasite was observed in the relic ochreous zone occurring as coatings on primary minerals. This observation indicates that, following a period of oxidation, metals were subsequently sequestered from solution in this zone. This finding further emphasizes the influence of reducing conditions and microbial activity on metal mobility within mine tailings. Results from this study provide insight for the submergence of sulfide-rich tailings under a shallow water cover as a viable method for long-term storage.

Isotopic fractionation of U(VI) during reduction by sulphide

NIKHIL MONGA[1*], STEPHEN J. ROMANIELLO[1], AND ARIEL D. ANBAR[1,2]

[1]School of Earth and Space Exploration, Arizona State University, Tempe, AZ, USA, nikhil.monga@asu.edu (* presenting author)

[2] Department of Chemistry & Biochemistry, Arizona State University, Tempe, AZ, USA, anbar@asu.edu

Understanding isotopic fractionation of $^{238}U/^{235}U$ between soluble U(VI) and insoluble U(IV) is useful in various ways, from undersanding the geochemistry of U to its use as a paleoredox proxy [1]. In the environment, deposits of uranium formed by low temperature redox processes (e.g. black shales, roll front deposits) are observed to be isotopically heavy compared to the fluid from which they precipitated by 0.4-1.0‰ (e.g. the $^{238}U/^{235}U$ of the Black Sea sediments is consistantly heavier than the overlying water column) [1,2,3]. This idea is consistent with theoretical calculations which predict that U^{4+} should be heavier than UO_2^{2+} by 1.3‰, primarily due to nuclear volume effects [4,5]. Despite the prevelance of this effect in nature, it has been suprisingly difficult to produce isotopically-heavy reduced U phases experimentally. Two independent studies have shown that the reduction of U(VI) using zero-valent Zn and Fe produces no isotopic fractionation [2,6]. In experiments with two different cultures of U-reducing bacteria, researchers found that the reduced phase was isotopically light by 0.31-0.34‰, opposite of observations in the environment.

Motivated by this discrepancy and reasoning that sulfide is a common and abundant reductant in environmental settings, we set up experiments to measure isotopic fractionation during abiotic U reduction by sulfide. We reduced a 4 ppm U(VI)-CO_3 solution in the presence of 2.1 mM sulfide and 4.11 mM bicarbonate, maintained at a pH of 6.8 using a TRIS/HCO_3 buffer under a UHP He atmosphere [7]. At regular time intervals, the solution containing the soluble U(VI) and a suspended insoluble precipitate, presumably U(IV) in the form of uraninite [7], was sampled using a syringe and rapidly separated using syringe filtration.

Our initial results are well-described by a Rayleigh model and indicate that the reduced uranium phase is lighter than the solution by 0.189±0.097‰ (α = 0.999811±0.000097, 2σ). This effect is opposite that observed in nature but similar to results observed for U-reducing bacterial cultures. Since all laboratory experiments so far produce moderately light or unfractionated reduced U, it is possible that isotopic equilibration of U(VI)⇌U(IV) is not achieved on laboratory timescales. Alternatively, the chemical details of the lab experiments may differ from natural systems and theoretical models in some key respect. For example, U speciation may have a large effect, or other reactions, such as U adsorption, could occur.

Growth of nanostructured calcite under hydrothermal conditions in presence of organic and inorganic selenium

G. MONTES-HERNANDEZ[1*], G. SARRET[1], R. HELLMANN[1], L. CHARLET[1], F. RENARD[1]

[1]Institut des Sciences de la Terre (ISTerre), OSUG/CNRS, UJF, BP 53X, 38041 Grenoble, France

Abstract

Selenium is an important trace metalloid, whose global cycle is controlled by fluid-rock interactions in the Earth's upper crust, interactions with bio-molecules in soils and living systems, and atmospheric transport in ashes. The cycling of selenium is often intimately associated with carbonate phases, with Se being generally incorporated as an impurity in calcite crystals or adsorbed on carbonate nanoparticles. In order to better understand the interaction of aqueous selenium species with carbonates, we studied the precipitation of calcite under hydrothermal conditions (30-90°C, 25-90 bar) in a CO_2-H_2O-$Ca(OH)_2$ medium in the presence of aqueous inorganic and organic selenium compounds. Aqueous carbonation reactions in the presence of selenium at elevated temperatures and pressures, relevant for long-term CO_2 sequestration in reservoirs and other natural geological systems, have until now not been investigated to the best of our knowledge. Macroscopic measurements, Electron microscopy (FESEM and TEM) and synchrotron X-ray absorption spectroscopy (XAS) were used in a complementary manner to investigate kinetic effect of Se, crystal size, structural order (crystallinity), morphology of crystal faces, crystal organization, and selenium speciation in the calcite samples. XAS data analysis showed clear evidence for the incorporation of selenite oxyanion (SeO_3^{2-}) into the calcite crystal structure. At low Se content (1.3 mg/g calcite), a single site was observed with Se surrounded by six Ca atoms, whereas additional sites, probably corresponding to surface sorption sites, were found with increasing Se content. XAS also showed that seleno-L-cystine (Secys) was chemically fragmented during carbonation, and the solid phase contained elemental and oxidized Se, in hexagonal or amorphous form depending on the experimental conditions, with a minor proportion of Se(IV). Moreover, FESEM and TEM measurements revealed a very complex effect of Secys on the particle size and aggregation/agglomeration process, leading to the following calcite morphologies: rhombohedra, elongated rhombohedra (*c*-axis elongation), scalenohedra, star-like and shell-like crystal aggregates, and irregular calcite polycrystals. The aggregates and irregular polycrystals, which we designate as nanostructured calcite material, were constituted of nanometer-sized calcite crystallites (<100nm). The star and shell-like crystal aggregates, which were observed only in the presence of Secys, may be due to crystal growth in the presence of associated secondary organic compounds due to a simultaneous chemical fragmentation of Secys. Overall, the results from this study show that selenium (of biotic or abiotic origin) can be integrated into the crystallographic structure of calcite under hydrothermal conditions. This has relevance for geological processes in diverse environments, such as hydrothermal systems along mid-ocean ridges, or underground reservoirs associated with massive injection of CO_2 for long-term geological sequestration. For more details refer to Montes-Hernandez et al. [1-3].

Introduction

Lithogeochemical analysis of alteration haloes is an important exploration vector towards hydrothermal ore deposits. Iron oxide copper-gold (IOCG) systems display a systemic development of hydrothermal alteration types from sodic, to calcic-iron, and high to low temperature potassic-iron and potassic alteration paragenesis that indiscriminately replace host rocks at local and regional scales. Where intense and pervasive, alteration leads to complete and systemic mineralogical, chemical and textural transformation of precursor rocks, resulting geochemical composition for each alteration type is reproducible irrespective of the nature of the original host. However the zoning in the alteration haloes and the types of deposits formed vary as a function of unidirectional, cyclical or non unidirectional evolution of the hydrothermal system [1]. To further the development of geochemical vectors to IOCG and affiliated deposits and orient exploration campaign in under-explored settings, we document the geochemical signature of hydrothermal alteration from the Great Bear magmatic zone (GBmz) IOCG systems through the application of compositional data analysis based on the log-ratio approach and principal component analysis (PCA).

Results and Conclusions

PCA has enabled the characterisation of the geochemical signature of the diagnostic alteration types. When compared to the other IOCG alteration types defined in the preceding section, potassic and potassic-iron alteration show relative enrichment in K, Al, Ba, Si, Rb, Zr, Ta, Nb, Th and U. In contrast, when compared with the other alteration types, calcic-iron alteration exhibit relative enrichment in Ca, Fe, Mn, Mg, Zn, Ni and Co. Sodic alteration is relatively enriched in in Na, Sr and Zr compared to the other alteration signatures.

The observed compositional variations established for each alteration type were thereafter portrayed in IOCG alteration indexes. Combined with the IOCG alteration vector to mineralization model, the resulting IOCG alteration indexes led to the development of an IOCG alteration discrimination diagram that provides a useful tool to quickly evaluate if a geochemical composition is related to IOCG –associated hydrothermal alteration. Plotting the alteration indexes on the GBmz regional geology map further demonstrates that the IOCG alteration indexes can provide a framework for field evaluation of the potential fertility and maturity of the GBmz IOCG systems and ultimately vector to ore during exploration.

[B]Nobuyoshi.Miyajima@uni-bayeruth.de

Owing to pervasive faults, sea water interacts with oceanic crusts and stabilizes a suite of layered hydrous silicate phases. As the oceanic crusts subducts, the hydrous phases are also dragged along with the subduing slab. These hydrous phases have limited thermal stabilities and they eventually dehydrate, releasing fluids. These fluids are less buoyant and hence migrates upwards. The fluids interact with the overlying mantle wedge. These released fluids rehydrates the mantle wedge i.e., rehydrates peridotitic mantle and stabilizes serpentinite. From geophysical observations, the mantle wedges of subduction zone are characterized by low seismic velocities and electrical resistivities. In order to asses the role of fluids and serpentine, we have measured the electrical conductivity of natural serpentinites at pressure (2 GPa) and temperatures (up to 1000 K) relevant to mantle wedge conditions. Among the two natural serpentinite sample investigated, one contained antigorite and traces of carbonate and the other contained chrysotile and carbonate. We distinguish the various polytypes of serpentine by careful analysis of the crystal structure using transmission electron microscopy (TEM). The measured contuctivity of serpentinite (10^{-4} Sm^{-1}) is higher than anhydrous olivine (10^{-6} Sm^{-1}) by two orders of magnidute at 1000 K. Upon dehydration, serpentine releases fluids which were also measured in our expreiment and showed a very high conductivity of the order of 10^{-2}-10^{0} Sm^{-1} range. This can easlily explain the high conductivities observed in many subduction zones.

Epitaxial garnet-muscovite interfaces: Molecular modelling

STEPHANIE J. MOORE[1*], KATE WRIGHT[2], JULIAN D. GALE[3], WILLIAM D. CARLSON[4]

[1]The University of Texas at Austin, Austin, U.S.A., sjmoore@utexas.edu (* presenting author)
[2]Curtin University, Perth, Australia, kate@ivec.org
[3]Curtin Univeristy, Perth, Australia, julian@ivec.org
[4]The University of Texas at Austin, Austin, U.S.A., wcarlson@mail.utexas.edu

Introduction

Computer simulations of garnet-muscovite interfaces provide a means of assessing the importance of interfacial energetics to epitaxial nucleation. Experiments and natural samples provide information about specific grain boundary orientations and their prevalence and invite speculation on the importance of particular orientations, but the determination of grain boundary energies from these data is difficult. Currently, there are few constraints on the interfacial energies of naturally occurring minerals and no studies have focused on garnet, a mineral that is of great significance to the metamorphic community. Combining data on grain boundary orientations from natural and experimental samples with molecular modelling that uses energy minimization allows for the determination of relative energies for naturally-occurring grain boundaries between garnet and muscovite.

Methods

Force-field simulations are particularly well-suited to the task of calculating grain-boundary energies for a specific set of conditions; here the General Utility Lattice Program (GULP) simulation code is employed for this purpose [1]. A 2-D periodic slab model is used to investigate muscovite-garnet interfaces. Here each phase is represented by two regions: an interfacial region in which the atoms are fully relaxed, in contact with a second rigid region that represents the underlying bulk material. The two unconstrained regions of garnet and muscovite are then placed in contact to create the interface, while the bulk regions are allowed to rigidly translate relative to each other in order to minimize the total energy. The total potential energy of this final configuration is compared to that of the two bulk structures and by dividing the difference between the two by the area of the interface, an interfacial energy is calculated. The parameters used to describe the energetics of the muscovite and garnet structures include Buckingham potentials, an oxygen core-shell spring constant, a three-body term to describe the O-Si-O bonding angle, and a Morse bond to describe the H-O bond [2,3].

Results

Initial simulations indicate that a garnet slab six unit cells thick and a muscovite slab five unit cells thick are sufficient for simulating the $(110)_{grt} \parallel (001)_{ms}$ with $[100]_{grt} \parallel [100]_{ms}$ interface. Additional simulations reveal that certain surface terminations of the muscovite and garnet slabs create more stable surfaces to be used in the garnet-muscovite interface simulations. The stability of these surfaces may be a guide to determining the precise interfaces between garnet and muscovite in natural samples.

Characterization of dissolved organic matter (DOM) from diverse oceanic environments by reverse osmosis and electrodialysis

KENNETH MOPPER[1*], JOHN R. HELMS[1], HONGMEI CHEN[1], NELSON GREEN[2], ARON STUBBINS[3], E. MICHAEL PERDUE[2], PATRICK G. HATCHER[1], AND JINGDONG MAO[1]

The oceans contain approximately 685 x 10^{15} g of dissolved organic carbon (DOC), a pool similar to current atmospheric CO_2 of ~861 x 10^{15} g C, and is thus a major component of the global carbon cycle. However, only a small fraction of marine DOM is readily identifiable. Determining the chemical nature of the remaining fraction of oceanic DOM has been impeded by the lack of efficient and non-fractionating methods of isolation/desalting. Here, reverse osmosis- electrodialysis (RO/ED) [1] was used for isolating a representative DOM fraction (~75%) for analysis by advanced solid-state 13C- NMR, UV-vis spectroscopy and wet chemical techniques. Samples were obtained from biogeochemically diverse environments; i.e., photobleached surface gyre, productive coastal upwelled, oxygen minimum, deep Atlantic, and old deep Pacific waters. NMR spectral editing revealed new insights into carbohydrate biodegradation, and preservation of carboxyl groups and condensed aromatic structures (deep sea samples). Quaternary anomeric carbons were identified as an important component of bio-refractory carbohydrates. However, despite some differences, these diverse samples yielded remarkably similar DOM compositions. Our results support the 3-pool DOM model (labile, semi-labile, and refractory) [2]. Evidence of 'background' refractory carbon was seen throughout the ocean DOM samples, and the high carboxyl signal in the deep Pacific sample supports the hypothesis that a major fraction of the refractory pool consists of carboxylic-rich alicyclic molecules (CRAM) [3].

RO/ED appears to be the most promising method to date for DOM isolation from seawater; as it can isolate up to 95% of marine DOM (average 75%; compared to 15-40% for other methods) and the extracted DOM has properties closely resembling the unextracted DOM [1,4]. As the method is capable of processing large volumes of seawater, it can potentially be used to collect marine DOM reference material from different oceanic environments, which currently do not exist and would be useful for comparison to terrestrial DOM reference materials.

Study Design

Snowmelt is an important component of groundwater recharge in high elevation watersheds of the western United States. In these watersheds, the predicted climate change impacts on snowmelt will likely alter the amount and timing of groundwater recharge, which may lead to reduced groundwater production, declining water tables, and reduced baseflow to streams.

We apply dissolved noble gas tracers to answer questions about recharge location and aquifer residence times in two catchments of differing size in the northern Sierra Nevada. The Olympic Valley near Lake Tahoe is a 22 km^2 alpine catchment while the Upper Merced catchment has an area of 465 km^2 and drains through Yosemite Valley. In both valleys, deep, high capacity production wells located in the upper portion of the valley draw groundwater from over much of the sediment thickness. These wells were sampled for tritium and dissolved noble gases in order to determine recharge temperatures (used to esimate to recharge elevation), and tritium-helium groundwater ages.

Results

Noble gas recharge temperatures point to the lower slopes of the mountains, just above the valley floor, as important recharge areas for both catchments. Tritium-helium aquifer residence times are somewhat greater in Yosemite Valley wells (10-28 years) than in Olympic Valley wells (<1-23 years), but in both areas the results indicate relatively rapid turnover of groundwater in the coarse alluvium of the upper valley reaches. The much larger Upper Merced catchment thus supplies only somewhat greater buffering to perturbations in recharge and runoff that would be expected due to warmer temperatures. Using the information gathered from these tracers, differing scenarios characterized by earlier snowpack melting and a higher proportion of precipitation as rain are evaluated with regard to potential impacts to recharge.

Dynamical and chemical modeling of terrestrial planet accretion

ALESSANDRO MORBIDELLI[1*], DAVID C. RUBIE[2]

[1]Observatoire de la Cote d'Azur, Nice, France, morby@oca.eu (*presenting author)

[2]Bayerisches Geoinstitut, Bayreuth, Germany, dave.rubie@uni-bayreuth.de

The "Grand Tack" dynamical model

The classic dynamical models of terrestrial planet formation, starting from a disk of planetesimals extended from the Sun to the current orbit of Jupiter, typically produce in ~ 100 Ma a few planets in the terrestrial zone on orbits comparable to the real ones [1], but the synthetic planets located near 1.5 AU are systematically more massive than Mars. The large Earth/Mars mass ratio seems to require a strong depletion of solid mass beyond ~1 AU [2]. The "Grand Tack" model [3] explains such a depletion by coupling the early orbital migration of the giant planets with the terrestrial planets accretion process. More precisely, the model assumes that, when the giant planets formed in a proto-planetary disk still dominated by gas, Jupiter first migrated towards the Sun and then, as a consequence of the formation of Saturn, reversed its migration and spiralled outwards. This possibility is supported by hydro-dynamical simulations [4]. If the reversal (or tack) of Jupiter's migration occurred when the planet was at ~ 1.5 AU, the region beyond 1 AU would have been strongly depleted by the passage of Jupiter. The simulations in [3] show that this model is consistent with the existence and the structure of the asteroid belt between 2 and 4 AU, it produces in 30-50 Ma terrestrial planets on orbits consistent with the real ones and, in particular, it explains why Mars is 10 times smaller than the Earth and formed 10 times faster [5]. Thus, the Grand Tack model is so far the most successful model of terrestrial planet formation from the dynamical point of view.

Chemical modelling

To test the Grand Tack model further, we are now applying geochemical constraints. The model is consistent with the delivery of 2000 ppm of water to the Earth from planetesimals of chondritic composition, which agrees with recent estimates of the Earth's water budget and its isotopic composition [6]. Moreover, we are modeling core-mantle differentiation [7] using the accretion history of the planets obtained in the Grand Tack simulations. Assuming that the material originally inside ~1.5 AU had a reduced composition and that beyond this threshold was oxidized, our chemical models result in a FeO content of 8 wt% for the Earth's mantle and ~18 wt% for the Martian mantle, results that are consistent with observed concentrations [8,9]. In the future we will extend our analysis to include more elements (e.g. sulphur, volatile elements, HSEs and water) and we will use more than two initial bulk compositions for accreting material.

Introduction

Natural colloid-borne transport of metal ions in ground water is known to occur. The implications of this kind of transport are especially important in the context of radionuclide migration in subsurface water to evaluate risks of pollutants migration in contaminated soils [1,2]. Furthermore, dissolved organic matter plays a crucial role on metal ions transport. In particular, phenolic acids, resulting from lignin degradation, may be involved in the process of metal ion adsorption onto mineral nanoparticles, as it is the case for aliphatic acids [3]. Our aim is to investigate the sorption of Eu(III) (rare earth and analogue of trivalent actinides) onto Al_2O_3 nanoparticles in the presence of a hydroxybenzoic acid series (4-hydroxybenzoic, 3,4-dihydroxybenzoic, and 3,4,5-trihydroxybenzoic acids).

Results

First, the binary systems were characterized. Eu(III) was shown to have a high sorption capacity on our Al_2O_3 sample, as already described elsewhere [4,5]. Combining sorption data analysis with time-resolved luminescence spectroscopy (TRLS) for Eu(III), at least 2 sorption sites of different energies were evidenced, as in *Rabung et al*. [5]. Complexation constants between Eu(III) and acids were determined using TRLS. It appears that the complexation constant increases from $\log_{10}K° = 2.1$ to 5.3 with the number of phenoxy groups on the benzoic ring. As expected, the sorption isotherms of the Al_2O_3-phenolic acid binary systems show different sorption capacities that cannot be explained by the hydrophobicity of the acids Indeed 4-hydroxybenzoic acid, which is the most hydrophobic compound of the series, has the lowest sorption capacity on Al_2O_3. These results are consistent with published data, demonstrating that increasing the number of phenoxy groups on the benzoic ring of analogue compounds increases sorption on alumina [6]. Besides, the sorption isotherm of 3,4,5-trihydroxybenzoic acid at pH 5 can only be fitted using sequential Langmuir isotherms, which evidences different sorption sites for this acid on Al_2O_3.

The same strategy was applied to study the ternary systems. Sorption isotherms were obtained as well as the TRLS spectra which permit to discuss the pertinency of mixed-surface complexes that involves Eu(III), hydroxybenzoic acids and aluminol sites.

Role of weak complexing agents in metal uptake by phytoplankton

FRANÇOIS M.M. MOREL*, LUDMILLA ARISTILDE, AND YAN XU*

Princeton University, Department of Geosciences, morel@princeton.edu (* presenting author)

The presence of weak ligands enhances the bioavailability of metals bound to strong chelating agents. For example, addition of cysteine (Cys) to EDTA-buffered media increases the rate of uptake of zinc (Zn) by model phytoplankton. Such enhancement of uptake may result from 1) specific uptake of the Zn-Cys complexes, 2) alleviation of diffusion limitation by dissociation of the complexes in the boundary layer of the cells, or 3) exchange of Zn with uptake ligands, X, via formation of a ternary complex X-Zn-Cys. Mechanism 1 is ruled out by the facts that L- and D- isomers of Cys are equally effective at enhancing the Zn uptake rate and that weak ligand addition increases rather than decreases uptake in the absence of EDTA. Mechanism 2 does not explain the effect of weak ligands, for this effect is seen when diffusion does not limit uptake of the free metal. The enhancement of Zn uptake kinetics by weak ligands under various conditions is consistent with mechanism 3: i) enhancement of uptake is particularly effective in Zn-deplete cells whose high affinity transport molecules should be most able to exchange Zn with external ligands; ii) a variety of weak ligands have similar effects on uptake, showing that the mechanism is relatively non-specific; and iii) ligands that bind Zn in complexes that make the formation of a ternary complex difficult do not increase Zn uptake. When essential metals are bound to strong chelating agents in natural waters, binding to weak complexing agents may increase their bioavailability to ambient microorganisms.

The amphoteric behaviour of water in silicate melts: Raman observations and physico-chemical description

ROBERTO MORETTI[1,2,*], CHARLES LE LOSQ[3], DANIEL R. NEUVILLE[3]

[1] Dipartimento di Ingegneria Civile, Seconda Università di Napoli, Italia, roberto.moretti@unina2.it (*presenting author)

[3] Géochimie&Cosmochimie, IPGP, Paris, France, lelosq@ipgp.fr neuville@ipgp.fr

Water plays a fundamental role in the dynamics and evolution of magmas in the deep interior and during volcano eruption. However, water speciation in silicate melts is not fully understood, despite Infrared, Raman and NMR spectroscopy had provided some valuable information about the H_2O/OH speciation and its variations as a function of temperature, pressure, and water contents of melts. Some issues still remain unsolved about OH and H_2O linkages to the silicate network and we lack a general physico-chemical description of acid-base exchanges of water in melts. This includes the amphoteric behavior displayed by the water component into depolymerized glasses and melts.

By adopting a Raman-spectroscopy calibration of water dissolved in aluminosilicate melts [1], we studied the Raman OH-stretching bands of hydrous glasses. OH-stretching Raman band records the vibrations of OH groups in molecular water or differently linked to the glass structure or metal cations. To constrain more in detail the evolution of such bands, we performed a set of in situ experiments on rhyolite, basalt and albite glasses using a micro-furnace at ambient atmosphere. We observed new high-temperature Raman features near 3650-3700 cm^{-1}, and also changes of water speciation that occurred below glass transition while quenching to room temperature. Our results will be used to constrain the acid-base exchanges occurring in melts and give insights into the relations between water and silicate network in melts.

The late Pleistocene trachytic Campanian Ignimbrite (CI; 300 km^3 DRE) covers the Campanian Plain near Naples, and is found behind ridges more than 1,000 m high at 80 km from source, the Campi Flegrei caldera (CFc). Very dilute pyroclastic density currents suggest a magma reservoir highly enriched in volatiles. Volatile concentration, H_2O particularly, exceeds significantly that of other explosive CFc eruptions. To understand such an enrichment and come out with a significant budget of discharged volatiles, particularly H_2O, we analyzed products from the different eruptive phases. Together with FTIR analyses on melt inclusions (MIs), we also characterized pumice glasses for their water content by adopting Raman spectroscopy. CI pumices display high values of porosity (> 60%, but typically > 70%), usually determined by density measurements on bulk samples. However, microscale analyses (2D and 3D) of natural pumices show a significant variability of porosity and permeability within samples. Such a variability may encompass up to 50% of porosity and contrasts with the typical values inherited by pumices at magma fragmentation. This variability is too often overlooked in the pertinent literature and ascribed to local effects within the large-scale dynamics occurring at the moment of the volcanic explosion and leading to generation of Plinian columns. Therefore, we also characterized, at the same micrometric scale of Raman investigations, pumice structure by means of conventional X-ray μCT tomography at the Elettra synchrotron facility in Trieste (Italy). Data substantiate a model in which water accumulation in the CI magma chamber is made possible by a melt fining process, similar to chromatographic separation, that occurs over a time scale comparable to that of magma residence time. This process produced extensive gas fluxing within the magma chamber, leading to an overpressurized CO_2-dominated gas cap (about 150 km^3), uniformly distributed at the top of the magma chamber. The main features of the magmatic "chromatographic" column can be retrieved by our joint Raman and synchrotron X-Ray μCT approach, that allowed investigating the effects of water exsolution and the structural changes in the polymeric network of the pre-fragmentation melt (quenched in the pumice glass).

Geochemical signature of an injection complex in the deep middle crust

Samuel Morfin[1*], Edward Sawyer[1] and Daniel Bandyayera[2]

[1]Université du Québec À Chicoutimi, Sciences Appliquées
[2]Bureau de l'Exploration géologique du Québec

Daniel.Bandyayera@mrnf.gouv.qc.ca

Introduction

Upward transfer of anatectic magma from its lower crustal source is the mechanism of crustal differentiation [1][2]. Recently, it has become evident that a large proportion of anatectic magma does not reach the brittle/ductile transition depth. Field studies show that in the granulitic crust, anatectic magma is mostly transported in a pervasive network of narrow veins. Consequently, the upward migration of magma is arrested at, or close to, the level of the granite solidus and much leucogranite is accumulated at the granulite/amphibolite transition in the form of an injection complex [3]. This changes our perspective on the overall process of chemical differentiation of the crust

Method

Since the formation of an injection complex is mostly controlled by the depth of the solidus, which changes over the time span of a regional metamorphic event, it is expected that at a single crustal depth leucogranites should show a wide degree of chemical evolution.

Results

Both major and trace elements indicate that the Opinaca Injection Complex (Québec) contains a continuum of leucogranite compositions ranging from cumulate to highly fractionated (Fig. 1).

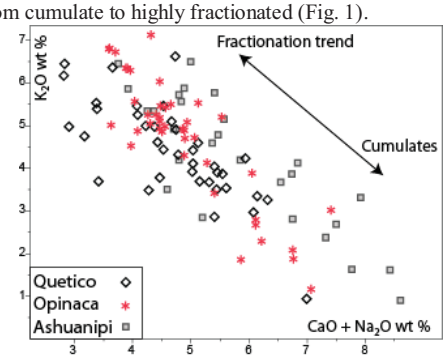

Figure 1: Na_2O+CaO vs K_2O plot showing that (1) the variety of fractionation degree in the Opinaca is similar to deeper crustal levels (Ashuanipi Subprovince) with (2) a greater proportion of evolved compositions although less evolved than higher crustal levels leucogranites (Quetico Subprovince).

Conclusion

Development of injection complex in the deep middle crust result in the accumulation of large volumes of leucogranites of various degrees of evolution close to the granite solidus depth. Evolved granites are thus not only concentrated in the upper crust, many remain in the deep middle crust. Crustal differentiation is thus not as efficient as presently thought both in terms of volume and chemical distribution. Consequences of these changes should be considered into future crustal scale models (e.g. presence of water, heat distribution).

Introduction

Molybdenum (Mo) is relatively conservative in oxic seawater but is removed to the solid phase under sulfidic conditions. Investigators have been encouraged to use Mo solid phase concentrations or accumulation rates to infer past changes in reducing conditions in sediments and/or overlying waters. However, difficulties in fully using Mo as a proxy derive from a lack of information regarding the controlling factors for the removal of Mo from the aqueous phase to the solid phase. A commonly accepted hypothesis involves the thiolation of molybdate to a form that is more easily scavenged by particles[1,2]. A subsequent hypothesis instead suggests that the precipitation of a nanoscale Fe(II)-Mo(VI) sulfide mineral dictates Mo removal from the aqueous phase[3]. However, persuasive correlations between Mo concentrations and sulfurized organic matter hint at a role for organic molecules in Mo fixation and preservation in sediments[4].

We seek to clarify the influence of organic matter on Mo sequestration by determining the role of organic molecules, either aqueous or bound to solid surfaces, in the transition of Mo between the aqueous and solid phases. Simple organic molecules and single minerals are used as analogs for more complex humic material and heterogenous sediments, respectively, present in the environment.

Results

Initial results suggest that the nature of the organic molecule and the type of functional groups are important for aqueous molybdate-organic interactions. Molybdate preferentially complexes with organic molecules that have two phenolic functional groups on adjacent carbons as seen using ^{1}H and ^{13}C NMR. Analysis of molybdate with either 1,2-dihydroxybenzene or 2-mercaptopropionic acid using UV/Vis and ESMS supports the formation of a 1:2 Mo:organic complex.

Molybdate adsorption to aluminum oxide or pyrite is pH dependent with greater adsorption under acidic conditions. All adsorption experiments are consistent with a one-site adsorption surface as modelled with a Langmuir isotherm. The addition of 2-mercaptopropionic acid possibly inhibits the adsorption of molybdate to pyrite, although it is still uncertain whether the thiol competitively occupies pyrite adsorption sites or complexes molybdate, thereby making it incapable of adsorbing to the solid surface. Ultimately, the results of this research should clarify the influence of organic matter on Mo sequestration in modern sediments.

[3]Surface & Aqueous Geochemistry Group, Department of Geological and Environmental Sciences, Stanford University, Stanford, CA, USA.

For the last few decades, a great deal of attention has been focused on better understanding and predicting the fate of arsenic in the environment. Indeed, due to natural as well as anthropogenic inputs, this element has been recognized as a pollutant in several countries, with major impacts on human health. One of the main conclusions drawn from the numerous studies conducted on natural and laboratory systems is that nanometer-sized iron-(oxyhydr)oxide minerals play a key role in the scavenging of arsenic in water, soils and sediments via sorption reactions. In addition, redox transformations of arsenic have been shown to greatly influence its mobility and toxicity, with As(III) species generally more mobile and toxic than As(V) species. Despite this extensive knowledge base, important questions remain about the detailed mechanisms of particular As oxidation and reduction reactions in complex heterogeneous media, and about the ultimate fate of this element in the presence of various electron donors and acceptors [1-4].

In the present communication, we will review important pathways for arsenic redox transformations that can be driven by either abiotic or abiotic processes. Examples will be chosen from recent studies using synchrotron-based X-ray absorption specoscopy (XANES, EXAFS) to monitor the redox state of arsenic in natural and laboratory systems. Focus will first be given to redox transformations that are usually slow at room temperature, but which can be catalyzed by chemical and physical factors. Particular attention will be paid to the complex interplay between Fe(II)/Fe(III) and As(III)/As(V) redox couples in the presence or absence of oxygen, and the role of photocatalysis in redox reactions [1-4]. Regarding these processes, classical artifacts involving catalysis of redox reactions during exposure to synchrotron radiation will be discussed as possible indicators of light-induced reactions.

In addition, examples of biotic redox transformations able to contribute to As sequestration by oxidized [5-7] or reduced iron-containing minerals [8] will be discussed in relation to the differing affinities of As(III) and As(V) species for specific mineral surfaces [9].

[2]Department of Geology, Tribhuvan University, Kathmandu, Nepal

In order to interpret continental sedimentary archives in terms of erosion processes in the past, we made an effort to characterise actual landslides and soils geochemical signatures, in order to trace these processes in the river suspended load (SL) throughout a monsoon season.

To assess this question, daily monitoring of SL chemistry have been conducted during 2010 monsoon in two watersheds : the Narayani river that drains whole central Nepal and the Khudi khola, one of its minor High Himalayan tributaries. In addition, systematic sampling was conducted on hillslopes material from soils and landslides in Khudi. This catchment was chosen because it represents typical South flank Himalayan basin exposed to severe precipitations (3.5 m/yr), and undergoes intense erosion rates as high as 2-3 mm/yr [1]. Characteristics of this watershed are : 800 to 4500 m elevation, 152 km^2, dense forest cover up to 3500 m, and active landslide erosion for at least one decade.

Source rocks, soil and landslide samples are compared to river suspended sediment using mobile to immobile element ratios. Data clearly show that soil material has undergone weathering with loss of Na, K and Ca relative to average source rocks. In contrast, landslide products and suspended sediments have close chemical signature and are only slightly depleted relative to source rocks. Geochemical composition of the Narayani SL have similar characteristics suggesting that even at large scale the erosion is dominated by physical erosion processes rather than by progressive soil development.

The results of this study show that chemical composition of SL are close to those of pristine source rocks, and contrasted with those of soil products. Therefore, active and steep reliefs are mostly eroded through landsliding rather than through soil erosion. The later is difficult to quantify using SL composition in spite of enhanced soil erosion by agricultural activity [2-3] that is significant in the Narayani Basin.

Electron microprobe and LA-ICP-MS analyses of ilmenite from lunar samples

CAROLINE-EMMANUELLE MORISSET[1*], SIMON JACKSON[2], MARIE-CLAUDE WILLIAMSON[2], VICTORIA HIPKIN[1] AND KIMBERLY TAIT[3]

[1]Canadian Space Agency, Saint-Hubert, Canada, (* presenting author: caroline-emmanuelle.morisset@asc-csa.gc.ca), victoria.hipkin@asc-csa.gc.ca
[2]Geological Survey of Canada, Ottawa, Canada, simon.jackson@NRCan.gc.ca, marie-claude.williamson@NRCan.g.ca
[3]Royal Ontario Museum, Toronto, Canada, ktait@rom.on.ca

Oxygen can be liberated from ilmenite at lower temperature than from silicates present in the lunar regolith, making ilmenite a key resource for human settlement on the Moon. Major and trace element concentrations of ilmenite contained in twelve samples selected from the six Apollo landing sites (10 basalts, one impact melt, and one impact breccia) and in one lunar meteorite (NEA 001) have been determined using electron microprobe and LA-ICP-MS. These analyses help us to understand the role of ilmenite in the crystallization of magma on the Moon and to determine if the ilmenite from different rock types has a specific chemical signature. Ilmenite can reach a modal proportion of up to 20% in basaltic rocks. Some ilmenite grains contain rutile, Cr-spinel and baddeleyite needles. The TiO_2 in the analyzed ilmenite from the Apollo samples varies from 52.4 to 55.9 wt% while it is noticeably lower in the meteorite sample (i.e. 51.7 to 52.8 wt%). In all samples, FeO varies from 37.4 to 46.7 wt% and MgO from 0.1 to 5.1 wt% except in the impact melt where it is higher (5.3-5.7 wt%). The largest variation observed in MgO within an ilmenite grain is of 0.3 wt% (e.g. 4.7-5.0 MgO wt%), implying that the observed variation between grains cannot be attributed to mineral zoning. So far, three basaltic samples have been analyzed by LA-ICP-MS. Cr varies from 1080 to 7580 ppm, V varies from 80 to 453 ppm and both elements are positively correlated with MgO. Zr (123-2330ppm) and Hf (5.95-85 ppm) concentrations are highest in the baddeleyite-bearing ilmenite grains. Nb (20-107 ppm) and Ta (1.85-8.52 ppm) are positively correlated but are not well correlated with Zr or Hf. REE patterns show enrichment in HREE (Ce_N/Lu_N: 0.0001-0.005) with a strong negative Eu anomaly (Eu/Eu* from 0.003 to 0.413). The ratio of MgO vs TiO_2 of the ilmenite permit discrimination of what type of sample the ilmenite is from. Ilmenite from the basaltic samples form a trend (n=355; slope=1.89; r^2=0.86) that is richer in TiO_2 for the same MgO than the impact breccias (n=11; slope=1.5; r^2=0.91) and the meteorite (n=10; slope=4.38; r^2=0.42) samples. LA-ICP-MS analysis of the remaining samples will permit evaluation of whether the observed geochemical distinctions between the three sample groups are identifiable using trace elements.

Abstract

Biomarkers are widely used as tracers of the processes affecting organic matter cycling in the environment. Lipids, or more specifically hydrocarbons, sterols and fatty acids, are used extensively as indicators of the sources of organic matter as well as its alteration by photochemical or microbial degradation. The extraction of these lipids from sediments consists in a liquid-solid extraction using a mixture of non-polar solvents (most often dichloromethane and methanol). Conventional extraction of lipids from solid matrices traditionally involves ultrasonic extraction combined with shaking, or Soxhlet-based solvent refluxing. These two techniques are long and tedious and use low temperature and low pressure conditions to extract lipids. We recently found out that iron oxides associate very intimately with sedimentary organic matter, leading to the preservation of labile organic material, likely through covalent bonding [1]. Our results show that a fraction of the extractable lipids are not quantitatively recovered when using low temperature and low pressure methods for iron oxide-containing sediments. An extraction at high pressure and high temperature using an accelerated solvent extractor (ASE) disrupts these iron-organic matter structures, releasing the lipids into solution. The reproducibility and lipid recovery of the ultrasonication and ASE methods will be presented and discussed.

Sourcing hydrocarbons at two continental sites of present-day serpentinization: The Tablelands, NL, CAN and The Cedars, CA, USA

PENNY MORRILL[1], AMANDA RIETZE[1], NATALIE SZPONAR[1], J.GIJS KUENEN[2],SHINO SUZUKI-ISHII[3], AND KENNETH H. NEALSON[3].

[1] Dept. Earth Sciences, Memorial University of Newfoundland, NL, CAN, pmorrill@mun.ca (* presenting author)

[3] J. Craig Venter Institute, San Diego, CA, USA

The hydration of ultramafic rocks, via the serpentinization reaction, is a suspected source of putative hydrocarbons (methane and possibility higher molecular weight gases hydrocarbons) on Mars. On Earth, serpentinization produces hydrogen gas and the reducing conditions necessary for abiogenic hydrocarbon synthesis, while also producing conditions amenable for chemolithotrophic life. Additionally, on Earth, continental sites of serpentinization are often assoicated with buried sedimentary organic matter (SOM) that can possibly contribute thermogenic hydrocarbons to the ultra-basic reducing springs associated with the serpentinization. This study sources hydrocarbons from two continental sites (the Tablelands, NL, CAN and The Cedars, CA, USA) of present-day serpentinization where methane and higher molecular weight hydrocarbons are present in the ultra-basic reducing springs discharging from altered ultramafic rocks.

The Cedars was the first site to be described where ultramafic rocks are undergoing present-day serpentinization at shallow depth and low temperature. The Cedars is part of California's Coast Ranges and is a section of a peridotite body that was obducted as part of the Franciscan Subduction Complex (Late Cretaceous). Conversely, the much older Tablelands Ophiolite, NL is part of the Bay of Island Ophiolite. The Tablelands Ophiolite is composed of ultramafic rocks that were obducted onto the eastern edge of ancient North America (Ordovician). Elevated concentrations of H_2, CH_4 and higher molecular weight hydrocarbons have been detected in the ultra-basic reducing springs discharging from The Cedars and the Tablelands. Our geochemical investigations show that the methane at The Cedars is primarily microbial in origin (for example C_1/C_{2+} = 6000, $\delta^{13}C$ = -68.0 ‰), while the methane sampled from the Tablelands is not (for example C_1/C_{2+} = 5, $\delta^{13}C$ = -26.3 ‰). However, the source of the higher molecular weight hydrocarbons may differ from the source of methane (The Cedars average $\delta^{13}C_{C2-C6}$ ~-23.6 ‰ and the Tablelands $\delta^{13}C_{C2-C6}$ ~-30.7‰). Both The Cedars and the Tablelands could have thermogenic and/or abiogenic hydrocarbons contributing to the hydrocarbons detected in the springs. The purpose of this study is to source the higher molecular weight hydrocarbons through the analyses of the hydrocarbons in the ultra-basic reducing springs and the SOM associated with the Ophiolite.

Microbial transformation of radionuclides - the radionuclide biomineral interface.

K. MORRIS[1*], D. BROOKSHAW[1], V. EVANS[1], C. THORPE[1], A. WILLIAMSON[1], G. T. LAW[1,2], A. RIZOULIS[1], F.R. LIVENS[1,2] AND J.R. LLOYD[1]

[1]Research Centre for Radwaste and Decommissioning and Williamson Research Centre, and [2]Centre for Radiochemistry Research, The University of Manchester, Manchester, M13 9PL. (*correspondence: katherine.morris@ manchester.ac.uk)

Microbial processes can have a profound effect on the solubility of radionuclides in natural and engineered environments. The scope of these processes is significant with clear evidence that radionuclide solubility may be altered enzymatically via mediated redox reactions, by indirect redox reactions with, for example, Fe(II)-bearing biominerals andfor non-redox active species, even by incorporation reactions into neo-formed biominerals formed as physicochemical conditions change. Understanding these reactions is important across radionuclide impacted environments from contaminated land environments where bioreduction and biomineralisation processes may be harnessed to control radionuclide mobility, through nuclear facilities where biological processes are often poorly constrained yet may be critical in long term management and control of radionuclides, and finally to radioactive waste disposal scenarios where there is a paucity of information on the influence of microbial processes on bio-mineralisation and radionuclide behaviour under geological disposal facility conditions.

Recent work exploring the behaviour of Sr, U and Np will be discussed with a focus on (bio)mineralisation, reduction and reoxidation reactions and their impact on radionuclide behaviour. The products of biomineralisation in terms of bulk element cycles and (bio)geochemistry will be discussed in the context of radionuclide solubility. Studies relevant to a range of environments including radioactively contaminated land, nuclear legacy ponds, and high pH environments relevant to environments expected in geological disposal of cementitious waste forms will be discussed. The biogeochemical fate of radionuclides across these systems and in the sometimes "extreme" environments that these systems pose will be highlighted.

Critical zone weathering of glacial till in the Prairie Potholes Region: A major control on wetland ecology

JEAN M. MORRISON[1]*, MARTIN B. GOLDHABER[2], CHRISTOPHER T. MILLS[2], KARL J. ELLEFSEN[2]

[1]U.S. Geological Survey, Denver, United States, jmorrison@usgs.gov (* presenting author)
[2]U.S. Geological Survey, Denver, United States

The Prairie Potholes Region (PPR), a vital ecosystem in North America comprising a 715,000 km^2 region in the north-central U.S. and south-central Canada, is characterized by millions of closed-basin wetlands. Sulfate is the dominant anion in these wetlands. A thick oxidized brown (iron oxide-bearing) zone which transitions to unoxidzed, gray till has been widely reported in the PPR.

The objective of this study is to characterize till alteration in the 92 hectare Cottonwood Lake Area (CWLA) near Jamestown, ND, where Pleistocene-age glacial till overlies pyrite-rich marine shale. We studied the geochemistry and mineralogy of three cores drilled along a topographic gradient from an upland position (ground surface at 569 m) to the edge of a low lying discharge wetland (ground surface at 560 m) referred to as P1, whose anion content is dominated by SO_4^{2-}. A brown-gray transition was recognized whose depth systematically decreased from 13.3 m in the upland core to 7.3 m at the wetland edge. We also analyzed archived cutting samples from a groundwater well drilled in 1978 near the margin of wetland P1. This well penetrated to bedrock at 136 m and the brown-gray transition was observed at 12.3 m.

Semi-quantitative X-ray diffraction (XRD) analysis of material from the cores and cuttings detected gypsum in the brown zone that ranged from trace amounts to 8 wt % with the highest concentrations at or below the water table. Gypsum was below detection (<1 wt%) in the samples from the gray zone. These results were confirmed by water leaches for soluble sulfates. Using a terrain conductivity meter, the electrical conductivities of subsurface were measured along a transect parallel to the core samples. The brown zone was more conductive than the gray zone (120-150 mS/m vs. <120 mS/m) likely due to the presence of gypsym. Both XRD and quantative reductive dissolution assays showed that gray zone samples, including those from the deep well, contain pyrite in the range 0.3 to 1.1 wt %.

We conclude that shale-derived pyrite in the till has been slowly oxidized to SO_4^{2-}, which is leached to groundwater and responsible for the consistently high content of S in the CWLA wetlands. These weathering processes drive groundwater and wetland geochemistry, resulting in dramatic variations in salinity over short distances depending upon where individual wetlands reside in local groundwater systems. Variations in wetland chemistry influence the flora and fauna that inhabit the wetlands. Therefore, understanding the long-term alteration processes in the till has a close link to wetland ecology in this region that is known as the duck factory of North America.

Molecular-scale interactions present at mineral-water interfaces and in clay interlayer galleries control numerous environmental processes, including chemical interactions in soils and transport of nutrients and pollutants through them.[1-4] Understanding these processes requires accurate knowledge of the structure, energetics, and dynamics of the interaction among the mineral substrate, ions, and water molecules.[5, 6] Challenges to this objective include experimental difficulties in probing these interfaces and interlayers at the molecular scale; fully characterizing the mineral substrate; and identifying how the mineral surface, ions, and water molecules each contribute to the overall structure, energetics, and dynamics of these systems.[6] Linked computational molecular dynamics (MD) simulations and experimental nuclear magnetic resonance (NMR) studies are particularly effective in addressing these issues.[7-9]

Here we focus on MD studies of Na- and Ca-smectite (hectorite) interlayer galleries to provide a molecular-scale picture of the structure and dynamics of their hydration[9, 10] and to complement our earlier NMR investigations of these systems.[7-9] Classical MD simulations were undertaken in the *NPT* and *NVT* ensembles to determine the structural and energetic changes with increasing hydration with focus on the single- and double-layer hydrates. The results show substantial changes in the hydration of the interlayer cations, the orientations of the water molecules, the hydrogen bond network involving the water molecules and basal oxygen atoms, and the resulting potential energies as the interlayer gallery expands.

Reconstructing a young martian history with igneous microbaddeleyite rimmed by metamorphic zircon

D. E. MOSER[1*], K.R. CHAMBERLAIN[2], K.T. TAIT[3], A.K. SCHMITT[4], I. R. BARKER[1], B.C. HYDE[3], J. DARLING[1]

[2]University of Wyoming, Laramie, U.S.A.

[3]Royal Ontario Museum, Toronto, Canada

[4]UCLA, Los Angeles CA, U.S.A.

A current paradox in martian geochronology is that basaltic shergottites yield whole rock and unradiogenic mineral isotopic Pb-Pb compositions consistent with a primary Noachian (>4 Ga) age for crystallization whereas mineral isotopic analyses consistently return 'young' post-Amazonian (<0.6 Ga) dates. To assess the significance of the mineral dates, we have combined single-grain isotopic SIMS U-Pb microbaddeleyite dating with chemical and deformation microstructure data obtained with electron nanobeam techniques (e.g. CL, EBSD) to resolve baddeleyite paragenesis and potential for isotopic disturbance by shock processes. We have focused on microbaddeleyites from shergottite NWA 5298, an enriched basaltic shergottite exhibiting a primary phaneritic igneous texture which has similarities to other basaltic shergottites. The baddeleyites are generally subhedral to euhedral blocky to bladed grains, 2 to 20 μm long, at the boundaries of larger main phase minerals. SE and BSE imaging of grain interiors showed that grains are often composed of equant microdomains that give the appearance of a granular texture. Grains are often surrounded by discontinuous rims of zircon a few microns wide identified by EDS and EBSD. CL zoning types in baddeleyite include simple bright, narrow rims of variable thickness surrounding dark cores, and patchy to diffuse and mottled CL domains at the margins of grains or in areas of crystal disruption and apparent granular texture. A subset of grains exhibits oscillatory planar growth banding similar to that which we have observed in terrestrial igneous baddeleyite. Our EBSD mapping indicates clearly that the baddeleyite is now quasi-amorphous and is hosted by amorphous maskelyinite, whereas zircon is crystalline and apparently unshocked, although an investigation at higher resolution for the high pressure polymorph, reidite, is ongoing. SIMS analysis of 12 grains yielded $^{206}Pb/^{238}U$ dates ranging from 209 ± 22 Ma (2σ) to 26 ± 2 Ma. An unforced discordia line has an upper intercept with concordia at 0.9 +1.2/-0.7 Ga and a zero age lower intercept. Our SIMS data together with microtextural data for the baddeleyites are consistent with U-Pb disturbance of primary, post-Noachian igneous crystals during shock, recent shock heating, and zircon growth. A scenario is favoured wherein bulk melting of ancient 4 Ga parent material produced the NWA 5298 source magma through volcanic or impact melting. This would reconcile 'young' mineral dates and isochrons with the unradiogenic and whole rock Pb-Pb age data from basaltic shergottites.

Remobilisation of uranium from contaminated sediments: effect of the bioturbation

MIKAEL MOTELICA-HEINO [1]*, F.LE MOING[2], SANDRA LAGAUZERE [2], JEAN-MARC BONZOM[2], LAURENINE FEVRIER[2] AND VIRGINIE CHAPON[3]

[1]ISTO, University of Orléans, Orléans, France, mikael.motelica@univ-orleans.fr
[2]IRSN, Cadarache, France, jean-marc.bonzom@irsn.fr
[3]CEA,Cadarache, France, virginie.chapon@cea.fr

Introduction

The main thrust of this work is to bring some answers to the following question: what either distinct or combined role do the different physico-chemical and biological (benthic macro-organisms) play on the reactivity, the transfer and the biotic impact of metallic contaminants in sediments? To achieve this goal, experimentations wre carried out in microcosmes with different forcing parameters (oxia, anoxia, with and without macro-benthic organisms).

Material and methods

15 sediment cores were samples in the Pontabrier lake within the village of Compreignac north of Limoges (Haute-Vienne, France). These sediments are heavily contaminated in uranium (34 317 Bq/Kg m.s.). Cores were untouched and were used as the characterisation cores (cores « C »). 6 other cores were then depleted in benthic macro-organisms by addition of niyrogen gas for 24 h. Half of the cores depleted in macro-organisms were populated with 1060 Tubifex tubifex by core with a mean density of 60 000 individualss /m² close to what observed in some environments (cores « T »). The three remaining cores were submitted to gamma irradiation (delivered dose: 40 Kgy) during 6 days t sterilise them (cores « S »). At day 0 and after a month, peepers-gels DET probes (diffusive equilibrium in thin-films) were inserted for 24 h in all probes to determine the concentration profiles of the dissolved species.

Results and conclusion

Results suggested the enhanced release of uranium from the sediment by bioturbation (figure 1). The present study provides further evidence of the enhanced release of uranium from the sediment by bioturbation, possibly from the dissolutive reduction of iron oxyhydroxydes coated with uranium. The bioturbation is in fact likely to shift the redox processes with the further addition of dissolved oxygen by the Tubifex activity.

Abstract

X-ray Raman spectroscopy (XRS) is a rapidly developing technique for in situ observation of the near edge structures in the soft x-ray regime. This region includes the K- and L-edges of most common silicate melt forming elements including Si, Al, Mg and O. This is the only technique that provides direct in-situ observation of the near edge features of these elements at high pressure. This study uses a panoramic diamond anvil cell and beryllium (Be) gasket in the through gasket geometry to investigate the oxygen (O) K-edge within $CaMgSi_2O_6$ glass, an important high pressure phase. Experiments were performed on the Taiwanese inelastic x-ray scattering beamline BL12XU at SPring 8, Japan.

Preliminary results show a prominent edge feature at 533 eV. With increasing pressure the edge first shifts to slightly lower values (~0.1 eV/GPa) until 17.5 GPa whereupon the edge shift becomes positive. At 8 GPa, the O K-edge changes from being a single asymmetric peak (537 eV) at ambient pressure to a distinct double peak (537 and 541 eV). Above 8 GPa, the main peak retains these features though the resolution becomes degraded. The changes in the O K-edge are related to the changes in Si-O-Si glass network.

In comparison to XRS studies on the O K-edge of SiO_2[1], and its polymorphs, the edge features for $CaMgSi_2O_6$ glass are substantially more broad, indicating more complex bonding interactions of local structures. Additionally, the development of an intense peak at 544 eV in SiO_2 glass, thought to represent the presence of $Si^{[6]}$ found in stishovite, is lacking. Although the absense of the 544 eV feature does not preclude the presence of higher coordinated Si species within the glass structure, it does suggest that a more in-depth understanding of the O K-edge under pressure is essential to directly observing, interpreting and understanding the structural role of O within silicate melts at high pressure.

[4]. SERNAGEONIM, Santiago, Chile, aamigo@sernageomin.cl

Estimates of volatile budgets for volcanic eruptions are often based on volatile concentrations measured in melt inclusions (MIs) versus groundmass glass and on measurements made by direct sampling and remote sensing techniques. Here, we present new measurements and estimates of volatile budget of the 2011 Cordon Caulle eruption in Chile. The eruption from the Cordón Caulle rift zone, part of the basaltic-to-rhyolitic Puyehue-Cordón Caulle volcanic complex, began on 4 June 2011. The first phase of the eruption was characterized by an explosion from Cordón Caulle that produced a 5-km-wide ash-and-gas plume that rose to an altitude of 12.2 km a.s.l. We used three different approaches to assess the volatile budget and how the volatile content of the magma controls the explosivity of such an eruption.

1- Pumice samples were collected on June 18th, a few hours after their eruption. Volatile (S, Cl, F) and major element concentrations were measured in MIs trapped in plagioclase (An54-56) and pyroxene (Mg#39-44) phenocrysts and also in groundmass. Homogeneous dacitic to rhyolitic compositions were observed in the MIs with maximum concentrations up to 160ppm S, 2600ppm Cl and 800ppm F. The difference between the maximum volatile concentrations in the MIs and those measured in the groundmass indicates that ~0.2Mt SO_2, 0.5Mt HCl and 0.3Mt HF were released into the atmosphere during the Cordon Caulle eruption.

2- Satellite remote sensing data from instruments in NASA's A-Train spacecraft constellation, including the Ozone Monitoring Instrument (OMI) on Aura and the Atmospheric Infrared Sounder (AIRS) on Aqua, indicate a total SO_2 emission of ~0.2 Mt from the initial explosive phase of the 2011 Cordon Caulle eruption. The Microwave Limb Sounder (MLS) also detected HCl in the volcanic plume, providing some constraints on the SO_2/HCl ratio.

3- These two previous preliminary results will be discussed and compared with ash-leachate analyses. Leachates from pristine ash collected on June 21st will also provide a plume-gas proxy.

Experimental simulation of brine re-injection under subcritical and supercritical conditions

BRUCE W. MOUNTAIN[1]* AND ROMAIN SONNEY[2]

[1]GNS Science, Wairakei Research Centre, Taupo, New Zealand, b.mountain@gns.cri.nz (*presenting author)
[2]University of Neuchâtel, Centre for Hydrogeology and Geothermics (CHYN), Neuchâtel, Switzerland, romain.sonney@unine.ch

The re-injection of flashed brine at geothermal power plants is used to avoid adverse impacts of surface disposal. These fluids contain solutes that can precipitate and thus are detrimental to re-injection aquifer permeability. The deposition of silica is a particular issue that must be managed through brine aging and/or acid/base dosing. These treatments modify brine properties such that it is highly out of equilibrium with the aquifer mineralogy. The re-injection of fluids into deep (>4 km) drillholes, that may encounter supercritical conditions, also poses interesting questions in terms of fluid-rock interactions influencing reservoir permeability. Existing thermodynamic data used in modelling programmes are insufficient to provide adequate information on the effects of fluid-rock interactions in these situations. A viable alternative is direct simulation using experimental apparati.

Re-injection scenarios have been simulated using a continuous flow apparatus. The experiments replicate the interaction between waste brine with fractured greywacke, a typical re-injection aquifer lithology at power plants in the Taupo Volcanic Zone. Deoxygenated brine from Kawerau power station (SiO_2 950 mg/kg, Na 799 mg/kg, K 131 mg/kg, Cl 1027 mg/kg, SO_4 423 mg/kg) was reacted with crushed, sieved and cleaned greywacke at T/P conditions of 157^{o}C/27 bar, 204^{o}C/35 bar and 400^{o}C/279 bar. At the lowest temperature both polymerized and depolymerized brine were used to assess the effect of fluid aging. SEM/EDS examination showed that polymerized brine produced a continuous coating of amorphous silica composed of variable size silica spherules (<500 nm) cemented by dissolved monomeric silica. Using depolymerized brine, amorphous silica was also produced, the spherule size was uniform (80 nm) and the coating was more discontinuous. At 204^{o}C, precipitated minerals include chlorite, potassium feldspar, a clay mineral phase and a Ca-Na aluminosilicate, most likely a zeolite, based on its morphology. SiO_2 concentration dropped below amorphous silica saturation but no SiO_2 polymorph was identified indicating that the decrease in SiO_2 concentration was the result of precipitation of the minerals listed above. At 400^{o}C, the surfaces of the greywacke fragments were covered with continous coating of acicular secondary minerals. These include a fibrous Na-Ca-Fe-Mg aluminosilicate (pargasite?), a Na-Fe silicate with a distinct amphibole morpholgy (riebeckite?) and an unidentified Ca-aluminosilicate. Titanite was also present, likely derived from the sample chamber. These experiments show that laboratory simulations can be successfully used to reproduce fluid-mineral interactions that correlate with temperature conditions found in re-injection aquifers. They also provide information on changes in surface roughness and permeability of fractures during re-injection of geothermal brines.

Abstract

Peraluminous two-mica granites are predominant in the late-Hercynian Penamacor-Monsanto pluton [1], intrusive into a massive schist-greywacke sequence, and most marginal granites contain tourmaline, hinting at late-magmatic boron-metasomatism. This is further supported by occurrences of quartz (± mica) -tourmaline rocks along the narrow contact aureole. Tourmaline colour and colour zoning patterns are related to Ti abundance and Fe/Mg ratios, according to X-ray mapping. Notwithstanding ubiquitous late crystallization of euhedral to subhedral tourmaline in the marginal granites, textural and X-ray compositional evidence suggest that some tourmaline may nucleate on biotite and eventually replace it. Given their high proportion of *X*-site vacancies (58 to 78%), tourmalines from marginal granites are classified as foitites and those in the quartz-tourmaline rocks as foitites and Mg-foitites. Schorl-type substitution predominates over elbaite-type substitution, especially in granite tourmalines, which tend to be richer in Fe^{2+} and Al (± Mn) and poorer in Mg and Na (± Ca, Cr, V, Ti) than tourmalines from quartz-tourmaline rocks. In spite of their chemical differences, both tourmaline populations seem to bear a close genetic relationship, as evidenced in the (Fe+Mn)/(Fe+Mn+Mg) *vs.* Al/(Al+Mg+Li) linear trend, strongly suggesting that the same late-magmatic, B-enriched aqueous fluid was involved in their genesis.

Analytical and isotopic work currently in progress will soon add to these preliminary results on the Penamacor-Monsanto tourmalines.

Previous studies in the Laurentian Channel revealed that 2/3 of the dissolved oxygen depletion of bottom water is caused by changes in ocean circulation patterns in the northwestern Atlantic [1]. Nevertheless, elevated organic matter fluxes to the seafloor, from eutrophication due to enhanced fertilizer use in the watershed, could also increase locally the bottom water and sedimentary oxygen demand. The aim of this study was to improve the knowledge of the N budget in the coastal environments of the St Lawrence Estuary in order to better evaluate system's capacity to buffer anthropogenic N loading. Some studies showed that macrofauna of these coastal environments have an impact on benthic biogeochemical fluxes. Develop the understanding on complex interactions between sediment and benthos requires the use of innovative approaches because fauna activity and patchy distribution of organic matter introduce another level of complexity and initiate a heterogenic pattern of microzones. In this perspective, a closed-circulation, water jacket-insulated laboratory basins, called benthocosms, were used to preserve sediment mesocosms of 0.16 m^2 surface area, with controlled conditions of salinity and temperature. 5 different treatments were set up to specify the impact of different functional groups of macrofauna on nitrification, denitrification, anammox. A treatment without fauna was compared to a treatement with biodiffusers (*Mya arenaria* and *Macoma balthica*) and to a treatment with biodiffusers + gallery-diffusers (*Nereis virens*). Additional treatments were amended with NH_4^+ to mimic NH_4^+ excretion by organisms or with allylthiourea to inhibit nitrification by sediment bacteria. Fluxes of O_2, NO_3^-, NO_2^-, NH_4^+ have been determined by incubations. O_2 profiles were realised with microelectrodes and the vertical distributions of NO_3^-, NO_2^-, NH_4^+ were measured on porewater extracted by centrifugation. Isotope Pairing Technique was used to determine denitrification, anammox rates.

Mineral reactions at high pH relevant to radwaste disposal: a 15 year experimental study

E.B.A. MOYCE[1]*, K. MORRIS[2], A.E. MILODOWSKI[3], C. ROCHELLE[3], S. SHAW[1]

The use of cement within waste forms, engineering and potentially as backfill in the geological disposal of radioactive waste will produce a high pH (~pH 13-10) leachate plume as the geological disposal facility (GDF) evolves over hundreds to millions of years. This plume will create a chemically disturbed zone (CDZ) within the host rock causing alteration, dissolution and secondary precipitation of minerals. This has clear potential to change the rock's physical and chemical properties and affect radionuclide transport in the geosphere through alteration of flow paths or change in the host rock sorption capacity for radionuclides.

Here we describe analysis of a unique series of batch experiments which contain Borrowdale Volcanic Group (BVG) rock (quartz, orthoclase and dolomite with clay coatings) reacted in CDZ leachates at 70 ºC for 15 years. Two leachates were used: young cement leachate (pH 13.00, KOH and NaOH dominated); and evolved leachate equilibrated with a model deep groundwater (pH 12.2, $Ca(OH)_2$ and NaCl dominated)[1]. Experiments were characterised at 15 months and in this most recent work, at 15 years.

At 15 months mineral dissolution and formation of Ca-bearing silicate phases, e.g. apophyllite and Ca-K-Al silicate clays, was observed. However, recent work shows that by 15 years, extensive de-dolomitisation had occurred; here the dissolution of $CaMg(CO_3)_2$ resulted in extensive $CaCO_3$ re-precipitation and release of Mg^{2+}. By 15 years, it is apparent that this Mg^{2+} had reacted with silica in solution and clay particles on the primary mineral surfaces to produce Mg(K)(Al)-silicates of varying composition, structure and morphology as the major alteration products. The Ca-bearing silicates observed after 15 months of reaction were not present at 15 years. At all points, the alteration level was greatest in the young leachate, but the processes described occurred in both fluids.

Overall, these results demonstrate that the stability of secondary phases formed within the CDZ may change significantly over time and may affect both flow and radionuclide speciation. Clearly, this has implications for GDF safety case development.

Isotopic anomalies in planetary materials may reflect both early solar nebular heterogeneity inherited from presolar stellar sources [1], and processes that generated non-mass dependent isotopic fractionations [2,3]. The characterization of isotopic variations in heavy elements among early Solar System materials brings important insight into the stellar environment and formation of the solar system, and may also provide critical information about initial isotopic ratios relevant to long-term chronological applications [4]. One such heavy element, strontium, is a central element in the geosciences due to the widespread application of the long-lived ^{87}Rb-^{87}Sr radioactive system ($\lambda=1.393x10^{-11}y^{-1}$ [5]) as a chronological tool.

Through high-precision Sr isotopic measurements we show that the stable isotopes of Sr were heterogeneously distributed at both the mineral- and the planetary-scale in the early Solar System, and also that the Sr isotopic heterogeneities correlate with mass independent oxygen isotope variations. This correlation implies that most Solar System material was formed by mixing of at least two isotopically distinct components: a refractory inclusion-like component (rich in *p*-process ^{84}Sr or *s*-process ^{88}Sr, and ^{16}O), and an H-chondrite-like component (poor in ^{84}Sr or ^{88}Sr, and ^{16}O).

The heterogeneous distribution of Sr isotopes, most notably with respect to ^{84}Sr, may indicate that variations in initial $^{87}Sr/^{86}Sr$ of early Solar System materials reflect isotopic heterogeneity instead of having a chronological significance, as interpreted previously. For example, the corrected age difference between the formation of refractory inclusions and eucrites, as determined from Sr isotopic differences, is much shorter than previously suggested, placing the Sr chronology in agreement with other long and short-lived systems, such as U-Pb and Mn-Cr [6].

Exploring the relative influence of fluid and particle residence times on chemical weathering using a coupled geomorphic and geochemical model

SIMON M. MUDD[1*], KYUNGSOO YOO[2], KATE MAHER[3]

[1]School of GeoSciences, University of Edinburgh, Edinburgh, UK, simon.m.mudd@ed.ac.uk (* presenting author)
[2]Department of Soil, Water and Climate, University of Minnesota, St. Paul, MN, USA, kyoo@umn.edu
[3]School of Earth Sciences, Stanford University, Stanford, CA, USA, kmaher@stanford.edu

Minerals enter the weathering zone as landscapes erode and weathering fronts propagate downward through the near surface. In many, if not most landscapes, this process involves minerals first being chemically weathered and subsequently being subject to both chemical weathering and mechanical disturbance. The timescale of mineral transformation is on the order of thousands to millions of years [1]; this timescale is similar to the residence time of minerals within the physically disturbed, mobile regolith of eroding landscapes [2]. The chemistry of mobile weathered material on eroding hillslopes will reflect the integrated effects of different weathering environments along the hillslope profile. Thus it is crucial to account for sediment transport if one is to use the solid state chemistry of hillslope materials to infer weathering rates over long (10^3-10^6 yr) timescales [3, 4]. It has been postulated that the rate that minerals weather is partly a function of the time they spend in the weathering zone [5] and this time is closely related to the erosion rate. It has also been suggested that fluid, rather than mineral residence time plays a dominant role in determining the rate of chemical weathering in near-surface materials [6]. To examine the relative importance of mineral vs. fluid residence time or to examine if these two factors co-evolve we have developed a numerical model that traces minerals through the weathering zone, including their transit through a mobile, mixed regolith. The model is designed to assimilate field data so that hypotheses concerning the controls of chemical weathering rates can be tested with solid state chemistry and mineralogy from soil pits or cores. Chemical weathering in the model can be simulated using either the time the mineral has spent in the weathering zone or using a geochemical model that accounts for fluid flow and chemistry. Here we use the model to examine the sensitivity of weathering zone evolution to erosion rate. We also compare model predictions to geochemical data from a transect in Tennessee Valley, California in order to explore if variations in either fluid or mineral residence times can explain the observed geochemical patterns.

Binding environment of As(V) during microbial reduction of As-bearing biogenic Fe(III) minerals

E. M. MUEHE[1]*, L. SCHEER[1], G.MORIN[2], A. KAPPLER[1]

[1] Geomicrobiology, University of Tuebingen, Germany eva-marie.muehe@uni-tuebingen.de (* presenting author)
[2] Environmental Mineralogy, IMPMC, CNRS-UPMC, France guillaume.morin@impmc.upmc.fr

Aqueous As in As-contaminated groundwater and soil enters the human food chain (in)directly via drinking water, plants and animals, potentially having a devastating impact on the health of people. Correspondingly, research has put its focus on (bio)geochemical processes leading to the mobilization (release) and immobilization (removal) of As from aquifers and soil. Previous studies by Hohmann *et al.* [1] revealed that Fe(II)-oxidizing bacteria efficiently immobilize the two most common inorganic As species, As(V) and As(III), in aqueous systems by the formation of biogenic Fe(III) oxyhydroxides (ferrihydrite and goethite). Detailed analyses of these biogenic precipitates formed in the presence of dissolved As indicated As is efficiently removed from the aqueous phase via sorption to the mineral surfaces [2].

Environments that contain Fe(III) minerals and organic matter are usually also inhabited by Fe(III)-reducing microorganisms, suggesting that potentially microbial reduction of the biogenic Fe(III) (oxyhydr)oxides occurs. The microbially-mediated dissolution of these biogenic Fe(III) minerals could cause a release of the bound As or result in further immobilization of As due to the formation of secondary Fe(II/III) mineral phases. Additionally, the redox state of As might change during microbial Fe cycling and thus affect the mobility of As, since As(III) is generally more mobile than As(V).

In the study presented here, we followed the reduction of biogenic As-bearing Fe(III) minerals by the Fe(III)-reducer *Shewanella oneidensis* MR-1. Arsenic concentration and oxidation state were monitored in the liquid and solid phases. Mineralogy of the incubated solid phases was determined by X-ray diffraction and electron microscopy, whereas the As redox species and bonding environment in the mineral precipitates were analyzed by X-ray adsorption spectroscopy. We found that As(V) is immobilized during microbial reduction of biogenic As-bearing Fe(III) (oxyhydr)oxides while As(III) is mobilized to a significant extent. The immobilized As(V) is bound either to the remaining goethite or to the newly formed Fe(II) minerals and no mobilization occurred even though As(V) was transformed to As(III).

Early planetary differentiation and volatile accretion recorded in deep mantle Xenon isotopes

SUJOY MUKHOPADHYAY [1*], MARIA PETO[1], RITA PARAI[1], AND JONATHAN TUCKER[1]

[1]Harvard University, Cambridge, MA, USA, sujoy@eps.harvard.edu

^{129}Xe, produced from the radioactive decay of extinct ^{129}I, and ^{136}Xe, produced from extinct ^{244}Pu and extant ^{238}U, have provided important constraints on early mantle outgassing and volatile loss from Earth[1,2]. The low ratios of radiogenic to non-radiogenic xenon (^{129}Xe/^{130}Xe) in ocean island basalts (OIBs) compared to mid-ocean ridge basalts (MORBs) have been used as evidence for the existence of a relatively undegassed primitive deep mantle reservoir[1]. However, the low ^{129}Xe/^{130}Xe ratios in OIBs have also been attributed to mixing between subducted atmospheric Xe with MORB Xe, obviating the need for a less degassed mantle reservoir[3,4].

We present new noble gas data from OIBs and MORBs that demonstrate for the first time that the lower ^{129}Xe/^{130}Xe ratios in OIBs are derived from a lower I/Xe ratio in the OIB mantle source and cannot be explained solely through mixing between atmospheric Xe and MORB-type Xe. As ^{129}I became extinct prior to 100 Myrs after the start of the Solar System, OIB and MORB mantle sources must have differentiated by 4.45 Ga and subsequent mixing must have been limited. Thus, if the Moon-forming giant impact led to large scale planetary equilibration, it must have happened within 100 Myrs of the start of the Solar System.

The new precise xenon measurements also allow us to compute the proportion of Pu to U-derived fission Xe. Our measurements indicate that the plume source has a higher proportion of Pu- to U-derived fission Xe, requiring the plume source to be less degassed than the MORB source and supporting the long-term separation of MORB and OIB mantle sources. These conclusion are independent of noble gas concentrations and the partitioning behavior of the noble gases with respect to their radiogenic parents.

Calculated I/Pu ratios for the plume source is lower than the MORB source. This suggests that early accretion was volatile-poor compared to later accreting material, supporting the hypothesis of heterogeneous accretion[5]. Overall, the noble gases suggest at least two separate sources of volatiles for Earth and require that 4.45 Gyrs of mantle convection have not erased the signature of Earth's early differentiation. Finally, if noble gases in OIBs are derived from the Large Low Shear Wave Velocity Provinces (LLSVPs), then our study requires LLSVPs to be stable features that have existed since the formation of the Earth and are not exclusively composed of subducted slabs.

Sr-Nd-Hf-Pb isotopic constraints on the origin of alkalic basalts in the northern Cascade Arc

E. K. MULLEN*, M. CARPENTIER AND D. WEIS

PCIGR, University of British Columbia, Vancouver, BC Canada V6T 1Z4, emullen@eos.ubc.ca (*presenting author)

Calc-alkaline basalts are the predominant primitive magmas in the Cascade Arc. However, the northernmost segment of the arc, the Garibaldi Volcanic Belt (GVB), shows a progressive northerly shift from calc-alkaline to alkalic basalts. At the northern end of the arc, hawaiite and basanite occur at Salal Glacier, Bridge River, and Mt. Meager volcanic complexes. The gradient in alkalinity is accompanied by a northerly reduction in the "arc signature" and increases in P and T of basalt generation. These trends may be related to the age of the subducting plate, which decreases by ~4 Myr, potentially leading to reduced slab inputs and consequently smaller melt fractions formed at greater depths [1]. We have obtained new high-precision whole-rock Sr-Nd-Pb-Hf isotope and trace element data on GVB basalts to geochemically characterize the mantle beneath each volcanic center and determine whether the geochemical gradients displayed by the basalts can be explained solely by changes in slab input or require multiple mantle components.

Relative to other primitive Cascade arc basalts, GVB basalts have lower ^{208}Pb/^{204}Pb at a given ^{206}Pb/^{204}Pb (18.67-18.92) and higher ε_{Nd} (3.8-8.5) at a given ^{87}Sr/^{86}Sr (0.70310-0.70396). The alkalic GVB basalts have the most depleted Pb isotopic ratios yet identified in the Cascade Arc. In Pb isotopic space, the GVB defines a linear array extending from Juan de Fuca MORB to subducting sediment in the northern Cascadia basin, which we interpret as a mixing line indicating variable sediment input to the mantle. A northerly La/Nb decrease from ~4.25 at Glacier Peak to ~0.78 at Bridge River confirms the reduction in arc signature, but an inverse correlation between ε_{Nd} and ε_{Hf} (8.7-13.3) indicates arc-parallel mixing between two isotopically distinct mantle sources, one dominating in the south and the other in the north.

Trace element modeling, phase equilibria and thermobarometry indicate that the alkalic GVB basalts segregated from the mantle at high pressures and MORB-like temperatures (up to ~2.7 GPa, 1475°C) and have garnet lherzolite residues. The mantle source is not modified by a subduction component and is isotopically depleted, yet it is enriched in incompatible elements. These correlations indicate either long-term mantle source depletion coupled with a recent metasomatic enrichment event, or extremely low melt fractions. In contrast, calc-alkaline basalts of the southern GVB (Mt. Baker, Glacier Peak) were generated near the base of the crust from depleted lherzolite or harzburgite metasomatized by sediment melt or fluid.

Because the alkalic basalts lack an arc signature, have a hot, recently-enriched mantle source, and are located at the termination of the currently subducting slab, we propose that they are generated by a "slab edge effect". Decompression melting is triggered by upwelling of asthenospheric mantle through a window between the active Juan de Fuca plate and near-stagnant Explorer plate [2,3].

Accuracy of in-situ Sr isotope analysis of biogenic phosphates by LA-MC-ICPMS – a problem reassessed

WOLFGANG MÜLLER[1, *)], ROBERT ANCZKIEWICZ[2]

[1]Dept. of Earth Sciences, Royal Holloway University of London, Egham, UK, w.muller@es.rhul.ac.uk

[2]Inst. of Geological Sciences, Polish Academy of Sciences, Krakow, Poland, ndanczki@cyf-kr.edu.pl

In-situ Sr isotope analysis by LA-MC-ICPMS has been available for more than fifteen years [1]. While precise and accurate data can be obtained in this way for (high-Sr) carbonates and other materials, for phosphates accuracy (and precision) of in-situ analyzed Sr isotope data have proven difficult to obtain [2, 3]. Specific to Ca-phosphates, CaPO, a molecular interference on mass 87 ($^{40}Ca^{31}P^{16}O$), as well as doubly-charged Yb & Er in case of REE-rich inorganic apatite have been invoked as analytical obstacles, besides $^{84,86}Kr$, ^{87}Rb, Ca-Argides. Moreover, all is exacerbated by the relatively low Sr concentrations of biogenic phosphates (<100 to few 100 ppm Sr).

In view of the importance of Sr-isotopes in biogenic phosphate as mobility proxy in vertebrates - in teeth potentially providing sub-seasonal resolution when analyzed in-situ by LA-MC-ICPMS - we have evaluated in-situ Sr-isotope analysis for a range of biogenic phosphates. Using a RESOlution M-50 193 nm excimer laser-ablation system, featuring a Laurin two-volume cell, coupled to a Neptune MC-ICPMS, we evaluate spectral interferences on ^{87}Sr by focussing on: 1) Routine 'robust' plasma conditions ($ThO^+/Th^+ < 0.1$ %), which because of the highest oxide bond strength for ThO [4] imply that all other oxides will be present in lower abundances. 2) Accurate naturally invariant $^{84}Sr/^{86}Sr$ ratio (0.0565 after mass bias correction) as monitor of appropriate interference corrections (Kr, CaAr, REE^{2+}). 3) Careful mass scans at medium mass resolution ($M/\Delta M = 4000$) because CaPO and ^{87}Sr are resolvable above $M/\Delta M = 3900$. 4) Focus on the accuracy of the ^{87}Rb-correction on mass 87 since mammalian bioapatite can have relatively high $^{85}Rb/^{86}Sr$ of up to ~0.01 and sometimes even higher.

For the analytical (plasma) conditions utilized, we find no evidence for any molecular interference (CaPO) at mass 87 using medium resolution mass scans. Furthermore we obtain accurate $^{84}Sr/^{86}Sr$ ratios (0.0565) for both shark teeth (high-Sr) as well as mammalian enamel (few 100 ppm Sr maximum). $^{87}Sr/^{86}Sr$ ratios for modern shark teeth of 0.70917 ± 3 (2 SD) are indistinguishable from modern seawater (0.70917). Comparing TIMS and LA-MC-ICPMS Sr isotope data of the same tooth enamel characterized by variable Sr-isotope ratios inevitably highlights the problem of scale because mg-sized fragments are utilized for TIMS vs. ~100 μm spot sizes for LA-ICPMS. Nevertheless we find very good agreement in $^{87}Sr/^{86}Sr$ for corresponding enamel sections using both methodologies, but the ultimate accuracy depends on the magnitude of the necessary ^{87}Rb correction; corresponding results will be presented.

Evaluation of contaminated sediment remediation techniques

CATHERINE N. MULLIGAN [1*]

[1*]Concordia University, Montreal, Canada, mulligan@civil.concordia.ca

Introduction

An evaluation of the management options must be made for contaminated sites. In particular, the various techniques must be considered for the remediation of sediments when the sediment leads to the accumulation of contaminants in aquatic life or when the release of hazardous materials from sediments becomes a serious problem. The options can include capping, dredging, or physical, biological, and/or chemical treatments. Sustainable management options for contaminated sediments are required and will be evaluated. In situ remediation could be beneficial over dredging due to a reduction in costs and lack of solid disposal requirements.

Approach

Selection of the most appropriate remediation technology must coincide with the environmental characteristics of the site and the ongoing sediment fate and transport processes. To be sustainable, the risk at the site must be reduced, and the risk should not be transferred to another site. The treatment must reduce the risk to human health and the environment. Cost-effectiveness and permanent solutions are significant factors in determining the treatment. Sites vary substantially, and there can be substantial uncertainty involved in the evaluation process. However, decisions must be made based on the information available.

Both in situ and ex situ treatment approaches are examined. For example, environmental dredging requires evaluation of the risk of dredging, determination of disposal methods and/or potential beneficial use. Innovative integrated decontamination technologies must be utilized.

Results and Conclusions

To work towards sustainability, indicators must be identified and quantified, including waste must be minimized, natural resources must be conserved, landfill deposition should be minimized and benthic habitats and wetlands must not be lost and must be protected. Innovative integrated decontamination technologies must be utilized. The fate and transport of contaminants must be understood more thoroughly to develop appropriate strategies. A long term vision is needed. Otherwise, natural resources will continue to be depleted, landfills will continue to be filled with contaminated sediments, and biodiversity in the aquatic geoenvironment will be diminished. Integrated innovative management practices need to be developed and applied such as in situ techniques that reduce waste management requirements.

Arsenic Mobility is Mediated by Bacterial Reduction in New Jersey Shallow Groundwater

A. C. MUMFORD[1*], J. L. BARRINGER[2], P. A. REILLY[2] AND L. Y. YOUNG[1]

[1]Rutgers University, New Brunswick, NJ, USA amumford@eden.rutgers.edu, (*presenting author) lyoung@aesop.rutgers.edu

[2]US Geological Survey, NJ Water Science Center , West Trenton, NJ, USA. jbarring@usgs.gov, jankowsk@usgs.gov

Introduction

The mobilization of arsenic bound to aquifer sediments is a source of contamination in groundwater in New Jersey. Deep Coastal Plain sediments have average As concentrations of 15-23 mg/kg [1,2], and As concentrations of 26 mg/kg have been recorded in shallow glauconitic sediments[3]. In a prior study [3] we demonstrated that As reducing bacteria promote As release and mobility in groundwater at a New Jersey Coastal Plain site. We have expanded this study to investigate the potential for microbial As mobilization beneath the streambeds at two other sites, Six Mile Run and Pike Run, in the New Jersey Piedmont. Groundwater at the Six Mile Run site has an As concentration of 27 µg/L, which is in excess of the 5µg/L limit set by the NJDEP, while the As concentration at the Pike Run site is 2.1 ug/L.

Methods:

Groundwater was sampled on gaining reaches of Pike Run and Six Mile Run in the New Jersey Piedmont Physiographic Province, and inoculated into anaerobic microcosms with acetate as a carbon source and As(V) as an electron acceptor. Arsenic reduction was monitored by HPLC. Groundwater was filtered on site, and DNA was extracted from the filters for amplification and cloning of the16S rRNA gene and the arsenate respiratory reductase gene, *arrA*, a biomarker for As(V) respiration [4]. 16S rRNA gene sequence data was analyzed using ARB [5] and the SILVA 108 NR 16S rRNA gene database [6]. *arrA* gene sequence analysis was performed using ARB [6]. Operational Taxonomic Unit (OTU) analysis was performed with mothur [7].

Results and Conclusions

Microcosms developed from Six Mile Run groundwater reduced 1 mM of As(V) to As(III) in 30 days, while microcosms from Pike Run did not reduce As. Based on a 97% similarity cutoff, 10 OTUs unique to Six Mile Run were identified, and 11 OTUs unique to Pike Run were identified. The sites shared 4 OTUS out of the 25 sequenced, suggesting that distinct bacterial communities were present at each site. Based on the *arrA* gene, distinct arsenic respiring communities were identified at each site, with 8 unique OTUs found at Six Mile Run, and 11 unique OTUs shared at Pike Run. Globally, the *arrA* sequences recovered from both Pike Run and Six Mile Run are most similar to those recovered from the Meuse River in France, and distinct from those recovered from marine environments. Our findings demonstrate that while the *arrA* gene may indicate the presence of As reducing organisms, microcosm studies are necessary to predict microbial As reduction and mobilization from sediments.

Combining macroscopic invasion percolation with mass transfer to model bubble-facilitated transport of VOCs in groundwater

KEVIN G. MUMFORD[1*], PAUL R. HEGELE[1], MAGDALENA M. KROL[2,3] AND BRENT E. SLEEP[3]

[1]Queen's University, Dept. of Civil Engineering, Kingston, Ontario, Canada, kevin.mumford@civil.queensu.ca (*presenting author)

[2]Western University, Dept. of Civil and Environmental Engineering, London, Ontario, Canada, mkrol4@uwo.ca

[3]University of Toronto, Dept. of Civil Engineering, Toronto, Ontario, Canada, sleep@ecf.utoronto.ca

Gas bubbles present in otherwise water-saturated porous media can affect the transport of volatile organic compounds (VOCs) in groundwater. The partitioning of VOCs to gas bubbles, with the bubbles acting as a variable-volume sink, can retard VOC transport, and can also affect the transport of other volatile species (e.g., dissolved atmospheric or biogenic gases). If sufficient gas volumes exist for bubbles to be vertically mobilized, the transport is also affected by the creation of an additional mass transport pathway – the buoyant advection of the bubbles – which can carry mass away from regions with higher aqueous concentration to those with lower aqueous concentration, resulting in mass partitioning from the bubble back to the aqueous phase. This type of transport has been observed in a variety of systems, including: the natural attenuation of hydrocarbon plumes, the expansion of trapped gases above non-aqueous phase liquid (NAPL) sources, and remediation by in situ thermal treatment.

In these types of systems, where the expansion and mobilization of the gas bubbles is controlled by the mass transfer between the aqueous phase and the trapped gas phase, it is important to model both the partitioning of multipe volatile species and the subsequent discontinuous bubble flow as mass transfer and immicible displacement occur over similar time scales. One promising approach is the use of macroscopic invasion percolation (MIP) to model gas movement, combined with continuum-scale simulation of aqueous-phase transport and mass transfer between phases. The MIP routine can be modified to include gravity for biased vertical growth, as well as fragmentation and mobilization to reproduce bubble behaviour, provided that gridblock sizes are less than a critical length scale required for mobilization. Here, simulations of VOC transport in the presence of mobilized gas bubbles were compared to an intermediate-scale laboratory flow cell experiment, where non-monotonic changes in concentrations were observed at higher-than-expected elevations above a dense non-aqueous phase liquid (DNAPL) pool. Additional simulations that investigated the potential role of bubbles during in situ thermal remediation showed greater mass removal from a targetted heating area due to bubble formation and mobilization. Finally, a third set of simulations investigated bubble-facilitated transport of VOCs in heated and unheated, heterogeneous systems.

Blatchford Lake intrusive suite, new geochronology and barometric estimates: implications for mineralization

THOMAS MUMFORD[1*], BRIAN COUSENS[1]

[1]Carleton University, Ottawa, Canada, tmumford@connect.carleton.ca (* presenting author)
[2]Carleton University, Ottawa, Canada, bcousens@earthsci.carleton.ca

Introduction

The Paleoproterozoic Blatchford Lake intrusive suite, can be subdivided into two cogenetic separate lobes: a metaluminous western lobe and a peralkaline eastern lobe which is host to the world class Nechalacho rare metal deposit. The western lobe consists of a multi-phase layered gabbroic sequence, cross-cut by a series of sills varying from syenite to granite. The eastern lobe comprises a large sub-circular granite that grades to a syenite core. Underlying the syenite core is a layered suite of silica-undersaturated rocks collectively known as the Nechalacho layered syenite series (NLSS). Rare metal mineralization occurs in the upper units of the NLSS, which have been overprinted by intense hydrothermal alteration. Approximately two kilometers east of the Nechalacho mineralized zone, two small plutonic stocks, believed to be related to the regional Compton Intrusive suite [2], cross-cut the peralkaline granite.

In situ U-Pb zircon laser ablation ion-coupled plasma mass spectrometry (LA-ICP-MS) was used to date the Compton Intrusives stocks (1895±5 Ma) and to provide the first reliable age estimate for the NLSS (2187±8 Ma). These new dates help define relationships between phases in the eastern lobe, and resolve discrepencies in the chronology of the Blatchford Lake intrusive suite.

Using the Al-in-hornblende barometer [1], pressure estimates were made on hornblende and edenite crystals from granitic and syenitic phases of the western lobe. These result indicate a mid-crustal emplacement (~3.5 kbar) for the late cross-cutting granite and syenite sills. Given that the ages between the eastern and western lobes are within analytical error, these pressure estimates can be used to infer the pressure conditions during crystallization of phases within the eastern lobe.

This new geohronological and barometric information helps to constrain the overall evolution of the Blatchford Lake intrusive suite, and therby aids in developing models to explain the exceptional enrichment in rare-metals in select phases.

PGE systematics of refractory mantle: role of Pt alloy

JAMES E MUNGALL[1*] FRANCES JENNER[2], RICHARD ARCULUS[2], JOHN MAVROGENES[2]

[1]University of Toronto, Canada [2]Australian National University, Canberra, Australia * mungall@geology.utoronto.ca

Pt/Pd variability in the mantle and picrites

The primitive mantle has slightly sub-chondritic Pt/Pd values close to 1.1 [1]. Extreme degrees of melt depletion, as recorded by decreases in CaO, Al_2O_3, and increases in Mg/(Mg + Fe) in whole rock or olivine, confer a distinctively high Pt/Pd ratio to the mantle restite, ranging from 5 to 10 in some massif peridotites to as high as > 100 in ultradepleted mantle xenoliths from the Kaapvaal craton [2,3]. A complementary reduction in Pt/Pd to values similar to unity is observed in a global compilation of data for picrites, which evolve to still lower Pt/Pd approaching 0.1 by fractional crystallization in the absence of sulfides [4]. We present data for primitive boninites from Chichi Jima and the northern Tonga arc, which equilibrated with $Fo_{>90}$ olivine and show extremely low Pt/Pd with values ranging from 0.1 to 0.5, while also showing strong depletions in Ir and Ru compared to Rh that we have previously attributed to the existence of Ir-Ru alloy or laurite in the restite [5].

Partition coefficients and models

Bulk partition coefficients D^*_{Pt} and D^*_{Pd} estimated from studies of fractionated lava lakes are approximately 0.2 - 0.6 and 0.1 - 0.2 [6]. Experimental determinations of D_{Pt} and D_{Pd} for olivine are < 0.01 and 0.006 at the FMQ oxygen buffer [7]; values for pyroxenes are similar and, even in chromite they are <0.03 [8].

The existence of Pt/Pd fractionations spanning two to three orders of magnitude between parental picritic magmas and their mantle residues positively requires the existence of a restite phase with dramatically higher D_{Pt} than D_{Pd}. Alloys of Os-Ru-Pt have been observed in mantle peridotite [9,10], and consideration of Os solubility in sulfide liquid and bulk Os concentration in the mantle requires the existence of Os alloy even in the presence of sulfide melt in the mantle [11]. Our models show that the range of Pt/Pd observed in peridotite massifs, mantle xenoliths, boninites, and tholeiitic picrites is consistent with the ubiquitous occurrence of alloy-hosted Pt in amounts ranging from 2 to 7 ppb, whereas Pd appears to be hosted only by sulfide phases, becoming extremely incompatible once sulfide has been consumed during partial melting.

The Bushveld complex of SA, with Pt/Pd between 1.5 and 5, is a unique exception [12]. An unusual process may have destabilized Pt alloy in the highly refractory SCLM of the Kaapvaal craton during emplacement of the Bushveld.

Is the bulk Earth Nb/Ta chondritic?

CARSTEN MÜNKER[1*], ANDREAS STRACKE[2], VERENA BENDEL[3], HERBERT PALME[4], ANDREAS PACK[3]

[1]Institut für Geologie und Mineralogie, Universität zu Köln, Germany, c.muenker@uni-koeln.de (* presenting author)
[2]Institut für Mineralogie, Universität Münster, Germany,
[3]GZG, Universität Göttingen, Germany
[4]Forschungsinstitut Senckenberg, Frankfurt, Germany

The accessible silicate Earth is characterized by a Nb deficit of ca. 30% relative to most groups of chondrites [1]. This Nb deficit has been attributed to a slightly siderophile affinity of Nb during high-pressure formation of the Earth's core [1,2]. The finding of low Nb/Ta ratios in CV chondrites (ca. 17 [1]), however has challenged this model, as CV chondrites closely resemble the Earth's composition in their relative abundances of volatile and refractory elements. If the bulk Earth indeed had a CV-chondritic or even lower Nb/Ta ratio, the Nb deficit in the silicate Earth would be much less pronounced, and models using Nb/Ta ratios to assess conditions during core formation [e.g., 3,4] would neeed some revision.

In order to investigate the cause for the low Nb/Ta in CV chondrites, we analyzed small ca. 0.6 g slices taken from a single piece of Allende [5], together with an aliquot of the Smithsonian powder that is representative for bulk Allende. Ratios of HFSE were determined at high precision using isotope dilution and the Neptune MC-ICPMS at Cologne-Bonn [6] and are compared to high precision data for REE previously determined at ETH Zürich and RSES Canberra [5, unpulished]. The Smithsonian Allende powder yielded a Nb/Ta of 19.1±0.8 (2σ), within error of values for other chondrite groups (19.9±0.6, [1]). Conversely, the Nb/Ta measured for the small Allende slices span a wide range from 14.2 to 22.0. Ratios of Zr/Nb are correlated with Nb contents and range towards values as low as 10, much lower than the chondritic value (13.5, [3]).

The Nb/Ta systematics found for Allende indicate that in contrast to Zr-Hf, Nb and Ta are not distributed homogenously in CV chondrites. However, the data for the large Smithsonian powder aliquot suggest that the bulk Allende parent body had a Nb/Ta indistinguishable from other types of chondrites. Notably, the Nb/Ta in the small Allende slices are negatively correlated with Tm/Er ratios (0.16 to 0.26). At near-chondritic Tm/Er (ca. 0.16 [7]), the mesured Nb/Ta in the Allende splits scatter around a value of 20, typical of the chondrite average. It has previously been argued that the elevated Tm/Er in many CV chondrites can be attributed to the presence of type II CAIs [5]. Low Nb/Ta ratios occasionally found in CV chondrites may reflect selective enrichment group II CAI.

The co-variation between Nb/Ta and Tm/Er could imply that the bulk Earth exhibits a superchondritic Tm/Er, if it had a low Nb/Ta. This is clearly not the case, as the silicate Earth displays a Tm/Er that is not resolvable from that of CI-chondrites [7]. The Nb/Ta of the bulk Earth should therefore overlap the chondritic value and the Nb deficit in the Earth's mantle reflects its siderophile behaviour.

Microchemistry of amphiboles near the roof of a mafic magma chamber

J. BRENDAN MURPHY[1*], STEPHANIE BLAIS[1], MICHAEL TUBRETT[2], DANIEL MCNEIL[1] AND MATTHEW MIDDLETON[1]

[1] St. Francis Xavier University, Earth Sciences, bmurphy@stfx.ca
[2] Memorial University of Newfoundland, MicroAnalysis Facility - Inco Innovation Centre (MAF-IIC),

The Late Neoproterozoic Greendale Complex is a suite of arc-related appinitic rocks ranging from ultramafic to felsic in composition that crystallized at shallow crustal levels under conditions of high pH_2O. Amphibole is the dominant mafic mineral in ultramafic to mafic rocks and displays the extraordinary variability in texture and modal abundance that is characteristic of appinite suites. These features allow sensitivity of amphibole composition (major, trace and REE) to the evolution of water-rich magma to be investigated.

All amphiboles in mafic and ultramafic rocks are calcic, with $(Ca+Na)_B \geq 1.34$ and $Na_B < 0.67$ apfu, with Si^{IV} between 6.1 and 7.3. They predominantly range in composition from tschermakite, to tschermakitic hornblende, to magnesio-hornblende and display a dominance of edenite ($Na,K_A + Al^{IV} = Si^{IV}$) substitution. Although each sample exhibits remarkably uniform $Mg/(Mg+Fe^{2+})$ over a wide range in Si of up to one formula unit, the mafic rock amphiboles are characterized by lower (0.5 to 0.7) $Mg/(Mg+Fe^{2+})$, compared to the ultramafic rocks (0.7 and 0.9). REE and trace element profiles of amphiboles from mafic rocks are remarkably consistent. REE profiles are bow-shaped, and are characterized by depletion in LREE (La/Sm ≈ 0.61), a slight depletion in HREE (Gd/Yb ≈ 1.55) as well as a negative Eu anomaly, which is attributed to co-precipitation of plagioclase. REE and trace element profiles of ultramafic amphiboles are divided into two groups that correspond to different textural settings: Group A amphiboles occur in all specimens analyzed and are very similar to the profiles of the mafic rocks. In contrast, Group B amphiboles display relative enrichment in light REEs (La/Sm ≈ 2.05), have lower ΣREE, and lack a negative Eu anomaly relative to Sm and Gd. Group B amphiboles are more enriched in Th and U and show a more pronounced depletion in Ta, Nb, Ti and Y. Group B amphiboles grew in a reaction relationship with olivine and pyroxene. Groups A and B are virtually indistinguishable with respect to the major elements used for amphibole classification, suggesting that REE and selected trace element data when combined with textural observations may provide important additional insights into phase equilibria and conditions of crystallization.

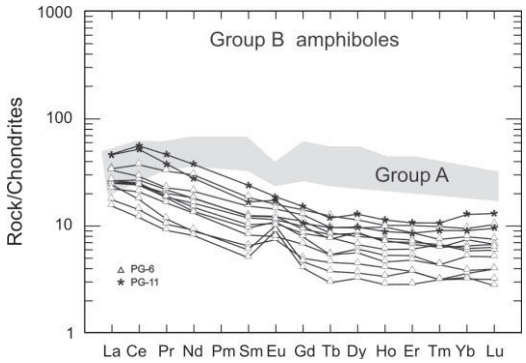

Figure 1. Contrasting REE profiles of amphiboles in ultramafic rocks

The fate of volcanic ash in marine sediments

RICHARD W. MURRAY[1](*), JULIE C. SCHINDLBECK[2], RACHEL P. SCUDDER[1], STEFFEN KUTTEROLF[2]

[1]Department of Earth Sciences, Boston University, Boston, MA, USA, rickm@bu.edu; rscudder@bu.edu.

[2]GEOMAR, Kiel, Germany, jschindlbeck@geomar.de; skutterolf@geomar.de

Volcanic ash transported to the oceans is one of the main mechanisms by which terrigenous material and nutrients are delivered to the deep sea. Alteration of volcanic glass in the ocean is an important component of marine biogeochemical cycling, with the ash acting as a source and/or sink of many major and trace species.

Ash in marine sediment also provides an important record of explosive subduction zone volcanism. Discrete, visible ash layers are common in the vicinity of subduction zones and have originated from larger explosive eruptions at the volcanic arc. The chemistry and provenance of these visible ash layers are mostly well known and the layers themselves facilitate direct or indirect dating and can therefore be used as marker horizons in marine sedimentology and stratigraphy. Ash layers may also help estimate eruptive volumes, and contribute to the chemistry of sediments and fluids in these regimes. Normal grading and mineral enrichment at the base, glass shard morphology, as well as changes in ash color that are mostly correlated to variations in the chemistry of the primary glass, are features that are relatively easily recognized within the marine sediment column.

The qualitative and quantitative fate of discrete ash layers in sedimentary sequences is only partly known. In theory, bioturbation should destroy layers less than ~10 cm thick, yet well preserved layers of a few cm's thickness are found even in bio-irrigated deposits. By detailed geochemical and sedimentologic study, we here quantify how the incorporation of the primary volcanic ash in marine sediments proceeds above ash layers and with distance from the source. We further discuss how ash is captured within the sediment column and recycled in subduction zones, and quantitatively address how ash layers compositionally affect the hosting sediment column.

Stratigraphic sampling of sequential 1-3 cm slices above primary ash layers from offshore Central America show that densities decrease due to lesser amounts of volcanic glass in the silty clay marine sediments. The bulk rock chemistry reflects this gradation as well and can be quantified for single elements like U, Cr, Zr, V, and Pb, depending on the composition of the volcanic glass (mafic versus felsic). The most important component for those changes is the <32 µm fraction, since ~14 wt% of this is still composed of volcanic glass. Additionally, we see a decreasing frequency of ash layers with increased distance from the source (e.g., 200 vs. 350 km). Quantification of this decrease will help establish a volcanic matter correction factor for chemical and sedimentological parameters with distance from source in subduction zone settings.

Analog studies of brine cryoenvironments in the Canadian high Arctic

The Canadian high Arctic offers several unique cryoenvironments including cold saline springs and extensive permafrost that are working analogs to the conditions that are known, or are suspected, to exist on Mars, and potentially on other astrobiological targets. In particular, fluvial features linked to past and current processes on the surface of Mars suggest that liquid brines near the surface exist and could have been a potential abode for past or extant microbial life. Our recent research focused on detecting and examining microbial life in the unique cold saline/brine springs on Axel Heiberg Island. The microbiology and geochemistry of a habitat found within the Gypsum Hill (GH) spring site will be presented, describing a constant circum-zero saline (7.5 % salinity) habitat that is host to chemolithotrophic sulfur-oxidizing bacterial filaments that flourish in the Arctic winter. The GH spring site is a sulfide (25-100 ppm) and sulfate (2300-3700 mg/L) abundant system serving as an analogue for the abundant sulfate deposits and potential sulfate-rich brines on Mars. The GH springs support viable, active (down to -10°C), and low diversity microbial communities dominated by *Thiomicrospira* spp.. Environmental meta-omic analyses (genomic, proteomic, transcriptomic) were aimed at uncovering insights into: a) the sulfur metabolizing community; b) the diversity of core metabolic genes required to utilize essential nutrients (C, N) within this extreme environment; c) the pathways of energy utilization i.e. CH_4, H_2, sulfur; d) the evolutionary and physiological traits required for microbial life in this subzero, hypersaline cryoenvironment. The meta-analyses provided greater insight into the predominant *Thiomicrospira* metabolic enzymes expressed as part of the active microbial growth, activity and adaptive traits during the late Arctic spring. *In situ* geochemical and isotopic analyses of the fractionation of multiple-sulfur isotopes resulting from bacterial sulfur-metabolism vs. abiotic isotope exchange illustrated the route of biogeochemical sulfur cycling and traced the formation and preservation of potential sulfur-based biosignatures ($\delta^{33}S$, $\delta^{34}S$ and $\delta^{36}S$ stable isotopes). These studies demonstrate how complimentary molecular tools provide a functional link between microbial life and the geochemistry of their environments, how we can predict potential biosignatures of microbial activity and illustrate unique traits linked to microbial survival within these brine cryoenvironments analogous to past or perhaps present conditions on Mars.

Iron is an essential element for all organisms, and it is a limiting nutrient in many parts of the oceans, including the unproductive regions of the Southern Ocean. Although Fe is not a common limiting nutrient in terrestrial aquatic systems, Fe-minerals control the solubility and bioavailability of several nutrients and contaminants. While the dominant fraction of Fe occurs in the form of particulates in aquatic systems, its speciation and mineralogy are less well understood. Here we show how Fe *L*-edge spectroscopy can be used to study the speciation of iron in Fe-rich colloids.

Previous studies have shown that Fe *L*-edge XANES spectra can be used to identify the distribution of ferrous and ferric species accurately. Our study shows that the spectral features in the L_3-edge XANES spectra are sensitive not only to the oxidation state of Fe, but also to small changes in the structural environment of Fe. We use the differences in energy and the spectral intensities of different Fe *p-d* transitions to identify different iron oxides and oxyhydroxide phases. However, saturation and self-absorption problems, associated with transmission and fluorescence spectra of Fe-rich compounds respectively, make positive identification of some of the Fe-phases difficult.

Using the *L*-edge XANES spectroscopy studies on crystalline and amorphous Fe-oxides and oxyhydroxides, we conducted speciation of Fe in the colloidal fraction of Southern Ocean water, and in several South African streams flowing into the Atlantic Ocean. We find that the Fe in the riverine environments is present in the ferric form, which is associated primarily with amorphous Fe-oxides. These Fe-oxides also often exhibit Al substitution. The colloidal Fe-speciation also changed dramatically with distance away from South Africa, and with different Fe-species in different frontal zones in the Southern Ocean. Characterization of colloidal Fe in freshwater lakes also indicates the abundance of amorphous Fe-oxide phases. Although crystalline iron oxides are found in several samples, amorphous Fe-oxides appear to be much more abundant than the crystalline phases, at least in the colloidal pool. A detailed discussion of the method, and its application to the identification of different Fe-phases will be discussed.

^{26}Al-^{26}Mg and ^{10}Be-^{10}B systematics in CAIs from CO and CV chondrites

Fine-scale chronology is very important to discuss the dynamic evolution of the early solar system. Most of the critical events such as the formation of Ca, Al-rich inclusions (CAIs) and chondrules as well as the accretion and early differentiation of planetary bodies have occurred within several Myr from the collapse of the molecular cloud [1]. Short-lived chronometers are extremely useful to obtain highly-precise ages for a variety of extraterrestrial materials. In contrast to the most commonly used ^{26}Al-^{26}Mg system, the ^{10}Be-^{10}B chronometer has been rarely used because of the uncertainty if the parent nuclide (^{10}Be, $T_{1/2}$=1.5 Myr) was homogeneously widespread in the solar nebula. In order to attest the usefulness of the ^{10}Be-^{10}B system, we have measured the ^{10}Be-^{10}B ages in CAIs from two CO chondrites (Moss and Felix) and one CV chondrite (NWA 2364) coupled with their ^{26}Al-^{26}Mg ages. CO chondrites are known to have chemical and mineral compositions similar to those in CV chondrites. However, *in-situ* analysis of CAIs in CO chondrites has been hindered by their relatively small mineral sizes compared to CV CAIs. In this study, fine-grained CAIs were measured by NanoSIMS installed at the AORI, Univ. of Tokyo.

The meteorite fragment containing CAIs was mounted in a resin, and thoroughly polished. Because boron contamination is one of the major problems in SIMS analysis for B-poor samples, we cleaned the polished sample surface with diluted HF prior to analysis. The mineral compositions of CAIs were observed by the SEM-EDX at the Univ. of Tokyo. We found some melilite grains (~50 μm) in CAIs from Moss and Felix, which were subject to the ^{10}Be-^{10}B and ^{26}Al-^{26}Mg analyses using NanoSIMS. We found no melilite in CAIs from NWA 2364, and only the ^{26}Al-^{26}Mg system was analyzed by using hibonite grains.

We observed excess ^{10}B/^{11}B ratios in Moss CAIs, which yielded an initial ^{10}Be/^{9}Be = $(1.05\pm0.56)\times10^{-3}$. This is consistent with the canonical value of Allende CAI, $(1.04\pm0.09)\times10^{-3}$, within analytical uncertainty [2]. In contrast, we were unable to obtained the initial ^{10}Be/^{9}Be ratio for Felix CAI, because of the limited Be/B ratios in the melilite grains analyzed. We speculate that this is caused by B contamination, because we cleaned the mounted Felix by relatively mild HF (0.01M), while Moss was cleaned by 0.1M HF. This implies that the removal of B contamination is critical for the measurement of ^{10}Be-^{10}B system in CAIs. For the ^{26}Al-^{26}Mg system, all CAIs yielded initial ^{26}Al/^{27}Al ratios identical to the canonical value (5.11×10^{-5}, [3]) within analytical uncertainties. This reinforces the usefullness of the ^{10}Be-^{10}B system as for a chronometer in the early solar system.

During the Pleistocene, large continental ice sheets episodically appeared in the Northern Hemisphere, covering large parts of Europe and North America. Besides the results based on benthic oxygen isotope records, which predominantly represent variations in global ice volume, little is know about the timing of and astronomical control on the advances and retreats of the continental ice sheets in the Northern Hemisphere during the late Pliocene and early Pleistocene (3-2 million years (Ma) ago).

Here we therefore present the first orbitally-resolved records of terrestrial higher plant leaf wax input to the North Atlantic covering the last 3.5 Ma, based on the accumulation of long-chain *n*-alkanes and *n*-alkanl-1-ols at IODP Site U1313 [1]. These lipids are a major component of dust, even in remote ocean areas, and have a predominantly aeolian origin in distal marine sediments. Our results demonstrate that around 2.7 Ma, coinciding with the intensification of the Northern Hemisphere glaciation (NHG), the aeolian input of terrestrial material to the North Atlantic increased drastically. Since then, during every glacial the aeolian input of higher plant material was up to 30 times higher than during interglacials. We argue that the increased aeolian input at Site U1313 during glacials is predominantly related to the episodic appearance of continental ice sheets in North America and the associated strengthening of glaciogenic dust sources. The records thus reflect the timing of the advances and retreats of the North American ice sheets. Evolutional spectral analyses of the *n*-alkane records were therefore used to determine the dominant astronomical forcing in North American ice sheet advances over the last 3.5 Ma. These results demonstrate that during the early Pleistocene North American ice sheet dynamics responded predominantly to variations in obliquity (41 ka), which argues against previous suggestions of precession-related variations in Northern Hemisphere ice sheets during the early Pleistocene [2].

A strain-heating model for the seismic low-velocity zone along the Main Himalaya Thrust

PETER I. NABELEK[1*] AND JOHN L. NABELEK[2]

[1]Dept. of Geological Sciences, University of Missouri, Columbia, MO 65211, USA, nabelekp@missouri.edu (* presenting author)

[2] College of Oceanic and Atmospheric Sciences, Oregon State University, Corvallis, OR 97331, USA, nabelek@oce.orst.edu

Seismic low-velocity zone along the MHT

Recent Hi-CLIMB seismic experiment, using an 800 km long, densely spaced seismic array across Nepal and southern Tibet, has revealed a narrow low-velocity zone along the Main Himalaya Thrust [1]. The zone extends approximately from the 28.5°N latitude, dipping to ~40 km depth at the latitude of the Yarlung Tsangpo Suture (YTS), and then continues horizontally beneath the Lhasa Block to approximately 32°N latitude. Nabelek et al. [1] interpreted this deep low-velocity zone to be the result of increased ductility and partial melting. The narrowness of the low-velocity zone along most of the length of the MHT requires a mechanism by which the partial melting is localized. Strain heating along the ductile portion of the MHT provides such a mechanism.

Parameters of numerical model

Development of the partially molten zone was modeled numericaly following [2]. The model domain is 600x140, 1 km grid. The initial conditions are steady-state with subduction of the Indian lithosphere beneath the Himalayas and Tibet at 3 cm/y. Temperature is 25°C at the surface and 1300°C at the bottom of the lithosphere. Radiogenic heat production (Ah) in the Indian crust was constrained by the average 70 mW/m^2 surface heat flux of the stable northern Indian crust. Ah in the upper plate was assumed to be 2 $\mu W/m^3$ throughout and in the mantle 0.01 $\mu W/m^3$. Subduction of the Indian lithosphere at 3 cm/y keeps the crust above the MHT refrigerated. The model accounts for temperature-dependent thermal diffusivity [2, 3] and power-law temperature dependence of the shear strength (τ) of quartz [4]. Strain heating in the ductile regime is given by $\tau \cdot \varepsilon$, where ε is the strain rate. Strain rate in a 3 km wide shear zone is $3 \cdot 10^{-13}$ s^{-1}. Heat production at this strain rate is ~100 $\mu W/m^3$ at 550°C and ~10 $\mu W/m^3$ at 750°C [2].

Model results

Strain heating was assumed to occur along the length of the MHT, but only within the ductile regime. With subduction only, shearing produces a narrow, partially molten zone that extends from below the Himalayas to the northern end of the model domain. The partially molten zone is underlain by an inverted temperature gradient. The ductile regime extends further to the south along the MHT, in accord with observations [1]. Thus, the calculations demonstrate the feasibility of producing the observed low-velocity, partially-molten zone along the MHT in the deep crust.

Depleted Mantle as the Source of Gold in Archean Alkaline Magmatic-Hydrothermal Systems

OLIVIER NADEAU[1*], ROSS STEVENSON[1], MICHEL JÉBRAK[1]

[1] UQAM-Géotop, Département des Sciences de la Terre et de l'Atmosphère , nadeau.olivier@uqam.ca (* presenting author)

Field relations, trace element and isotopic compositions and isotope dating suggest that 2.6 to 2.7 Ga. old gold-bearing syenites, lamprophyres (sensu stricto) and carbonatites of the Abitibi greenstone belt are genetically related. Their chondrite-normalized REE signatures are very similar and a survey of isotope data in the literature reveals ε_{Nd} and $^{87}Sr/^{86}Sr$ values that are consistent with a depleted mantle source. Preliminary results from syenites and lamprophyres of the Duquesne gold mine indicate that they have similar REE patterns in addition to both mantle and crustal isotopic compositions.

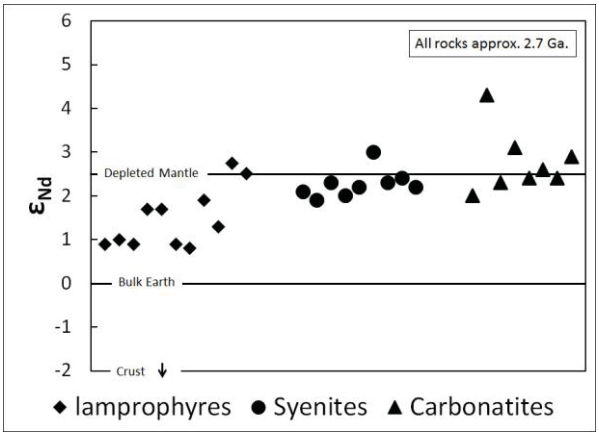

Figure 1: ε_{Nd} values for 2.6 to 2.7 Ga. lamprophyres, syenites and carbonatites of the Abitibi greenstone belt. The three lithologies display similar, mantle values, although the lamprophyres show some crustal alteration.

These results allow us to shed light on the petrogenesis of these rocks and their relationship to the gold deposits. Lamprophyres are quenched, volatile-rich, mafic porphyric rocks that interact very little with the crust as they rise from the mantle. Syenites also appear to be derived from a depleted mantle source that has interacted very little with the crust during their evolution. We propose that the syenites were produced by fractional crystallization of lamprophyre magmas in the crust. In this model, gold could have been carried from the mantle to its site of deposition in shallow level syenitic porphyries via a mantle-derived, carbothermal fluid. This model also finds support in the coexistence of carbonic-fluid-saturated, hybrid silicocarbonatites of Abitibi and most late-Archean gold deposits.

SO_2 emissions and their role in eruptive activity at Fuego Volcano, Guatemala

PATRICIA A. NADEAU[1, 2*], GREGORY P.WAITE[1], AND JOSÉ L. PALMA[1, 3]

[1]Michigan Technological University, Department of Geological and Mining Engineering and Sciences, Houghton, MI, USA, panadeau@mtu.edu (*presenting author)

[2]Now at: American Museum of Natural History, Department of Earth and Planetary Science, New York, NY, USA

[3]Now at: Center for Geohazards Studies, University at Buffalo, Buffalo, NY, USA

Magmatic volatiles have an important role in many aspects of volcanism, from magma generation to initiation of seismic phenomena to influence on eruption style. It follows that many models of volcanism and volcanogenic phenomena rely on behavior of such volatiles. UV cameras offer enhanced temporal resolution over previous SO_2 emission rate measurement techniques and also offer a synoptic view of plumes and degassing behavior. Integrated UV camera and seismic measurements recorded in January 2008 and January 2009 at Fuego volcano, Guatemala, provide new insight into the system's shallow conduit processes.

In 2008, an inter-explosion period was marked by pseudo-cyclic patterns of SO_2 emission rate. Comparison of the data with band-pass-filtered seismic data indicates that the onsets of increases in SO_2 emission rate are accompanied by very long period (VLP) seismic events. Larger amplitude VLPs are associated with larger pulses of SO_2 and shorter preceding inter-event times. Other VLPs associated with explosions at Fuego have been linked to pressurization at the intersection of two cracks [1], but the non-explosive nature of these VLPs may indicate a different source process.

UV camera data in 2009 reveal patterns of SO_2 emission rate relative to explosions and low-frequency seismic tremor that indicate tremor and degassing share a common source process. Progressive decreases in emission rate appear to represent inhibition of gas loss from magma as a result of rheological stiffening in the upper conduit. Measurements of emission rate from two closely-spaced vents, made possible by 2-dimension nature of camera data, help constrain this model.

Eruptive activity at Fuego appeared superficially similar in January 2008 and 2009, with a passive gas plume and sporadic, ash-rich explosions. Gas emission data obtained via UV camera, in combination with seismic data, enabled elucidation of different eruptive processes driven by the movement and escape of volatiles.

Alteration and isotopic vectoring at the syenite-hosted Young-Davidson gold deposit, Matachewan, Ontario

N. NADERI[1*], R. MARTIN[2], R. LINNEN[1], J. ZHANG[3], S. LIN[2] AND N.R. BANERJEE[1]

[1]University of Western Ontario, Department of Earth Sciences, London, Ontario, Canada, nnaderi@uwo.ca (*presenting author)
[2]University of Waterloo, Earth and Environmental Sciences, Waterloo, Canada
[3]University of Hong Kong, Earth Sciences, Hong Kong, China

The Young Davidson mine is a syenite-hosted orogenic gold deposit at the western end of the Cadillac-Larder-Lake deformation zone in the southern Abitibi greenstone belt, Canada. The earliest stage of veining (V_1) consists of folded and boudinaged quartz-ankerite veins. V_2 is comprised of folded quartz-pyrite veinlets and disseminated sulphides and V_3 consists of en echelon or planar quartz-carbonate veins with sulphide minerals. The major phase of Au mineralization is associated with V_2 veins. Gold occurs as inclusions in V_2 pyrite, along quartz-carbonate grain boundaries in V_3 veins and as inclusions in disseminated pyrite in zones of intense potassic-hematite alteration.

Contouring of whole rock drillcore data indicate that Au is correlated with K_2O, S and Ba, consistent with the result of core logging, which established an association of Au with intense potassic-hematite alteration, quartz veining, pyritization and decreased magnetic susceptibility. Increases of K_2O (2 to 9 wt%) and Ba (600 to 3800 ppm) and a decrease of whole rock $\delta^{18}O$ values (11.4 to 9.2 ‰) is observed for some of the mineralized zones. Thus potassic alteration and whole rock $\delta^{18}O$ contours show promise as vectors to Au mineralization likely associated with high temperature magmatic fluids.

Bulk rock XRD analysis supports the idea of different alteration zones extending from shallower to deeper parts of the deposit. In shallower parts, ankerite abundance increases and that of calcite decreases towards the zone of mineralization. In deeper parts, this distribution pattern is reversed. In terms of oxide minerals, shallow mineralization is dominated by hematite (the concentrations of rutile and barite are also high enough to be identified in XRD patterns). In the deeper zones of mineralization hematite abundance decreases and magnetite abundance increases towards the mineralized zones.

Temperatures calculated from mineral pair oxygen isotope thermometry indicate the fluids ranged from approximately 330° to 460°C.Calculated V3 vein fluid compositions range from 6.4 to 11.9 ‰ and V1 from 6.6 to 7.4 ‰. In the deeper zones Au mineralization is correlated to high K_2O alteration, high sulphur concentrations and low $\delta^{18}O$ values, which indicate magmatic fluid involvement. However, in shallower zones gold mineralization is consistent with high $\delta^{18}O$ values, which is interpreted that the fluids were at lower temperatures and/or dominated by metamorphic fluids reflecting a separate and possibly later mineralizing event. We conclude that there are multiple stages of Au mineralization at Young-Davidson and that $\delta^{18}O$ whole rock values, potassic alteration and sulphur concentrations can be used as vectors for mineralization within different alteration zones.

Magnetite - An indicator mineral for hydrothermal ore deposits

PATRICK NADOLL[1]*, JEFFREY L. MAUK[2], RICHARD LEVEILLE[3], LOUISE FISHER[1], ROBERT HOUGH[1]

[1]CSIRO, 26 Dick Perry Ave, Kensington, 6151 Perth, WA, Australia
[2]University of Auckland, New Zealand
[3]Freeport McMoRan, Phoenix, United States

Magnetite and other Fe-Ti –oxides have been recognized as potential indicator minerals for exploration purposes since the 1980s. However, only recent studies have presented data that illustrate characteristic variations among magnetites of hydrothermal origin and describe distinct compositional signatures that can discriminate specific geologic settings such as hydrothermal ore deposits. The major controls for the geochemistry of hydrothermal magnetite are lithology/fluid composition, T, fO_2/fS_2 and re-equilibration processes. Exploratory data analysis has established the following upper threshold concentrations for hydrothermal magnetite from Ag-Pb-Zn veins, porphyry Cu-Mo, and skarn deposits (Table 1). The most important overall discriminators for the minor and trace element geochemistry of hydrothermal magnetite are Mg, Al, Ti, V, Co, Mn, Zn, and Ga. Nickel and Cr, which can have significant concentrations in igneous magnetite, are not commonly present at levels above their respective detection limits. Hydrothermal magnetite is typically depleted in Ti compared to igneous magnetite. Aluminum and V display a similar trend although the overlap between hydrothermal and igneous magnetite is more pronounced for these elements. Depleted Ti and V concentrations in combination with enriched Mg contents up to wt% values are in particular characteristic for hydrothermal magnetite from magnesian skarn. Manganese concentrations vary significantly among hydrothermal and igneous magnetites but concentrations are commonly lesser in hydrothermal magnetite with values up to several 1000 ppm. Cobalt, Zn, and Ga are enriched in hydrothermal magnetite from skarn compared to other hydrothermal magnetite. In addition to minor and trace element concentrations, the occurrence, abundance and composition of inclusions in magnetite is a potential tool to discriminate magnetite sample populations and fingerprint mineral deposits. Minor and trace elements that are commonly associated with micro- or nano-inclusions in magnetite include Ca + REEs (apatite and carbonates), Si (silicates), Cu (Cu-sulfides), Nb (rutile). Copper can be particularly indicative for mineralized zones where magnetite is closely associated with Cu-sulfides such as chalcopyrite or chalcocite.

Table 1: Upper threshold concentrations in ppm for n-number of hydrothermal magnetites from a range of geological settings.

	Ag-Pb-Zn	Porphyry	Mg-skarn	Skarn
n	30	126	17	57
Mg	740	490	25810	8780
Al	900	3180	2730	11330
Ti	4160	10500	20	8820
V	170	1460	20	14190
Co	10	40	5	320
Mn	1220	1880	1600	2900
Zn	110	280	260	5470
Ga	10	60	30	600

Earth's lithosphere likely experienced an evolution toward the modern plate tectonic regime, due to secular changes in mantle temperature. Gradually declining growth rates of the continental crust through time has been suggested, and recent estimates suggest that ≥70% of the present continental crustal reservoir was extracted by the end of the Archaean [1]. Patterns of crustal growth and reworking in rocks younger than 3.0 billion years (Ga) are thought to reflect the assembly and breakup of supercontinents by Wilson Cycle processes and mark an important change in lithosphere dynamics. It has been argued that subduction settings and crustal growth by arc accretion go back to 3.8 Ga in southern West Greenland [2-4]. We present in-situ zircon U/Pb, Hf and O isotope data from basement rocks in southern West Greenland across the time-period where modern style tectonic regimes might have started. Our data show that pronounced differences in the εHf-time patterns occurred, implying changing source rock characteristics. The observations suggest that 3.9-3.5 Ga rocks differentiated from a ≥3.9 Ga initially chondritic to slightly depleted mafic proto-crust. In contrast, rocks formed after 3.2 Ga register the first additions of juvenile depleted material since 3.9 Ga. Crustal growth after 3.2 Ga is characterised by upward εHf shifts and correlate in age with regional meta-volcanic supracrustal belts, stabilised felsic crust are characterised by downward εHf excursions, a pattern that compare with Phanerozoic accretionary orogens [5,6]. The isotope data reveal a transition from a crustal evolutionary signature unlike that of modern subduction-related orogens that didn't seem to generate or stabilise juvenile zircon-bearing crust, to an isotope-time pattern after 3.2 Ga that is compatible with arc accretionary processes and plate tectonics.

Oxygen isotopic exchange reaction between silicate melt and ambient gas

HIROKO NAGAHARA[1]* AND KAZUHITO OZAWA[2]

[1]The University of Tokyo, Department of Earth and Planetary Science, Tokyo, Japan, hiroko@eps.s.u-tokyo.ac.jp (* presenting author)
[2] The University of Tokyo, Department of Earth and Planetary Science, Tokyo, Japan, ozawa@eps.s.u-tokyo.ac.jp

Oxygen Isotopic Variation of Planetary Materials

Chondrite, nonchondritic meteorites, and planets show wide variations of oxygen isotopic compositions, which incude mass-dependent and mass-independent fractionations. Mass-independent oxygen isotopic fractionation has been one of the most extensively studied subjects of meteorite study, whereas mass-dependent isotopic fractionation has not been paid attentions. It is, however, contorlled by physics, and is potentially an excellent indicator for environments. Here, we quantitatively study the role of isotopic exchange reaction between silicate melt and gas, and evaluate mixing lines on the oxygen three isotope plot.

Method

We have developed a kinetic condensation model that assumes totally molten silicate melt sphere cooling from an above liquidus temperature in a closed or open system, which has a composition of the solar abundance except for hydrogen. The model includes three free parameters; cooling rate of the system, initial oxygen abundance in gas relative to metallic elements, and oxygen isotpopic exchange efficiency. The model consists of the Hertz-Knudsen equation that describes condensation/evaporation flux and isotopic exchange reactions.

Results

We found that isotopic exchange reactions play a critical role in evolution of condensing silicate melt: silicate melt gets highly mass-fractionated composition if isotopic exchange does not work, which results in deviation of a straight mixing line but in formation of a fractionation trend with a slope of 1/2 on a oxygen three isotope plot. An isotopic exchange reaction greatly suppresses mass-dependent isotopic fractionation, which is tends to form a straight mixing line. The effect of fractionation is more conspicuous when the relative abundance of oxygen in the ambient gas against silicate melt is small. The degree also depends on isotopic exchange efficiency, but it is not dependent on cooling rate of the system. If the oxygen isotopic exchange efficiency does not change largely, the degree of deviation from a straight mixing line corresponds to the melt/gas ratio in a planetary environment or dust/gas ratio in a protoplanetary disk environment.

Discussions

The calculation results show that the straight mixing lines observed in various chondritic components such as CAIs and chondrules are explained by condensation in the presence of oxygen in the ambient gas by more than two orders of magnitude than the metallic elements. Otherwise, the mixing lines should be curved toward □^{18}O-rich side. The average O/M ratio (M: metallic elements) of the solar abundance is ~100, which suggests that CAIs and chondrules that show straight mixing lines were formed in an oxygen enriched environment than the average solar abundance. The model is further applied to the Earth-moon system, where homogenization of oxygen isotopic composition is easy at the stage of magma ocean.

Separation of Mo, W and HFSEs from rock samples for the study of isotope anomalies in meteorites

YUICHIRO NAGAI[1*], TETSUYA YOKOYAMA[1] AND RICHARD J. WALKER[2]

[1] Dept. of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan. (* nagai.y.ab@m.titech.ac.jp)
[2]Dept. of Geology, Univ. of Maryland, College Park, MD, USA

Recent innovations in mass spectrometry have enabled detection of small isotope anomalies in some heavy elements present in a variety of meteorites. To make highly-precise and "accurate" isotope analysis, chemical separation of the target element from various types of meteorites must be developed from the following standpoints: 1) Achieve of nearly 100% recovery to avoid mass fractionation during chemical separation. 2) Complete removal of unwanted elements that can interfere with isotope analysis. 3) Maintain high sample/blank ratios. 4) Simultaneously separate as many elements as possible from a single sample. The last point is important not only to preserve precious meteorites, but also for performing multi-elemental isotope analysis on heterogeneous samples. In this study, we have developed a chemical separation method for Mo, W and HFSEs (High Field Strength Elements; e.g., Zr, Hf) from meteorite samples, all of which are intriguing elements for the study of isotope anomalies in the early solar system. We also show our prelimiary analysis of Mo isotope compositions in bulk chondrites and their acid leachates.

The separation method consists of a two-stage column chemistry using anion exchange resin (BioRad AG1X8). We have evaluated the performance of our technique by using a synthesized multi-element solution and some terrestrial rock samples decomposed by HF. A quadrupole-type ICP-MS (*ThermoFisher X SERIES II* at Tokyo Tech.) was used to determine the elution profile, as well as the recovery yield of Mo during the column chemistry. Molybdenum isotopes were analyzed by N-TIMS (TRITON-*plus* at Tokyo Tech).

In the first column, HFSE, W and Mo were successively eluted by 9M HCl-0.05M HF, 9M HCl-1M HF, and 6M HNO_3-3M HF, respectively. Unwanted elements in the Mo fraction (Zn, Nb and trace Ru) were further separated in the second column. The column size and total amount of acids were dramatically reduced compared to previous techniques. The Mo recovery was 94.5 ± 2.9 % in the first column and 101.3 ± 5.0 % in the second column. By applying this technique, we have determined Mo isotope compositions in bulk samples of Murchison (CM2) and Allende (CV3), as well as their acid leachates. The Mo isotope anomalies in bulk Murchison and a leachate indicate deficits of *s*-process Mo isotopes, consistent with previous studies [1, 2]. In contrast, anomalies observed in bulk Allende and its leachates are enigmatic, which may require a reassessment of the isotopic compositions of end-member components calculated by current nucleosynthetic theories.

Characterizing the cessation of arc-normal mid-crust extrusion, NW Nepal Himalaya

CARL NAGY [1*], LAURENT GODIN [1], JOHN COTTLE [2] AND BORJA ANTOLÍN [1]

[1] Queen's University, Department of Geological Sciences and Geological Engineering, Kingston, Canada, carl.nagy@queensu.com (* presenting author)
[2] University of California, Department of Earth Sciences, Santa Barbara, USA

The metamorphic and anatectic core of the Himalaya, the Greater Himalayan Sequence (GHS), has been hypothesized to represent exhumed mid-crustal material via a channel flow model [1 and references therein]. Characterizing the cessation of this lateral mid-crustal extrusion is integral in providing a comprehensive understanding of mid-crustal flow during orogenesis.

Field mapping, structural and microstructural analysis, geochronology, and thermochronology confirm the existence of the Gurla-Mandhata-Humla fault, an orogen-oblique strike-slip dominated fault in the High Himalaya of northwestern Nepal. Detailed across-strike transects reveal shallow-dipping mylonitic foliations and strongly-developed shallow plunging mineral stretching lineations interpreted to represent the terminal stages of arc-normal directed extrusion of mid-crustal material, and onset of orogenic extension [2]. Furthermore, late-stage deformation along this fault system overprints the GHS and its upper bounding fault, thus confirming a cessation of and transition from extruding GHS to subsequent arc-parallel deformation. A study of this fault system therefore provides documentation of the final stages of arc-normal directed extrusion of mid-crustal material.

The shear zone is characterized at upper structural levels by well-developed type-1 cross-girdle quartz c-axis fabrics and symmetric a-axis fabrics, indicating plane strain conditions. C-axis fabrics transition to type-2 cross girdles at ~ 1.2 km below the fault, suggesting an ostensible contribution of constrictional strain at depth. This deviation towards constriction is consistent with measured quartz a-axes, which show a progression towards upright cleft girdle patterns at similar depths. Quartz c-axis opening angles and quartz and feldspar recrystallization mechanisms show a progressive increase in deformation temperatures from ~ 350°C along the zone of maximum strain, to upwards of ~ 630°C at depths greater than ~ 5.5 km below the fault. Abundant asymmetrical fabric elements and conjugate shear bands in conjunction with a calculated mean kinematic vorticity number of 0.60 (c. 58% pure shear) attest to an important contribution of pure shear. U-Th-Pb in situ monazite geochronology, U-Pb zircon geochronology, and $^{40}Ar/^{39}Ar$ muscovite thermochronology reveal crystallization, decompression melting, and cooling within ≤ 7 Myr.

These data indicate that the final stages of the extruding mid-crust are characterized by a particularly high vertical gradient in deformation temperatures, deviations from plane strain at depths, and a significant contribution of pure shear. Furthermore, chronological data suggest that cooling and cessation of arc-normal extrusion of the mid-crust occurred within a geologically confined period.

Phase relations in meta-komatiites during dehydration melting

NAIR,R.[1*] CHACKO, T.[2] VERWIMP, J.[1]

[1]Department of Geoscience, University of Calgary, Canada T2K 1N4(*rnair@ucalgary.ca)

[2]Department of Earth and Atmospheric Sciences, University of Alberta, Canada T6G 2E3

Komatiitic-basalts and komatiites are relatively abundant in the volcanic record of Archean cratons compared to Phanerozoic terranes. It has been suggested that these rocks may have constituted the Archean oceanic crust. It is important to understand the role these rocks would have played in the transformation of oceanic crust during purported processes like slab melting, eclogite formation etc. Whereas metamorphic phase relations of mid-ocean ridge (MORB) type basalts have been widely studied in the past, there is a paucity of knowledge on the phase relations of komatiitic basalts and komatiites.

We report results of preliminary dehydration melting experiments (1000°C, 7-20 kbar) on a natural amphibolite of komatiitic composition with starting composition in wt.% oxides : SiO_2 48.26, TiO_2 0.50, Al_2O_3 7.19, Fe_2O_3 13.31, MnO 0.23, MgO 18.66, CaO 8.49, Na_2O 0.51, K_2O 0.05 (1). The experiments were conducted on a piston cylinder apparatus for a duration of 2-7 days using procedures outlined in (2).

Experiment	P (kbar)	T (°C)	Phases Present
7IG006	7	1000	Ol,Cpx, (Opx), Melt
7IG005	10	1000	Ol,Cpx, Opx, Melt
7IG004	12.5	1000	Ol,Cpx, Opx, Melt
7IG001	15	1000	Grt, Cpx, Opx, Melt,(Amph)
7IG003	15	1000	Grt, Cpx, Opx, Melt,[Amph]
7IG002	17.5	1000	Grt, Cpx, Opx, Melt
7IG007	20	1000	Grt, Cpx, Opx, Melt

Table 1: Experimental conditions and phase relations. Abbreviations after (3). (), [] indicate minor and trace proportions, respectively.

Phase relations (Table 1) indicate a melt residue dominated by ol, opx and cpx at P <15 kbar and grt, opx and cpx at P ≥ 15 kbar. The incoming of garnet is at a significantly higher pressure than in MORB compositions (~10 kbar). Our results present interesting comparisons with recent crystallization experiments on a komatiite bulk composition at similar P-T conditions (4). This earlier study reported Ol coexisting with grt at P >14 kbar and no olivine at P<14 kbar. A melt phase was not reported at 1000°C and 10-18 kbar in these earlier experiments, but is ubiquitous in our experiments. A first order implication of the new results is that if Archean oceanic crust were komatiitic, crustal thickness >45 km is required to stabilize garnet in the melt residue. This is important to consider in Archean geodynamic models like crustal delamination that invoke density inversions resulting from stabilization of garnet bearing assemblages in the mafic lower-crust.

merkel@geo.tu-freiberg.de

Uranium is a naturally occurring radioactive and chemically toxic metal, which is widespread in nature. Reactive transport of U(VI) with various ligands and different minerals has been studied extensively. Arsenic is analogous to phosphate and is a well-known contaminant to the environment. Uranyl-arsenate complex formation at near-neutral to alkaline pH conditions was proved by XAS and XANES [1]. They reported the formation of $UO_2AsO_4^-$, analogous to $UO_2PO_4^-$. However, little information is available about the migration of U(VI) and As(V) in systems containing both elements. The changes in sorption behaviour of U(VI) and As(V) in columns containing bentonite [2] and iron-coated sand [3] were reported. Since As(V) co-exists with U(VI) in several mining areas, it is important to understand the species behaviour to implement proper remediation procedures. Less or no information is available about the transportation of U(VI) and As(V) in the presence of SiO_2, Al_2O_3, TiO_2 and FeOOH, which are very common in natural environments. Hence column experiments were carried out for uranium (0.5 µM/L), arsenate (0.5 µM/L) and both uranium and arsenic containing solutions (0.5:0.5 µM/L) with SiO_2 (10 g), Al_2O_3 (10 g), TiO_2 (0.5 g) and FeOOH (0.1 g) at pH 6.5. Transport behaviour of U(VI) and As(V) through SiO_2 packed columns are identical for solutions containing either U(VI) or As(V) separately, or both together. Almost identical transport behaviour was observed for TiO_2 column also. In the presence of equimolar U(VI) and As(V) a substantial increase in As(V) mobility and slight decrease in U(VI) migration through Al_2O_3 was observed. When Al_2O_3 is replaced by FeOOH, a significant change in the pattern of mobility was shown for As(V) and minor changes for U(VI). The changes in transport behaviour of both elements can be attributed to the competitive sorption between uranyl and arsenate species or due to the formation of the above mentioned uranyl-arsenate species. Further investigations are recommended in order to understand the migration of contaminants in the environment and to implement proper measures in the remediation process.

An experimental study on stable isotope fractionation of rare earth elements during the adsorption on iron and manganese oxides

RYOICHI NAKADA[1*], YOSHIO TAKAHASHI[1, 2], AND MASAHARU TANIMIZU[1, 2]

[1] Hiroshima University, Higashi-Hiroshima, Hiroshima, ryo-nakada@hiroshima-u.ac.jp

[2] Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Nankoku, Kochi

Recent development of analytical instruments, especially multiple collector (MC) ICP-MS, has enabled us to discuss the mass-dependent isotopic fractionation of heavy elements. Although several rules controlling the isotopic fractionation has have been suggested, it is still insufficient to discuss which chemical properties are the most important factor to evaluate bond stiffness in the equilibrium isotopic fractionation. This study, therefore, exhibits the results of stable isotopic fractionation of rare earth element (REE) during the adsorption experiment to discuss the cause of the isotopic fractionation among REE.

Lanthanum, Ce, Nd, and Sm chloride solutions with various concentrations were respectively added to both synthesized ferrihydrite and δ-MnO_2 suspensions. In all the systems, pH was adjusted to 5.00 (±0.05) and shaken for 6 hours before the filtration. Stable isotope ratios in both liquid and solid phases were determined using MC-ICP-MS. REE-Cl_3 solutions used in the adsorption experiment were employed as standard solutions and the isotope ratio of each element was expressed in epsilon notation relative to the average standards, which is shown in the equation as follows: $\varepsilon = (R_{sample}/R_{STD} - 1) \times 10^4$, where R was defined as $^{139}La/^{138}La$, $^{142}Ce/^{140}Ce$, $^{145}Nd/^{143}Nd$, or $^{149}Sm/^{147}Sm$, respectively. For the solid phase, K-edge EXAFS of filtered samples was measured at BL01B1 in SPring-8 to obtain the information of the coordination environment.

Though accurate determination of La isotope ratio was difficult due to the large difference in the isotopic abundance between ^{138}La and ^{139}La, a broad trend obtained in this study suggested that the lighter La isotope was selectively partitioned into the solid phase. In Ce system, it is clearly shown that the lighter isotope was partitioned into solid phase, whereas in Nd and Sm systems, lighter isotopes remained in the liquid phase, suggesting that physicochemical factors have been changed between Ce and Nd. According to the EXAFS analysis, split first shell (La-O bond) was observed for La-adsorption system, suggesting that the first coordination sphere is distorted in the system. Such distortion was also expected for Ce-adsorption system from their EXAFS results. On the other hand, split first shell was not observed for Nd and Sm systems. Thus, it is expected that the slight change in coordination environment, which can also cause the difference in their hydration numbers, affects the direction and degrees of mass-dependent isotope fractionations among REE.

Mechanism and conditions for strain softening in gabbro

PRITAM NASIPURI[1*], HOLGER STUNITZ[1], LUCA MENEGON[1], AND ALFONS BERGER [2]

[1] Departmnent of Geology, University of Tromsø, Norway, pritam.nasipuri@uit.no (* presenting author), holger.stunitz@uit.no, luca.menegon@uit.no

[2] University of Copenhagen, Denmark, ab@geo.ku.dk

Introduction

Weakening of lower crustal rocks due to fluid infiltration and metamorphism is responsible for the development of ductile shear zones. In this contribution, we describe the mechanism of formation of ductile shear zones in a granulite facies gabbro, followed by fabric formation during retrogression after eclogite facies metamorphism in rocks from Flakstadøy, Lofoten, Norway [1].

Results

Several mm to cm wide ductile shear zones are observed within the leuco-gabbro. Pl_0, Ol_0 and Opx_0 form the cumulus igneous texture. Opx_1 and Grt_1 corona around Pl_0 and Ol_0 indicate granulite facies metamorphism (M_1). Alternate bands of mafic (Opx_0+ Omp + $Grt_{I/II}$) and felsic (Pl + Amp + Spl) layers characterize the shear zone. The Opx_0 porphyroclasts are mantled by recrystallized Opx_{II} grains (20-30 mm) and show asymmetrical σ-porphyroclast indicative of sinistral sense of shear (D_1). Static overgrowth of Omp ± Grt_{II} around $Opx_{0/II}$ is the peak pressure metamorphic stage (M_{2A}). Subsequently, Cpx - Pl symplectite (M_{2B}) form at the outer rim the Omp. Breakdown of Grt $_{I/II}$ to Amph ± Pl (An rich) ± Spl with opposite shear sense in the $Opx_{0/II}$ defined fabric characterize M_3 metamorphism.

Alternate bands of mafic (Cpx + Pl + Qtz + Grt_{II} – Ol_0 - Opx_0 - Omp) layer (≈M_{2B})and felsic (Pl+ Amp + Cz – Spl) layer characterize the fabric in the retrograde eclogite. Amp and Cz overgrows at the contact between the mafic and felsic layers (≈ M_3).

In the ductile shear zone, chemical similarity and CPO data of Opx_0 and Opx_{II} indicate that Opx_0 deformed by cracking (D_1) at the onset of M_1-metamorphism. The fine-grained Pl shows a strong CPO indicative of inheritance of the CPO from D_1 deformation. The CPO of amphibole suggests that amphibole re-orients by rigid body rotation forming aligned (100) planes during post D_1 deformation.

In the retrograde variety, the CPO data of Cpx from the mixed phase mafic layers is consistent with the (010) [001] dominant slip system but is interpreted as oriented-growth-fabric during diffusion creep, because the mixed-phase-fabric does not indicate dislocation creep microstructures. CPO data of recrystallized plagioclase in the mono-mineralic felsic layers indicate (010) [100] as dominant slip system during dislocation creep.

Conclusions

This study indicates that deformation of Opx via cracking (D_1) requires very high differential stress at lower crustal conditions [3] during M_1 stage. However, in the retrograde eclogite, Omp breakdown will produce fine-grained Cpx+Pl mixtures [4] and promotes diffusion creep accommodated fabric formation.

Origin of Magnetite "Lava Flows" at El Laco Volcano, Chile

H.R. NASLUND[1*], F.J. HENRIQUEZ[2], J.O. NYSTRÖM[3], J.A. NARANJO[4] AND R.D. MATHUR[5]

[1]SUNY-Binghamton, Geological Sciences, Naslund@Binghamton.edu (*presenting author)

[4]SERNAGEOMIN, Santiago, Chile, cotonaranjo@gmail.com
[5]Juniata College, Huntingdon, PA, MATHUR@juniata.edu

Introduction:

Iron ore bodies at El Laco volcano have the appearance of dikes, lava flows, scoria, ash, and other pyroclastics and are composed of almost pure magnetite. Although an origin as Fe-oxide magmas has been proposed by many investigators [1], others have suggested an origin as hydrothermal or metasomatic replacement deposits [2, 3].

Magnetite Composition:

Excluding samples with obvious minor pyroxene or apatite, magnetite ore samples are 95 to 97% iron oxide with: 0.6-1.5% SiO_2; 0.01-0.03% TiO_2; 0.15-0.69% Al_2O_3; 0.002-0.039% MnO; 0.09-1.20% MgO; 0.18-1.18% CaO; 0.03-0.38% Na_2O; 0.05-0.21% K_2O; and 0.8-2.5% P_2O_5. Trace element abundances in the ore average: 90 ppm Ba; 96 ppm Co; 26 ppm Cr; 212 ppm Ni; 9 ppm Sc; 147 ppm Sr; 793 ppm V; 105 ppm Zn; 5 ppm Zr; and 24 ppm Y. Relative to associated unaltered andesites, the ores are enriched (ores/andesites) in Ni (7.7), P (7.3), V (5.3), Cu (2.6), and Zn (1.6), and depleted in Cr (0.7), Sc (0.6), Sr (0.3), Ba (0.2), Mn (0.1), Zr (0.03), and Ti (0.02). The ores are enriched in REEs (La 150X and Yb 14X chondritic) with steep LREE slopes (La_N/Sm_N = 8.1), relatively flat HREE slopes (Sm_N/Yb_N = 1.7), middle REE depletions (Sm/Sm* = 0.23), and negative Eu anomalies (Eu/Eu* = 0.5). In contrast, associated unaltered andesites have similar abundances (La 145X and Yb 12X chondritic) but less steep LREE (La_N/Sm_N = 4.6), steeper HREE (Sm_N/Yb_N = 2.7), less middle REE depletion (Sm/Sm* = 0.39), and less Eu depletion (Eu/Eu* = 0.65). Fe isotopes in the ores (δ56 = 0.52-0.90‰) are elevated relative to fumarolic and vein deposits (δ56 = 0.23-0.29‰) or andesites (δ56 = 0.49‰) at El Laco. In a single ore sample measured, Re = 460 ppt, Os = 23 ppt, $^{187}Os/^{188}Os_{measured}$ = 0.52, $^{187}Re/^{188}Os_{measured}$ = 2, and $^{187}Os/^{188}Os_{initial}$ = 0.51 indicates that there is a large contribution of Os from the continental crust.

Conclusions:

The high abundance of some relatively immobile elements (V, Ni, Y, and REEs) and the low abundance of other immobile elements (Zr, Ti, Cr, and Sc) is inconsistent with a hydrothermal or replacement origin for the ores. δ56 Fe in the ores is systematically higher than δ56 Fe in hydrothermal magnetite. Immiscibility between silicate magma and volatile-rich Fe-P-S-O magma, possibly initiated by crustal contamination, is compatible with all of the data.

Mudstone pore networks: characterization and flow modeling

ALEXIS NAVARRE-SITCHLER[1*], KATHERINE MOUZAKIS[1], GERNOT ROTHER[2], JASON HEATH[3], TOM DEWERS[3], JOHN MCCRAY[1]

[1]Department of Civil and Environmental Engineering, Colorado School of Mines, Golden CO, USA, asitchle@mines.edu (*presenting author)
[2] Oak Ridge National Laboratory, Oak Ridge TN, USA
[3] Sandia National Laboratories, Albuquerque NM, USA

In geochemically active systems the pore network is arguably the most important physical characteristic of a rock because it provides pathways for reactive fluid flow and solute transport. The pore network is defined by an interface that advances and retreats with mineral precipitation and dissolution. These geochemical reactions can change important physical rock properties, such as interfacial roughness and area, and pore volume and connectivity, that in turn influence rates and mechanisms of future geochemical reactions and fluid flow. Despite their importance on geochemical behaviour of rocks, pore networks and their evolution with geochemical reaction are poorly understood. However, characterizing pore networks is not straightforward due to their dynamic nature and features at different length scales (nm to mm).

Problems associated with the characterization of pore networks are compounded in fine-grained rocks such as shales and mudstones that have a high percentage of nm scale pores. However, these rock types are increasingly important due to the role they play in unconventional natural gas production and geologic CO_2 storage. Small angle neutron scattering (SANS) is an ideal tool to study structural heterogeneties in porous materials on nanometer to micron length scales and compliments other traditional techniques such as sorption, mercury intrusion porosimetry (MIP), or microscopy.

In this study we characterized the nm to mm scale pore network in samples from three different mudstone formations using SANS, MIP, BET gas adsorption techniques and focused ion beam scanning electron microscopy imaging. These formations all serve as seals for containment of CO_2 in prospective geologic storage sites. Porosity and surface area in pores < 700 nm diameter was measured with small angle neutron scattering. According to this data pores < 10 nm radius contribute 20-50% of the total porosity and > 80% of the total surface area of these mudstones. The total pore volume determined from small angle neutron scattering is higher than porosity determined from mercury instrusion porosity for most of the samples. The discrepancy between these measured porosities may be related to low pore connectivity or the inability of MIP to fully access the pore network due to pressure limitations of the method. A comparison of cumulative pore fractions determined from SANS and MIP suggests that < 30% of the total porosity is accessible through pore throats < 1 nm radius. At these length scales Fickian diffusion of solutes and Knudsen diffusion of gas become the dominant transport mechanisms.

These data demonstrate the importance of very small pores to the overall pore structure of the mudstones. To really understand pore scale processes we need to not only develop a fully realized view of what the pore network looks like at multiple length scales but also understand how different techniques provide windows into that view. Results from flow simulation using pore networks created from FIB-SEM data will be presented. These simulations will help determine the contribution of different types of flow mechanisms and will form the basis for reactive transport models of geochemial processes.

Sandia is a multiprogram laboratory operated by Sandia Corporation, a Lockheed Martin Company, for the U.S. DOE under contract DE-ACOC4-94AL85000.

Abstract

The work presented here is part of the Changing Arctic and Sub-Arctic Environment (CASE) program which is an Initial Training Network (ITN) that focuses on biological proxies and their use in reconstructing climate change and, in particular, the marine environment. One of these proxies is the sea ice diatom biomarker IP_{25} which is a highly branched isoprenoid (HBI) alkene synthesised by some Arctic sea-ice diatoms and has been shown previously to be a specific, stable and sensitive proxy measure of Arctic sea ice when detected in underlying sediments [1].

The current study focuses on three key elements: (1) An analytical calibration of IP_{25} isolated from marine sediments and purified using a range of chromatographic methods was conducted in order to improve the quantification of this biomarker in sediment extracts [2]. (2) Analysis of >30 near-surface sediments from the Nordic Seas was carried out to quantify biomarkers previously suggested as indicators of open-water phytoplankton (brassicasterol) [3] and sea-ice (IP_{25}) conditions [4]. The outcomes of the biomarker analyses were used to make comparisons between proxy data and known sea ice conditions in the study area derived from satellite record over the last 20 years. (3) A consideration of possible processes occurring within surface sediments and the implications of these on downcore analysis of biomarkers for palaeo-climate reconstructions.

Energetic Studies of Nanophase and Amorphous Carbonate Minerals

ALEXANDRA NAVROTSKY[1]*

[1]Peter A. Rock Thermochemistry Lab, University of California Davis, Davis, CA 95616 USA, anavrotsky@ucdavis.edu

13f. Physicochemical constraints of the marine carbonate system: recent insights into the reactivity of carbonate minerals in aqueous solutions

Solution calorimetric methodology has been applied to measuring the energetics of formation and transformation of amorphous and nanophase carbonates in the CaCO3 - MgCO3 - FeCO3 system. The data point to several general conclusions, summarized here. (1) Amorphous calcium carbonate (ACC) exists in two forms: a heavily hydrated material initially precipitated from strongly oversaturated aqueous solution and a less hydrated form, which is energetically similar whether formed by biomineralization or by thermal dehydration of the initially precipitated phase. Transformation in the sequence hydrated ACC – relatively anhydrous ACC – vaterite – aragonite – calcite is energetically downhill and thus ACC can be a precursor to any of these crystalline phases. (2) Amorphous magnesium carbonate (AMC), despite being energetically more metastable than ACC, is more persistent (can be kept for a year rather than a few days before crystallizing under ambient conditions). This is attributed to the kinetic difficulty of removing water of hydration from the environment of Mg2+. (3) Amorphous iron carbonate (AFC) is energetically similar to AMC but is very susceptible to crystallization and oxidation. The energetics of the amorphous versus crystalline carbonate phases may be controlled by the ionic radius of the cation. (4) The ACC – AMC system shows a striking change in energetic behavior near Ca/Mg = 1. More Mg-rich compositions, though amorphous, appear to be heterogeneous and consist of nanoscopic regions of dolomitic and magnesitic composition. The amorphous material with Ca/Mg = 1 may be a precursor to dolomite. (5) Measurement of the surface energies of calcite, aragonite, and vaterite is currently in progress. These general trends are discussed in the context of carbonate formation in biological, carbon sequestration, diagenetic, and fresh water and oceanic environments.

Nanoscale Effects on the Thermodynamics of Oxidation-Reduction Equilibria in Transition Metal Oxide Systems

ALEXANDRA NAVROTSKY[1]*

[1]Peter A. Rock Thermochemistry Lab, University of California Davis, Davis, CA 95616 USA, anavrotsky@ucdavis.edu

Keynote Speaker

Many low temperature aqueous geochemical processes involve the precipitation, dissolution, and redox reactions of fine - grained (nanophase) transition metal oxide minerals. Because phases with different oxidation states have different structures and, often, different surface energies, their redox phase boundaries can be significantly shited in oxygen fugacity - temperature space at the nanoscale. We have shown, for example, that FeO (wustite) has no stability field at the nanoscale, and that the stability field of magnetite is expanded relative to both reduction (to iron) and oxidation (to hematite) for small particles. A current calorimetric study suggests that fayalite has a higher surface energy than the assemblage magnetite plus quartz, thus shifting the QFM buffer to more reducing conditions for nanoparticles. In the manganese oxides, the phase field of Mn3O4 (hausmannite) is expanded relative to reduction to MnO and oxidation to Mn2O3, and the Mn2O3-MnO2 equilibrium is also affected. Furthermore, there appears to be complex involvement of water in these redox reactions, with possible reversible formation of hydrated amorphous layers at the nanoscale. The thermodynamic effects of particle size on reactions at bulk and nanoscale in the system magnetite - maghemite - ulvospinel are also under investigation. Thus significant nanoscale thermodynamic effects are a general phenomenon and must be considered, in addition to kinetic factors, in redox reactions in mineral and mineral - water systems at low temperature.

Amphiboles from the subcontinental lithospheric mantle of the Northern Victoria Land (Antartica): implications for the water activity and metasomatism

S. NAZZARENI[1*], C. BONADIMAN[2], P. COMODI[1], B. FACCINI[2] , P.F. ZANAZZI[1], M. COLTORTI[2], AND G. GIULI[3]

[2]Department Earth Sciences, University of Ferrara. Italy

[3] Scuola di Scienze e Tecnologia, University of Camerino

Spinel-bearing lherzolites and wehrlites from Baker Rocks (Northern Victoria Land, Antartica) have pargasitic amphiboles as metasomatic phase [1]. We investigated the amphiboles in order to estimate the physico-chemical conditions of their formation and, combined with the H2O content in coexistent pyroxenes, to estimate the total water budget of this mantle domain. The samples were analysed by Single-Crystal XRD, EMPA, SIMS and XANES to have an accurate crystalchemical formula and to calculate the fH2 and ultimately the fO2 and aH2O. The crystalchemical data showed that these amphiboles have similar composition, irrespective of the textural position and lithotype. The high equivalent thermal factor and cation off-centering suggest partition of Ti at M1 site. The high M3 site distortion and low <M3-O> distances suggest the presence of Fe3+ at M3 site. Starting from the crystallographic data we calculated dehydrogenation using the Oberti et al.'s method [2], whereas Fe3+/Fetot was measured by Fe K-edge XANES spectroscopy at GILDA beamline. Dehydrogenation varies from 0.80 to 1.07 a.f.u., with the lowest values for samples with lowest Ti and Fe. The measured Fe3+/Fetot and the crystallographic data suggest that dehydrogenation occurred by Ti-oxy substitution with only a minor Fe-oxy component. These data were used to estimated the aH2O and the fO2 of the mineral assemblage, following Lamb & Popp [3] and Ballhaus et al. [4] methods. Pressure estimates indicate a relatively shallow lithospheric mantle (P: 0.5-1.6 GPa) and T in the range of 800-1000 °C, implying an aH2O for the amphibole formation in the range of 0.01- 0.02. The calculated aH2O values are quite low if compared with those reported for the stability field of the reaction in the T-aH2O diagrams [3]. Δlog fO2 values relative to FMQ buffer range from -1.4 to -0.4. This range perfectly overlaps that of anhydrous samples from a locality nearby, as well as those obtained from peridotite xenoliths from continental setting [Δlog (FMQ) = -1.5 - +1.5; T=900-1100; P= 1.0-1.5 GPa. The low water content of amphibole is in agreement with that of the coexisting pyroxenes, which are about two times lower than those from other intraplate off-craton mantle xenolith [5], discharging the hypothesis that their low H2O contents may have resulted from the OH being preferentially partitioned in amphibole. This fact confirms the anomalously low whole-rock water content shown by the Antarctic sublithospheric mantle domain in a rifting setting.

Biogeochemical weathering of serpentinite in field and laboratory studies

K. NEGRICH[1*], J.L. BAUMEISTER[2], E. YARDLEY[1], J. MACRAE[1], E.M. HAUSRATH[2], AND A.A. OLSEN[1]

[1]University of Maine, Orono, USA, kimberly.negrich@maine.edu (*presenting author); eileen.yardley@maine.edu; jean.macrae@umit.maine.edu; amanda.a.olsen@maine.edu

[2]University of Nevada, Las Vegas, USA, baumeis5@unlv.nevada.edu; elisabeth.hausrath@unlv.edu

Biological processes, specifically mediated by microbial communities, are closely tied to mineral weathering. Serpentinites, for example, exert strong controls on the biota that develop on them. The bulk chemistry of serpentinite rocks is high in Mg and trace elements and low in nutrients such as Ca, K, P, and N. This causes an extreme and stressful environment for plants and microbes, that has been extensively studied by ecologists [1]. However, the role that serpentine biota play in development of serpentine soils has not been examined. In order to address this question, we have observed biogeochemical weathering of serpentinite in the field, and we are conducting laboratory studies to examine how iron-oxidizing bacteria and oxalic acid influence weathering rates of serpentine minerals.

Field samples from the Trinity Ultramafic Complex in the Klamath Mountains, California were analyzed by biological activity reaction tests (BART™) to test for the presence of iron-related bacteria. The BART™ indicators tested positive for iron-related bacteria in both rock and soil cores, [2] suggesting that biological impacts on Fe cycling may be important. However, future work is needed to compare lizardite dissoltuion in the presence and absence of Fe-oxidizing bacteria.

Lab experiments were performed to test the effect of oxalic acid on lizardite dissolution. Oxalic acid is an exudate from many soil fungi, and is an important ligand that binds to metals in the surrounding soil. We found that oxalate in concentrations of 50 mMol enhanced lizardite weathering by a factor of six [3].

We also plan to complete similar lab experiments with iron-oxidizing bacteria. We hypothesize that iron-oxidizing bacteria enhance lizardite dissolution, contributing to early serpentinite weathering in deep profiles. Crushed lizardite grains will be reacted in batch solutions with *Acidithiobacillus ferrooxidans*; a species common in acid mine drainage [4], *Ferritrophicum radicicola*; a neutrophilic species isolated from a wetland rhizosphere, and in abiotic solutions [5]. Experiments will be conducted at a range of pH values, but constrained by the survival needs of each species. Aliquots of solution will be extracted and analyzed for Mg, Si, Fe, Al, Ni, Cr, Cu, Co, and Ti using ICP-MS. Magnesium and silicon release rates will be used to calculate dissolution rates of lizardite in both biotic and abiotic experiments. Iron-oxide precipitates will be analyzed with SEM-EDS. Measured dissolution rates in the presence of microorganisms will be compared to abiotic dissolution rates, and used in reactive transport modeling of the field area.

Chemical zoning of eclogite lenses in subduction complexes: an example from the Leaota Massif, South Carpathians

ELENA NEGULESCU[1*] AND GAVRIL SĂBĂU[1]

[1]Geological Institute Of Romania, Bucharest, Romania elinegu@yahoo.com (*presenting author), g_sabau@yahoo.co.uk

The Leaota Massif basement comprises several concordant units characterized by internal lithologic and metamorphic contrasts. Eclogite and metagabbronorite lenses, hosted in a semipelitic matrix, appear sandwiched between two units of pelitic/meta-igneous composition.

The eclogite lenses are chemically zoned, as best exemplified by the Bughiţa Albeştilor (BA) occurrence, displaying several well-defined concentric zones, from fine-grained massive phengite-free domains that grade outwards into phengite-rich zones. The mineral assemblage of the phengite-free domain is garnet + omphacite + amphibole + zoisite + quartz + rutile. The phengite-rich zone preserved a low-variance mineral assemblage of garnet - omphacite - phengite - paragonite - amphibole - kyanite - clinozoisite - quartz – rutile. Mg-rich staurolite (X_{Mg} = 0.29 – 0.40) was rarely identified in kyanite porphyroblasts. Whole-rock compositions approach N-MORB to E-MORB, the latter ones also displaying HFSE-depletion.

The macro- and the microscopic features of these zones, together with their trace elements patterns that resemble N-MORB except the LILE (Rb, Ba, K, U) enrichment in the rind (fig. 1, 2), support the interpretation of the phengite-rich domains as a metasomatic rind of the phengite-free inner part, ensuing interaction with subduction-zone fluids.

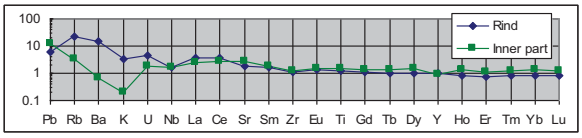

Figure 1: N-MORB-normalized [1] trace elements abundance of the inner part and its metasomatised rind of the BA-eclogites

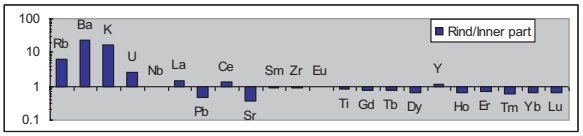

Figure 2: Chemical variation between the inner part and its metasomatised rind of the BA-eclogites

The geochemical features of the eclogite and metagabbronorite knockers, especially the distinctive LILE enrichment, document subduction-zone metamorphism of normal and SSZ ocean floor remnants enclosed in a subduction mélange. The LILE-metasomatism of the semipelitic matrix rocks themselves, demonstrated by high Ba contents of K-white micas [2], also support this interpretation.

Micas and columbite-tantalite from some Portuguese granitic aplite-pegmatites

A.M.R. NEIVA[1*], P.B. SILVA[2], AND J.M.F. RAMOS[2]

[1]University of Coimbra, Geosciences Centre Earth Sciences, Portugal, neiva@dct.uc.pt (* presenting author)

[2]National Laboratory of Energy and Geology, S. Mamede de Infesta, Portugal, paulo.bravo@lneg.pt; farinha.ramos@lneg.pt

Different micas occur in granitic beryl-columbite-phosphate subtype aplite-pegmatite veins and sills from the Sabugal area. Subhedral lithian muscovite surrounds relics and penetrates along cleavages of primary muscovite, showing sharp contacts. The lithian muscovite containing higher Fe^{2+}, Li and F contents replaces primary muscovite. Radial lithian muscovite from aplite presents lighter areas (richer in Fe^{2+}, Li and F) surrounding and penetrating darker areas (richer in Al^{VI}, $Al^{IV} + Al^{VI}$ and OH) in BSE images and showing sharp contacts, suggesting that the former areas replace the latter areas. Primary muscovite and lithian muscovite from aplite and aplite-pegmatite have higher Fe^{2+}, Li, Rb and F contents and lower Mg content than primary muscovite from the parent granite and define a trend in the Li-Mg diagram. Very rare lepidolite from aplite-pegmatite surrounds lithian muscovite. In aplite-pegmatite, zinnwaldite penetrates along cleavages and partially surrounds lithian muscovite, suggesting that the former replaces the latter. Locally zinnwaldite and lithian muscovite seem to show different orientations. All contacts are sharp. Rare polylithionite partially surrounds lithian muscovite from aplite. The rim has higher Si, Li, Rb and F contents and lower $Al^{IV} + Al^{VI}$ and OH contents than the core. The compositions of the micas studied are well distinguished in Li-R^{3+} + Ti-R^{2+} and $Al^{IV} + Al^{VI}$ versus Fe + Mg diagrams. The lithium micas resulted from the accumulation of F and Li in derivative silicate liquids. Primary muscovite is texturally and chemically identified. Lithium micas have higher Li, F contents and lower Al^{VI}, $Al^{IV} + Al^{VI}$ and OH contents than primary muscovite.

Columbite-tantalite from granitic aplite-pegmatites veins and sills from the Sabugal area occurs associated with K-feldspar, albite, quartz, muscovite and beryl. Columbite-(Fe) is more abundant than columbite-(Mn) and tantalite-(Fe) is rare. Individual crystals of columbite-(Fe) are complexely zoned, showing alternating light BSE contrast zones high in W, Ta, Sn and F and dark BSE contrast zones high in Nb and Ti. Other complexely zoned crystals have col-(Mn) containing higher Nb, Mn contents, and lower Ta, Fe contents and Ta/(Ta+Nb) value than col-(Fe). A zoned columbite-(Fe) crystal shows the lighter zones containing higher Ta, Fe contents and Ta/(Ta+Nb) value and lower Nb content than the darker zones. In this crystal, a partial thin rim of tantalite-(Fe) is the richest in Ta, Sn, Ti, Sc, Fe and Mg contents and Ta/(Ta+Nb) value and the poorest in W, Nb and Mn contents. Columbite-tantalite is a primary phase. Crystals are complexely zoned, showing sharp contacts between zones, with exchange of Nb↔Ta and Fe↔Mn, suggesting that magmatic fluxes may have played a role, but diffusive reequilibration was not very important. The increasing content of fluxing elements like Li, F. B and P increase the solubility of columbite-(Mn). This type of zoning may be due to disequilibrium conditions.

Using a surface precipitation approach to model the continuum between Hg adsorption and precipitation onto *Bacillus subtilis*

RYAN M. NELL*, JENNIFER E.S. SZYMANOWSKI, JEREMY B. FEIN

University of Notre Dame, Civil Engineering and Geological Sciences, Notre Dame, IN 46556 (*presenting author, rnell@nd.edu)

The effect of bacterial cell wall adsorption on the precipitation of mineral phases in supersaturated systems is not well constrained experimentally, although there is circumstantial evidence for enhanced precipitation in these systems with the presence of bacteria. Surface complexation modeling has been applied successfully to model the adsorption of a wide range of aqueous metal cations onto bacterial cell walls. Surface precipitation theory represents an extension of surface complexation modeling that can bridge the continuum between adsorption and precipitation. However, only a small number of studies have examined the effect of bacteria on mineral precipitation reactions in well-controlled experiments, so testing and calibration of the surface precipitation modeling approach is limited for bacterial systems. In this study, we measured the extent of Hg(II) removal from solution, in the presence and absence of non-metabolizing cells of *Bacillus subtilis* in both sulfide-free and sulfide-bearing systems under a range of concentrations from undersaturation to supersaturation with respect to solid phase HgO and HgS, respectively. Initial Hg molalities ranged from 10^{-5} to 10^{-2} m at pH 4.5; ionic strength was buffered by conducting the experiments in 0.01 M $NaClO_4$, and the wet mass of bacteria used in each biotic experiment was held constant at 5 g/L. Sulfide-free experiments were conducted aerobically with a two-hour equilibration period. Sulfide experiments were conducted with varying concentrations of Na-sulfide under anaerobic conditions. Samples from both types of experiments were filtered and analyzed for aqueous Hg by a Hydra II AF Mercury Analyzer following the ASTM International standard test method for mercury in water.

The biotic systems exhibited enhanced Hg(II) removal relative to the abiotic controls in undersaturated conditions, likely due to Hg(II) adsorption onto cell wall functional groups. However, under the highest Hg concentrations studied in the sulfide-free system, the bacteria inhibit precipitation, maintaining high concentrations of Hg in solution. We use surface precipitation modeling to account for the range of Hg removal that we observed in the sulfide-bearing system, yielding equilibrium constants that can quantitatively account for Hg adsorption and precipitation with a single set of parameters. This approach offers promise for modeling the fate and distribution of aqueous metals in geologic systems with a wide range of saturation state conditions.

Microstructures in lunar zircon: key to interpretation of U-Pb ages

ALEXANDER A. NEMCHIN[1*], MARION L. GRANGE[1], NICHOLAS E. TIMMS[1] AND ROBERT T. PIDGEON[1]

[1]Curtin University, Perth, Australia, nemchina@kalg.curtin.edu.au

The interpretation of internal microstructures has become an integral part of geochronological studies using the U-Pb system in zircon from terrestrial samples. However, U-Pb analysis of lunar zircon was abandoned in late 80s and only recently resumed and combined with imaging utilising different methods available to reveal internal microstructures in these grains. Extensive study of lunar zircons during the last few years resulted in accumulation of data sufficient to build a preliminary classification of their internal structures. This classification is essential for the correct interpretation of U-Pb ages. It is particularly important because majority of lunar zircons occur as abraded, broken fragments in the matrix of the breccias, with no evidence of their origin or history. Also, increasingly, we are finding zircon grains with complex U-Pb age patterns, which makes interpretation difficult. The only way of addressing these issues is studying the textures and structures in lunar zircons and cross correlating this information with the observed pattern of U-Pb ages determined by ion microprobe analyses.

Lunar zircons are classified according to: (i) textural relationships between zircon and surrounding minerals in the breccias, (ii) the internal microstructures of the zircon grains and (iii) in-situ analyses of Th-U-Pb isotopic systems with ion microprobe. Both igneous (primary) and impact (secondary) features can be identified in lunar zircon.

Primary zircons occur as part of a cogenetic mineral assemblage (lithic clast) or as individual mineral clasts and are unzoned, or have sector zoning or rarely oscillatory zoning. U-Pb ages of zircons exhibiting these microstructures determine the timing of magmatic crystallisation.

Secondary microstructures include locally recrystallised domains, localised amorphization, crystal-plastic deformation, planar deformation features and fractures, and are associated with impact metamorphism. The first two types often yield internally consistent, concordant U-Pb ages that date impact events. The absolute ages of other secondary microstructures cannot be determined. Nevertheless, it is possible to define their relative timing from the relationships with other microstructures. In addition, regular occurence of these features (e.g. planar deformation features are found in lunar zircon along {001}, {110}, and {112}, typically with 0.1-25 μm spacing and {112} commonly contain micro-twin lamellae with 65° / <110> misorientation relationships, while dislocation creep commonly forms deformation bands parallel to {100} planes) can be explained in terms of elastic anisotropy of zircon and used to predict conditions experienced by different zircon grains during the impacts.

Planar deformation features, crystal-plastic deformation and micro-fractures can provide channels for Pb diffusion and their identification can explain some instances of partial resetting of the U-Pb isotopic system. Consequently their identification in a zircon grain should prompt a careful examination of the U-Pb ages obtained in this grain and their significance.

Metal speciation and dynamics of carrier phases in a boreal forested catchment under transient chemical conditions

ELISABETH NEUBAUER [1*], STEPHAN KÖHLER [2], FRANK V.D. KAMMER [1], HJALMAR LAUDON [3] AND THILO HOFMANN [1]

[1]University of Vienna, Department of Environmental Geosciences, Vienna, Austria, elisabeth.neubauer@univie.ac.at, thilo.hofmann@univie.ac.at (*presenting author)

[2]SLU, Department of Aquatic Sciences and Assessment, Uppsala, Sweden

[3]SLU, Department of Forest Ecology and Management, Umeå, Sweden

The formation and fate of natural aquatic colloids was investigated in a boreal catchment (68 km^2) with transient pH conditions (pH 3.8-6.4) and diverse landcover types (wetland, forest and sediment dominated). We examined the influence of colloids on metal speciation, i.e. iron, aluminum, arsenic, manganese, and rare earth elements (REE).

Flow-Field Flow Fractionation [1], membrane filtration (0.2 μm), cation exchange column separation [2], ultrafiltration (1 kDa) and scanning electron microscopy were used to characterize colloids and to quantify colloid-metal associations.

In the small headwater catchments, complexation with natural organic matter (NOM) was dominating the speciation of iron, aluminum, manganese and REEs. 50-70% of the total arsenic was associated with NOM, and substantial concentrations were present as dissolved species. Along the natural pH gradient we observed a gradual increase of iron in form of iron-oxy(hydr)oxide particles (50 nm up to several hundred nm). Despite this increase, REEs were still associated to colloidal NOM, while up to 30% of arsenic and manganese adsorbed or co-precipitated with the iron particles.

Chemical equilibrium modelling confirmed that complexation of REEs to NOM was stronger than the sorption of REEs to iron-oxy(hydr)oxides. The concentration of iron minerals can only be explained by a stronger than expected Fe-NOM complexation. The complexation constant would then be higher than in the data base of Minteq [3].

We quantified fluxes from all sub-catchments and used landscape type analysis for the estimation of metal export. Mass balances indicate that there is no loss of iron and trace elements during the transport through the catchment, despite the formation of relatively large iron-oxy(hydr)oxides particles. An additional source of iron, manganese, and sulphate through groundwater influx accounts for the observed total export from the catchment. Our study implies that the trace metals mobilized from the different upstream sites behave mainly conservative despite shifts in speciation. Mass balance calculation does allow for the quantification of the relative contribution of the different landscape elements for total metal flux.

Interfacial Fe(II)-Fe(III) electron transfer and atom exchange in smectites: effect of smectite properties

ANKE NEUMANN[1*] AND MICHELLE M. SCHERER[1]

[1]Department of Civil and Environmental Engineering, The University of Iowa, Iowa City, USA, anke-neumann@uiowa.edu (* presenting author)

Heterogeneous reactions between aqueous Fe(II) and Fe(III) oxides have extensively been studied, leading to a new conceptual framework which includes electron transfer between aqueous Fe(II) and structural Fe(III), bulk electron conduction, and Fe(II)-Fe(III) atom exchange [1]. A recent study showed that interfacial electron transfer between aqueous Fe(II) and structural Fe(III) also occurred in one clay mineral [2]. Whether this observation can be generalized for all clay minerals and whether similar processes as observed for the heterogeneous redox reaction in Fe(III) oxides are also crucial for clay mineral redox reactions is unclear.

Studies on chemical reduction of structural Fe in smectites showed that the type of reductant as well as smectite structural properties determined the extent of Fe reduction and the resulting structural Fe(II) entities. Thus, we investigated well-characterized smectites differing in structural Fe content, location of structural Fe (octahedral vs. tetrahedral), and location of excess charge (octahedral vs. tetrahedral) for their reaction with aqueous Fe(II), a reductant abundant in natural anaerobic environments.

Stable isotope specific Mössbauer spectroscopy was used to determine the extent of reduction of structural Fe in smectites after exposure to aqueous ^{56}Fe(II), which is invisible in Mössbauer spectra. Experiments with aqueous Fe(II) enriched in ^{57}Fe were carried out to determine the exchange of stable Fe isotopes between aqueous Fe(II) and structural Fe(III) in smectites. Different pools of Fe(II) and Fe(III) were investigated by sequential extraction procedures and solid reaction products were characterized with X-ray diffraction and electron-based microscopic methods.

[1] Gorski & Scherer (2011) *Aquatic Redox Chemistry*, **1071**, 315-343, [2] Schaefer, Gorski & Scherer (2011) *Environ. Sci. Technol.* **45**, 540-545.

Paired ^{87}Sr/^{86}Sr - $\delta^{88/86}$Sr values in Paleozoic conodonts

LEONID NEYMARK*, WAYNE PREMO, AND POUL EMSBO

US Geological Survey, Denver, Colorado, USA lneymark@usgs.gov (* presenting author), wpremo@usgs.gov, pemsbo@usgs.gov.

The isotopic composition of Sr (^{87}Sr/^{86}Sr) is widely used as a tracer in paleooceanographic, paleoclimatologic, paleotectonic, and stratigraphic investigations. Until recently, the stable Sr-isotopic ratio (^{88}Sr/^{86}Sr) was assumed to be constant and was used for internal normalization to correct for instrumental mass fractionation, thus masking any natural mass-dependent Sr-isotopic fractionation. Newly developed MC-ICPMS and Double Spike (DS) TIMS methods, however, document measurable Sr isotope fractionation in natural systems.

We present the first DS TIMS $\delta^{88/86}$Sr (‰) data ($\delta^{88/86}$Sr = (^{88}Sr/^{86}Sr$_{sample}$/^{88}Sr/^{86}Sr$_{NBS\text{-}987}$-1)×1000) for fossil biogenic marine phosphates (conodonts). The ^{84}Sr-^{87}Sr DS preparation and data reduction followed recommendations in [1]. Our DS was calibrated against NIST SRM-987 assuming ^{88}Sr/^{86}Sr = 8.375209 to give $\delta^{88/86}$Sr = 0.002 ± 0.024 ‰ (2SD). External reproducibility was evaluated using USGS Sr isotope standard EN-1 (a carbonate shell of a giant clam Tridacna collected live from the floor of the Enewetak lagoon, Marshall Islands), which yielded $\delta^{88/86}$Sr = +0.262 ± 0.032 ‰ (2SD) and NRC Canada sea-water trace element reference material NASS-6, which yielded $\delta^{88/86}$Sr = +0.371 ± 0.026 ‰ (2SD).

Paired ^{87}Sr/^{86}Sr - $\delta^{88/86}$Sr values were measured in 30 Paleozoic conodont samples from different stratigraphic horizons (Middle Ordovician to Middle Mississippian). The samples were screened for diagenetic alteration so that only conodonts with Color Alteration Index CAI≤ 3.0 were analyzed. The $\delta^{88/86}$Sr values in these samples vary from slightly positive to significantly negative (up to –1.05 ‰). This range is significantly broader than the variability observed in Paleozoic marine brachiopods [2] but is similar to the range in human tooth enamel and bone [3]. The reasons for this variability in conodonts are not well understood, but likely reflect changes in seawater composition and/or biogenic fractionation of Sr isotopes. The range in $\delta^{88/86}$Sr also causes ^{87}Sr/^{86}Sr values based on DS measurements to deviate appreciably from ^{87}Sr/^{86}Sr values determined using conventional mass-fractionation corrections.

Our results indicate that the study of conodont $\delta^{88/86}$Sr values has the potential for better constraining the marine Sr cycle and its relation to secular changes in marine chemical and biologic systems.

Using PLFA to constrain microbial distribution related to S-cycling in oil-sands composite tailings during reclamation

NGONADI, N.*[1], ZIOLKOWSKI, L.A.[1], PENNER, T.[2], SLATER, G.F.[1]

[1]McMaster University, Hamilton, Canada gslater@mcmaster.ca
[2] Syncrude Environmental Research, Edmonton, Canada

Understanding the extent and nature of biogeochemical cycling by microbial communities is a critical component of predicting and managing their impact within systems. This study is applying phospholipid fatty acid (PLFA) analysis to investigate the microbial communities associated with reclamation of composite tailings recently initiated at Syncrude's Mildred Lake site. PLFA concentrations and distributions were determined within the sand cap that separates the fen reclamation from the CT below, as well as in the CT itself. The goal was to determine how cell densities and microbial community parameters varied between the CT and the sand cap, and to determine the relatively importance of these communities to biogeochemical cycling of sulphur, particularly H_2S generation.

Results from sand cap samples show cell densities in the 10^7 range based on generic conversion factors, not unexpected for oligotrophic conditions. The presence of branched PLFA, particularly iso and anteiso C15:0 are indicative of the presence of sulphate reducing organisms in the sand cap. Such organisms have also been enriched from these samples. Analysis of CT samples in on-going and will be compared to these surface samples to determine whether microbial cycling rates are expected to be lower or higher within the CT which has a highly distinct geochemistry to the sand cap, including the presence of abundant sulphate, used in flocculation of tailings.

The results of these studies will yield insight into the cycling that may be carried out by these communities. They also provide the foundational understanding for on-going isotopic studies of microbial carbon sources and cycling.

Identifying the arsenic source in glacial aquifer sediments, west-central Minnesota, USA

SARAH L. NICHOLAS[1]*, BRANDY M. TONER[2], MELINDA L. ERICKSON[3], ALAN R. KNAEBLE[4]

[1]Land and Atmospheric Sciences Graduate Program, Department of Soil, Water, and Climate, University of Minnesota, Saint Paul, MN, USA (*presenting author) nich0160@umn.edu
[2]Department of Soil, Water, and Climate, University of Minnesota, Saint Paul, MN, USA toner@umn.edu
[3]United States Geological Survey Minnesota Water Science Center, Mounds View, Minnesota USA merickso@usgs.gov
[4]Minnesota Geological Survey, Minneapolis, Minnesota USA knaeb001@umn.edu

X-ray absorption spectroscopy (XAS) and sequential extractions were used to identify and quantify different arsenic (As) species present in glacial aquifer materials from west-central Minnesota, USA. Sample locations were chosen based on proximity to domestic drinking water wells with As concentrations exceeding the $10 \mu g L^{-1}$ maximum contaminant level for drinking water in the United States. Glacial sediments were collected from rotary-sonic drill cores (25-100m depth).

Sequential extractions were used to quantify arsenic species concentrations. Total (all species) arsenic concentrations of the glacial aquifer sediments are not unusually high, however the concentration of labile species of arsenic are unusually high. Here the labile species are defined operationally as those liberated by anion exchange with Cl^- and PO_4^{-3}. Labile As concentrations in many samples are near or above the crustal average of about 1-1.8mg kg^{-1} for all forms of solid-phase arsenic.

X-ray absorption spectroscopy of the samples shows that arsenic is present in three oxidation states: As^{5+}, As^{3+}, and $As^{1-\text{ to }2-}$. Non-uniform distribution of oxidized arsenic may explain the spatial heterogeneity of high As wells in the area.

Arsenic-bearing sulfide minerals in the Cretaceous shale fragments found in these glacial sediments are frequently hypothesized to be the source of arsenic in drinking water in west-central Minnesota. Our data suggest that the solid-phase arsenic sources in water are likely to be the more labile, oxidized species found in unusual abundance in these samples. Most As-bearing sulfide minerals would be expected to be chemically refractory in the reduced groundwater of the area.

[3] Lundin Petroleum Norway, Strandveien 50D, 1366 Lysaker, Norway

Introduction

Widespread areas of the seabed in the southwestern Barents Sea are dominated by pockmarks, being manifestations of hydrocarbon venting and are, therefore, of considerable interest as possible indicators for deeper hydrocarbon reservoirs. Concomitantly, they form specific habitats for microbial communities. These pockmarks and the associated microbial ecosystems are in the focus of the current study using biogeochemical and microbiological approaches.

During two research cruises in 2009 and 2011, funded by the Swedish oil company Lundin, about 42 surface sediment cores of up to 2.5 m length were selected. For comparison cores were taken inside and outside of the pockmark structures.

Results and Conclusion

The analysis of methane within the pockmarks reveals only marginal amounts of gas, indicating that nowadays the pockmarks system is more or less inactive. Also microbial activity is astonishingly low in the entire sampling area as indicated by low sulfate reduction rates. Processes like anaerobic oxidation of methane (AOM) can be excluded for this depth interval since methane concentration and net sulfate consumption are very low.

Different biomarkers have been analyzed being indicators for fossil hydrocarbons (e.g. *n*-alkanes, hopanoids and steranes), or past microbial populations (glycerol dialkyl glycerol tetraethers (GDGTs)). Biomarker profiles do not show significant differences between pockmark and reference sites, inferring that fluid flow through the present pockmarks is currently not taking place. However, in the deeper core section an increase for hydrocarbons and microbial markers is detectable which might indicate the transition to the interval of paleo-seepage.

The results show that the observed pockmarks are rather relicts of paleo-seepage than indicators for active fluid flow. Their formation is most likely related to paleo-events of decaying gas hydrates induced by the pressure release from the melting ice shield during last deglaciation (approx. 13ka B.P.). [1]

Microorganisms, which are involved in the methane cycle, show a characteristic light carbon isotopic composition ($\delta^{13}C$). [2] Currently, the $\delta^{13}C$ values of GDGTs from top and bottom part of the sample cores are investigated to unravel a possible correlation of the biomarker increase to paleo-seepage.

Furthermore, a piece of a carbonate crust, sampled from an active seep in the Norwegian Sea is being analyzed to compare its biomarker composition to our previously investigated samples.

Bulk redox status or redox microenvironments: Which is more important for controlling trace element transport?

PETER S. NICO[1*], CHARULEKA VARADHARAJAN[1], HARRY R. BELLER[1], RUYANG HAN[1], LI YANG[1], EOIN L. BRODIE, MARK CONRAD, MARKUS BILL, AARON J. SLOWEY[1], WILLIAM MOSES[1]

ajslowey@lbl.gov
wwmoses@lbl.gov

The redox form of trace elements is frequently the major control on the tansport of those elements within soil and sediment systems. However, what controls the transformation from one redox form to another is much more debatable. Clearly the dominant or bulk redox condition of a sytem has an important impact on the chemical form of the trace metals therein. However, rarely can trace metal behavior be simply predicted by bulk redox measurements. The current presentation will focus on recent work studying the bioreduction of Cr(VI) to Cr(III) under differing dominant terminal electron acceptor (TEA) conditions (i.e. NO_3^-, native Fe(III)-containing minerals, and SO_4^{2-}) and the subsequent remobilization of that Cr via reoxidation.

For the bioreduction phase of the experiment, advective flow laboratory columns packed with Hanford 100H aquifer sediments were subject to oxygen-free, synthetic groundwater containing Cr(VI) and lactate in the presence of different electron acceptors (NO_3^-, native Fe(III)-containing minerals, and SO_4^{2-}). Chromate removal was observed under all conditions to varying degrees. The nitrate-treated columns, all of which exhibited denitrifying conditions, as well as in some of the sulfate-amended columns in which fermentative conditions were dominant, showed the most rapid removal of Cr(VI). After approximately one year, selected replicates of the nitrate-amended and sulfate-amended (one fermenting, one not) conditions were removed from the glovebox and presented with oxygen and nitrate containing, lactate- and chromate-free synthetic ground water in order to promote oxidative remobilization of Cr.

Interestingly, the solid-state form of Cr at the end of the bioreduction phase of the experiment appeared to be relatively independent of the dominant TEA present. However, in the reoxidation phase of the experiment, the rate and degree of Cr remobilization was strongly influenced by the bulk redox condition history of the system. These results present an interesting contrast between those behaviors controlled by local conditions and those controlled by bulk conditions.

Contrasting on- and off-axis melt delivery: a Sr and Nd isotopic study of the Moho transition zone of the Oman ophiolite

MARIE NICOLLE[1]*, DELPHINE BOSCH[2], LAURIE REISBERG[1], DAVID JOUSSELIN[1] AND AURORE STEPHANT[1]

[1]Université de Lorraine, CRPG-CNRS, Vandoeuvre les Nancy, France, mnicolle@crpg.cnrs-nancy.fr (* presenting author)
[2]Université Montpellier 2, Géosciences Montpellier, Montpellier, France

Recent tomographic images from the East Pacific Rise [1] indicate that nearly 50% of the melt is delivered off-axis instead of beneath the ridge axis. The consequences of this process can be studied on land in the Oman ophiolite, where structural mapping has shown the existence of both on- and off-axis melt delivery systems [2]. Off-axis diapirs impinge directly on hydrothermally-altered lithosphere and may be contaminated by this material. Petrologically, off-axis melt delivery results in the development of an unusually thick Moho Transition Zone (MTZ) composed largely of clinopyroxenite, whereas on-axis MTZ contains troctolite and gabbro lenses. We are analyzing the Sr and Nd isotopic compositions of pyroxenites, gabbros, diorites, and dunites, from an on-axis (Maqsad) and an off-axis (Mansah) diapir in the Semail massif of the Oman ophiolite to explore the geochemical consequences of these contrasting settings. Leached and unleached whole rocks, as well as clinopyroxene (cpx) separates are being studied, to allow us to investigate both magmatic and later hydrothermal processes. Initial Nd isotopic compositions from unleached whole rock powders are comparable for the two diapirs (ε_{Nd} = 8.5-9.2 on-axis; ε_{Nd} = 5.6-10.3 off-axis), although off-axis rocks display a larger range of variation. In contrast, whole rock Sr isotopic ratios differ markedly, with on-axis samples displaying a limited range of enriched MORB-like compositions ($^{87}Sr/^{86}Sr$ = 0.703010 - 0.703438) whereas off-axis samples have more radiogenic and highly heterogeneous compositions ($^{87}Sr/^{86}Sr$ = 0.703277 - 0.706192). We attribute this difference to the presence of a magma chamber above the on-axis diapir, which protects the MTZ from the effects of hydrothermal circulation. Separated cpx and leached whole rocks from off-axis pyroxenites have less radiogenic compositions ($^{87}Sr/^{86}Sr$ = 0.703218 - 0.703576) than the corresponding unleached whole rocks. Nevertheless, several of these samples have $^{87}Sr/^{86}Sr$ ratios that approach the upper limit of the Indian MORB field. In outcrop, a mixing zone is observed between pyroxenites and crustal gabbros in the MTZ overlying the off-axis diapir. Samples from this mixing zone have more radiogenic cpx compositions than samples collected further from the Moho, suggesting magmatic contamination of the pyroxenites by incorporation of hydrated material rich in seawater-derived Sr.

Weathering in the Rhizosphere Analyzed with Transmission Electron Microscopy

S.M. NIEDZIELA[1]*, A. DOHNALKOVA[2,3], K.A. GREENBERG[1], B.W. AREY[2], Z. BALOGH-BRUNSTAD[1], Z. SHI[3], AND C. K. KELLER[3]

Introduction and Methods

It is generally accepted that bacteria and mycorrhizal fungi enhance mineral weathering and nutrient translocation to their host plants. The role of biofilm in rhizosphere (root zone), on the other hand, is not well known and poorly characterized. The goal of our study was to examine the mineral-fungus-biofilm interface under conditions of calcium and potassium limitation, using transmission electron microscopy. We hypothesized that tree-fungus-bacteria association increases biofilm formation under calcium and potassium limitation, and enhances mineral weathering that will be indicated by distinct depletion profiles of elements under fungal and biofilm cover [1].

Red pine (*Pinus resinosa* Ait.) trees were grown in leach tubes filled with quartz sand amended with 0.5 wt% biotite and 1 wt% anorthite. Half of the trees were inoculated with *Suillus tomentosus* and a group of forest soil bacteria, and the other half were left without microbial inoculation. Additional columns without any biology served as controls. Calcium and potassium were supplied in irrigation water at 0, 10, 30 and 100% of rates for healthy tree growth. A subset of the columns were destructively sampled after three months. Whole mount transmission electron microscopy (TEM) grids were prepared from root-system wash solutions used to collect the rhizospheric microbial community. Anorthite and biotite grains were also collected from the rhizosphere to prepare thin sections using focused ion beam – scanning electron microscopy (FIB-SEM). Thin sections of the 0% treatment and a control were analyzed with high resolution TEM coupled with energy dispersive x-ray spectoscopy to test our hypothesis. Multiple chemical profiles were analyzed on the FIB sections under the fungal cover of anorthite and biofilm cover of biotite.

Results and Discussion

Whole mount TEM shows that the 0% treatment has the greatest species diversity, but all treatments have one or two types of bacteria. The overall bacterial population by number is the largest in the 100% treatment. Fungal hyphae are only oberserved with SEM. On the anorthite FIB sections, a slight decrease of Ca is seen under the fungus compared to the control. The same slight depletion is seen for K, Mg and Fe in biotite under biofilm cover, compared to the control. However, these chemical profile differences between treatments and controls are not significant after 3 months reaction time. Further work after 6, 9 and 12 months is planned to further explore our hypothesis.

Thermodynamic feedbacks in kinetic trace metal-calcite solid solution formation

LAURA C. NIELSEN[1*], DONALD DEPAOLO[1,2], JAMES J. DEYOREO[3]

[1]University of California-Berkeley, Berkeley, CA, USA, lnielsen@berkeley.edu (* presenting author)
[2]Center for Isotope Geochiemistry, Lawrence Berkeley National Laboratory, Berkeley, CA, USA
[3]The Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, CA, USA

Calcite precipitated from natural terrestrial fluids typically incorporates trace to mole percent amounts of impurities. The resulting solid solutions have solubilities different from the pure phase. To understand the relationships between trace element concentration and the environment of calcite precipitation, it is necessary to know how thermodynamic controls on solid solution composition also affect mineral precipitation kinetics. These two factors together determine the solid solution composition. To evaluate the feedbacks between thermodynamics and kinetics we developed a microscopic model of ion-kink attachment-detachment rates which predicts the inhibition and incorporation behaviour of impurities, and its relationship to solution composition.

For solution supersaturations typical of biomineralizing fluids in seawater and of most natural surface waters, ion attachment and detachment occur primarily at kink sites along step edges on the calcite surface. The net ion attachment rate is controlled by the density of compatible kink sites (i.e. a carbonate site for a calcium ion) and by the kinetic barrier for ion attachment, which is thought to reflect ion and kink desolvation kinetics. Ion detachment from kink sites occurs when the solid-solid bonds between the ion and the adjacent lattice sites are broken. Lattice strain induced by incorporation of poorly fitting trace elements will speed ion detachment kinetics. Ion attachment kinetics are primarily governed by solution properties, whereas ion detachment is controlled by bond energetics of calcite. At equilibrium, ion attachment and detachment rates are equal, so the detachment frequency can be calculated from the equilibrium ion activities, which in turn are dependent on the composition of the calcite. Ultimately, with some assumptions about the form of the kinetic rate laws, we can derive a model that simultaneously accounts for the trace element incorporation and its effects on calcite growth rates.

Our results indicate that step velocities of strontian calcites vary non-linearly with aqueous Sr concentration due to the effect of lattice strain on Ca detachment kinetics. The growth rate of Mg-bearing calcite with increasing aqueous Mg, on the other hand, is inhibited primarily by kink blocking, and Mg incorporation is typically controlled by the relative rates of Ca and Mg desolvation. This suggests that the Mg isotopic composition may similarly be controlled by dehydration kinetics. This model can be used to constrain the composition of fluid from which a given calcite precipitated.

The geochemical behavior of thallium in mantle-derived basalts

NIELSEN, S.G.[1*], LEE, C.T.A.[2], SHIMIZU, N.[1]

[1]WHOI, Dept. of Geology and Geophysics, 266 Woods Hole Rd, 02543 Woods Hole, MA, USA, snielsen@whoi.edu
[2]Department of Earth Science, MS-126, Rice University, 6100 Main St., Houston, TX 77005, USA

Thallium (Tl) isotopes are a new stable isotope system that shows great potential as a tracer in igneous systems [1, 2]. One of the main difficulties when doing any geochemical study of Tl is the scarcity of knowledge about the general behavior of this element in various environments. This problem stems from the fact that historically Earth scientists have rarely analyzed Tl. The physical and chemical properties of Tl allows for the possibility that it can act in four different ways, depending on the geodynamic setting: 1) Chalcophile, 2) Lithophile, 3) Fluid mobile, 4) Volatile.

The few studies that have investigated Tl behavior in igneous systems present somewhat conflicting evidence. McGoldrick et al. [3] concluded that sulfur imparts a strong control on Tl concentrations in mid ocean ridge basalts (MORB), which contrasts the general behavior of Tl in more evolved igneous systems, where Tl appears to follow the alkali metals [2]. The more recent studies present more reliable data produced with inductively coupled mass spectrometers (ICP-MS), but the number of data points is either limited or lack some key complimentary geochemical data that might help reveal the processes that control the transport of Tl from the mantle to the Earth's surface [1, 2, 4, 5].

To obtain a more complete understanding of Tl in primitive igneous systems we will present Tl concentration data for a number of MORB glasses, back arc lavas and melt inclusions. These data are complemented by concentrations of alkali metals, water, Cl and S, which will enable us to identify if Tl changes its geochemical affinity in different geologic settings.

U–Pb isotopic systematics on shock-metamorphosed baddeleyite

TAKAFUMI NIIHARA[1,2,3]*

[1]Center for Lunar Science and Exploration, Lunar and Planetary Institute, Houston, Texas 77058, USA. niihara@lpi.usra.edu (* presenting author)
[2]Antarctic Meteorite Research Center, National Institute of Polar Research, Japan
[3]Dept. of Polar Science, SOKENDAI, Japan

The issue of the duration of Martian magmatic activity is one the controversial debates recently [e.g. 1]. The young radiometric ages of ~180 Ma for shergottites, a class of Martian meteorites, reflect the timing of crystallization from a magma or rather later events related to shock metamorphism or fluid infiltration. Baddeleyite (ZrO_2) occurs as an accessory mineral in Martian meteorite and is useful for U–Pb isotopic analyses as well as zircon ($ZrSiO_4$) [e.g. 2-4]. Martian meteorites contain varied shock effects; however, there are no available data on the effect of high-pressure/temperateure lead or uranium diffusivities in baddeleyite. To examine whether the U–Pb isotopic systems of baddeleyite are easily reset by shock metamorphism, our group have undertaken shock-recovery and annealing experiments using a propellant gun at NIMS and a vertical gas-mixing furnace and at Univ. of Tokyo, respectively [5].

High-shock pressure slightly caused damages on baddeleyite crystal structures. The brightness of Cathode Luminescence emission increased with the shock pressure of up to 57 GPa. Annealed sample did not show any detectable change from pre-annealing sample (shocked at 47 GPa sample). In addition, Raman peak shifts of 2-4 cm^{-1} from unshocked baddeleyite were observed associate with shock pressures. Those peak shifts were reported on high pressure static experiments [6]. However, there is no evidence on phase transformation from baddeleyite to high-pressure and temperature phases [5].

Lead loss from baddeleyite was not observed for the experimentally shocked samples. In addition, the U–Pb and ^{206}Pb–^{207}Pb ages of shocked and heated baddeleyites are indistinguishable from those of unshocked baddeleyite within errors except minor lead loss from the baddeleyite shocked at 57 GPa and heated 1 h at 1300 ^{o}C. Although duration of peak shock-pressure and grain size of baddeleyite are different from the nature of shock events, our experimental results suggest that it is hard to completely reset U–Pb isotopic systematics of baddeleyite by shock metamorphism.

In some terrestrial crater, occurrences of some baddeleyite grains are explained as breakdown products from zircon to baddeleyite and silica ($ZrSiO_4 \rightarrow ZrO_2+SiO_2$) by shock effects. The baddeleyite grains in RBT 04261, shergottites, do not associate with zircon or silica materials and no signature of Raman peak shift; it imply that grains are not breakdown products from zircon and not affected by shock pressure so much. Three large grains (~10 μm) are found for isotopic analyses, two grains occurred with ilmenite and one grain found in melt pocket. U–Pb age of ~200 Ma was obtained from these grains although the grain sizes are still slightly smaller than primary ion beam of SHRIMP, and may imply the magmatic activity on Mars [4].

Rapid reductions in North Atlantic Deep Water during the last interglacial period and their relationship to Greenland ice sheet variability

ULYSSES NINNEMANN[1*], EIRIK GALAASEN[2], NIL IRVALI[3], HELGA KLEIVEN[4], YAIR ROSENTHAL[5], CATHERINE KISSEL[6]

[6] Laboratoire des Sciences du Climat et de l'Environnement/IPSL, France, catherine.kissel@lsce.ipsl.fr

One uncertainty in future climate and CO_2 projections involves changes in the Atlantic meridional overturning circulation (AMOC) and its response to climate change. Models and proxy data suggest that AMOC is vigorous under interglacial climate conditions with minor changes on millennial timescales. Yet, with the exception of the notable changes associated with the 8.4 kyr BP flood outburst, little is known about the stability or thresholds of deep ocean circulation on shorter timescales. Here we use deep-sea sediment cores to assess the response of North Atlantic Deep Water (NADW), the main constituent of the deep limb of AMOC, to source region warming, Greenland ice sheet (GIS) melting, and ocean freshening.

We present new high-resolution (~20 yr/sample) foraminiferal $\delta^{13}C$ and $\delta^{18}O$ records of near surface and bottom water properties spanning MIS 5e from a core site on the Eirik Drift south of Greenland (MD03-2664). The site lies at 3440m, just below the main axis of the sediment-laden Western Boundary Undercurrent and is optimally situated for recording changes in newly formed NADW. In addition, we use ice rafted detritus (IRD) and foraminifera-based surface property proxies ($\delta^{18}O$, MAT-SST's, Mg/Ca) to assess changes in the GIS and Arctic to North Atlantic freshwater transport.

Bottom water $\delta^{13}C$ values gradually increase through MIS 5e. Superimposed on this trend are large-amplitude (>1‰) reductions in bottom water $\delta^{13}C$, similar in scale to those observed during the 8.4 kyr BP event. These $\delta^{13}C$ decreases last a few centuries before recovering to background values. Using an array of records spanning the abyssal Atlantic we show that the magnitude and spatial geometry of the deep water anomalies is consistent with an expansion of southern source deep water as the influence of NADW waned—a geometry analogous to deep ocean changes during the 8.4 kyr BP event and to millennial scale events of the last glaciation. Surface water proxies and IRD content suggest that these NADW changes occur during a period of rapid GIS retreat and surface water freshening. Taken together, our results demonstrate that "8.4kyr-style" deep ocean property changes occurred at a time when North Atlantic climate was similar to that projected for our future.

Deformation experiments of mantle materials at the conditions of deep Earth interior

YU NISHIHARA[1*]

[1]Ehime Universtiy, Senior Research Fellow Center and Geodynamics Research Center, yunishi@sci.ehime-u.ac.jp

Introduction

Knowledge on rheology of mantle materials is indispensable in understanding thermal evolution and material transport in the Earth. Since rheological properties strongly depend on temperature and pressure, it is critacally important to conduct deformation experiments at *P-T* conditions corresponding to the deep mantle for accurate understanding of Earth's interior. Recently, quantitative rheological measurements at relatively high pressures (up to 10–20 GPa) and high temperatures (up to 1000–2000 K) are possible by using large-volume presses in conjunction with synchrotron radiation. In this presentation, our recent results on rhelogy under Earth's deep mantle conditions determined by deformation experiments using deformation-DIA appratus are discussed.

Mechanical property of fine-grained forsterite

In order to understand mechanical behavior in grain-size-seisitive creep in the deep upper mantle condition, deformation experiments on dry fine-grained (grain size of ~1 μm) forsterite were performed at P = 3–5 GPa, T = 1473–1573 K and strain rate of 9×10^{-6}–2×10^{-4} s^{-1} [1]. The stress-strain rate data together with data at 0.1–300 MPa by Tasaka et al. (unpublished data) were analyzed using a flow law equation for diffusion creep (n = 1, p = 2) and dislocation creep accommodated grain-boundary sliding (GBS, n = 3.5, p = 2). Based on the analysis, the activation volume both for diffusion creep (V^*_{dif}) and GBS (V^*_{GBS}) of olivine was determined to be ~8 cm^3/mol. Calculation based on the present results implies that typical mantle deformation conditions are close to the mechanism boundary between the diffusion creep and the GBS.

Mechanical property of wadsleyite

Uniaxial deformation experiments on wadsleyite were carried out at P = 14–16 GPa and T = 1500–1700 K with strain rates of 3.4–15 × 10^{-5} s^{-1} [2]. Results suggest that flow strength of wadsleyite is more sensitive to water content than that of olivine.

Lattice preferred orientation (LPO) of olivine

The effects of hydrogen and pressure on LPO of olivine were investigated through simple-shear deformation experiments under asthenospheric upper mantle conditions (P = 2.1−5.2 GPa, T = 1490−1830 K) [3,4]. Formation of the A-type olivine fabric developed by the (010)[100] slip system was observed under water-depleted (C_{OH} < 650 H/10^6Si in olivine), while B-type fabrics by the (010)[001] slip system (or B-typre like fabric) were predominantly formed under water-rich conditions (>1000 H/10^6Si). The water-induced olivine LPO transition from A-type to B-type (-like) fabric results in flow-parallel and flow-perpendicular shear wave splitting under water-depleted and water-rich conditions, respectively.

Formation condition of mono-hydrocalcite from Ca-Mg-CO_3 solutions

RISA NISHIYAMA[1*], TAKASHI MUNEMOTO[2], AND KEISUKE FUKUSHI[1]

[1] Kanazawa University, Ishikawa, Japan, rinrin@stu.kanazawa-u.ac.jp (* presenting author)

[2] The University of Tokyo, Tokyo, Japan,

Monohydrocalcite ($CaCO_3$·H_2O: MHC) is rare mineral in geological settings. MHC has been most frequently found in the recent sediment in saline lakes [1]. It also was found from the calcareous sinter of cold spring of Shiowakka, Hokkaido, Japan [2]. A lot of kinds of calcium carbonate minerals, including calcite, vaterite, ikaite and MHC, were also occurred in Shiowakka. MHC occurred in only summer season and frequently associated with green algae. In order to understand the preferential formation of MHC with green algae, we conducted synthesis experiments of carbonate minerals from various concentrations of Ca, Mg and CO_3 to clarify the formation condition of MHC.

The mixing solutions containing $CaCl_2$ and $MgCl_2$ was prepared in the reaction vessels, and Na_2CO_3 solution was added to 50mL of the mixing solutions. The initial concentrations of Ca, Mg and CO_3 in the solutions were 0.025~0.1M, 0~0.05M and 0.03~0.1M, respectively. Immediately after Na_2CO_3 solutions were added to the solution, the whitish suspensions were formed in the reaction vessels. The syntheses experiments were conducted in closed polycarbonate vessels at 25 °C, and the resulting suspension was constantly stirred and aged with mix-rotor for 24 h. After the aging time, the suspensions were filtered. The solids were analyzed by X-ray diffraction and examined by scanning electron microscope. The filtrates were analyzed for the concentration of CO_3 by alkalinity titration. The Ca, Mg and Na concentrations of filtrates were measured by high-performance liquid chromatography.

Four mineral assemblages were obtained from all of the experimental conditions from the XRD results. They are mixture of vaterite and calcite, mixture of aragonite and calcite, MHC and amorphous material. Based on the observations, the formation conditions of MHC can be summarized that the initial Mg concentration is more than 0.01 M and the CO_3/Ca ratio of the initial solutions are more than 1. The IAP of the reacted solutions with MHC formations were greatly higher than anhydrus calcium carbonates. The activity of Ca^{2+} is lower than that of CO_3^{2-} when MHC was formed. Furthermore, the activities of Mg^{2+} and CO_3^{2-} in the solution after MHC and amorphous material formation were almost equilibrium with respect to nesquehonite. By integrating the formation conditions of MHC from both initial solution and reacted solution, we considered that MHC formation requires simultaneous formation of magnesium carbonate (nesquehonite), i.e., the concentration of CO_3^{2-} in the solution must be high enough to produce both MHC and magnesium carbonate.

In Shiowakka, the pH increase by photosynthesis of green algae. The local concentration of CO_3^{2-} near the green algae must increase drastically. Inclease of the cintribution of CO_3^{2-} to HCO_3^- enables to the formation magnesium carbonate even spontaneously with MHC formation. Thus, the MHC is selectively formed in summer season associated with green algae.

Preliminary Pb and Pb isotopes from the US GEOTRACES North Atlantic Transect

ABIGAIL E. NOBLE[1*], YOLANDA ECHEGOYEN-SANZ[2], AND ED BOYLE[3]

[1]Massachusetts Institute of Technology, Cambridge, USA anoble@mit.edu (* presenting author)
[2]Universidad de Zaragoza, Zaragoza, Spain, yolandaechegoyen@gmail.com
[3] Massachusetts Institute of Technology, Cambridge, USA, eaboyle@mit.edu

This study presents preliminary Pb and Pb isotope data from the US GEOTRACES North Atlantic Transect which was sampled during two cruises that took place during the Fall of 2011 and 2012. Almost all of the Pb found in the modern ocean is derived from anthropogenic sources, and the North Atlantic has received significant Pb inputs from the United States and Europe due to emissions from leaded gasoline and high temperature industrial processes. During the past three decades, Pb fluxes to the North Atlantic have decreased following the phasing out of leaded gasoline in the United States and Europe. Following the concentrations and isotope ratios of Pb in this basin over time reveals the temporal evolution of Pb in this highly- affected basin. This cruise included a re-occupation of the Bermuda Atlantic Time Series station (BATS) that was one of 8 occupations since 1979 for Pb and one of 6 for Pb isotopes at approximately 5-year intervals,. Two stations in the Eastern North Atlantic were previously occupied in 1989, 1999, and the data from this expedition provide some comparison of the temporal evolution of Pb in this region. The Pb isotope signatures reflect the relative importance of inputs from the United States and Europe as leaded gasoline was phased out faster in the United States relative to Europe. This is observed in a surface trend towards slightly lower ^{206}Pb / ^{207}Pb ratios in the last decade. Pb concentrations decrease with time in the upper water column (<2000m) with higher concentrations observed in mid-latitude northern stations decreasing southward at the eastern end of the basin. Concentrations and isotopes converge in deep waters with longer residence times. Further results from the section will be presented as data become available.

Isotopic Variability of the Ninetyeast Ridge – Implications for its Mantle Sources

INÊS G. NOBRE SILVA[1]*, DOMINIQUE WEIS[1], JAMES S. SCOATES[1], MALCOLM S. PRINGLE[2] AND FRED A. FREY[2]

[1]Pacific Centre for Isotopic and Geochemical Research, Earth & Ocean Sciences, Univ. of British Columbia, Vancouver, BC V6T 1Z4, Canada, inobre@eos.ubc.ca (* presenting author)
[2]EAPS, MIT, Cambridge MA 02139 USA.

The ~5000 km long north-south oriented Ninetyeast Ridge in the eastern Indian Ocean Basin represents the age progressive, ~80 to ~40 Ma products of the 120 Ma old Kerguelen mantle plume. Basaltic basement samples recovered during DSDP and ODP drilling campaigns are however scarce and debate concerning the nature and number of components in the mantle source of the Ninetyeast Ridge persists. Dredging during a National Science Foundation-funded 2007 cruise recovered basaltic basement from 21 locations along ~3200 km of the ridge. New high-precision isotopic compositions by MC-ICP-MS (Pb, Hf, and Nd) and TIMS (Sr) were obtained on 59 basaltic samples from 21 dredges. Sample choice was based on the lowest degree of alteration (lowest LOI), high Mg#, and variable trace element ratios (e.g., Zr/Nb, Y/Nb, La/Sm). Altogether these samples cover a greater range of Pb-Sr-Nd-Hf isotopic compositions and wider within-site isotopic variability than that covered by the drilled samples recovered during ODP Leg 121, and are generally intermediate between those of the volcanic products of the Kerguelen and Amsterdam-St. Paul mantle plumes. This attests to a compositionally heterogeneous mantle source, and at least three, possibly four, distinct source components with relatively enriched and depleted signatures are required to explain the observed isotopic variability along the Ninetyeast Ridge. Mixing with shallow level Indian MORB does not account for the lower $^{87}Sr/^{86}Sr$ and higher Nd and Hf isotopic ratios of basalts from some of the dredges (i.e., $^{87}Sr/^{86}Sr$ 0.70369-0.70428, $^{143}Nd/^{144}Nd$ > 0.51300 and $^{176}Hf/^{177}Hf$ > 0.28322 for 5 samples from 2 dredges). These depleted signatures are instead consistent with the presence of a previously depleted, garnet-enriched component intrinsic to their deep mantle source that had been identified based on incompatible trace element abundances alone. Together with other Indian Ocean island basalts of typical EM-1-like compositions, the Pb-Hf-Sr-Nd isotopic compositions of the Ninetyeast Ridge basalts are consistent with provenance from a deep mantle source that has incorporated a mixture of recycled sediments and lower continental crust together with altered oceanic crust. This supports a deep origin for the EM-1-like Dupal signatures encountered in ocean island basalts.

[3]CNRS-CEMHTI, Orléans, France, valerie.montouillout@cnrs-orleans.fr

Boron isotopes measurements in marine carbonates are used as a proxy of the paleo-pH of the oceans. The reliability of these pH reconstructions lies in our understanding of the mechanisms of boron incorporation in carbonates. The paleo-pH calculations are based on the assumption that one of the two boron species in solution (borate $B(OH)_4^-$) is preferentially incorporated in calcium carbonates [1],[2]. Experiments show that there is a shift between expected and measured boron isotopic ratios ($\delta^{11}B$) at a given pH, which is attributed to the specifics of boron incorporation in biological organisms ("vital effect").

In order to better understand the mechanisms of boron incorporation in carbonates and by comparison, the modifications induced by vital effects, we carried out inorganic precipitation experiments of calcite and aragonite in NaCl solutions of wide-ranging pH values and at temperatures of 25°C and 5°C. Boron isotopic compositions of the carbonates were then measured by MC-ICP-MS and the proportions of trigonal and tetragonal B by ^{11}B MAS NMR.

Our results confirm that the boron isotopic ratio of the carbonates is dependent upon the growth solution pH, but also upon crystal type and temperature. In calcite, both NMR and boron isotopic composition show that boron incorporation is not consistent with the single incorporation of the aqueous borate species $B(OH)_4^-$. Moreover, the NMR measurements show that the proportion of trigonal boron (BO_3) in calcite is higher than what is inferred from the isotopic signal by assuming that both boron aqueous species are incorporated in the carbonate. In aragonite, BO_3 is present in smaller proportions depending on pH and both NMR measurements and $\delta^{11}B$ are in good agreement with the hypothesis of the preferential incorporation of the borate species in calcium carbonates .

As, Sb, Mo, V, W, and Se oxyanions in Yellowstone's thermal waters

D. KIRK NORDSTROM[1*] AND R. BLAINE MCCLESKEY[2]

[1]US Geological Survey, Boulder, USA, dkn@usgs.gov (* presenting author)

[2]US Geological Survey, Boulder, USA

Concentrations of As, Sb, Mo, V, W, and Se have been determined in hundreds of water samples from thermal features in Yellowstone National Park and from the Firehole and Gibbon River systems. Analytical methods include ICP-AES, ICP-MS, HGAAS, and GFAAS. Selenium is consistently less than 1 µg/L everywhere, V is often below detection up to 130 µg/L, Mo occurs up to 360 µg/L, Sb up to 370 µg/L, and As up to 14,600 µg/L. Concentrations of W are limited but generally similar to or a bit higher than those of Sb and Mo.

Arsenic concentrations are typically 0.5 to 3 mg/L but they are highest in Norris Geyser Basin waters, especially in the western part of the basin. This area seems to have accumulated arsenic through precipitation of considerable orpiment and realgar at low pH at or just below the ground surface. One pair of springs demonstrate remarkable mixing between two end-member compositions, a near neutral pH high-As and high-Cl water and a low-As, low-Cl acid water. This range of composition can explain the variable water compositions for many waters occurring in Norris Basin. Most waters exhibit a linear relation of As concentrations relative to Cl concentrations suggesting that arsenic is largely conservative and tends to stay with the aqueous fluid during boiling and dilution. More surprising, arsenic concentrations are not attenuated during 20-30 miles of river drainage. The Gibbon River maintains more than 100 µg/L dissolved As and the Firehole River increases to more than 400 µg/L in the lower reaches. The most likely hypothesis is that the high silica concentrations in the thermal waters precipitate in the river and coat the river bed sediments, decreasing its sorption capacity. There is also very little Fe in the overflows.

A complicating factor for speciation of As, Sb, Mo, and W is the formation of thio-complexes which have been explored for As and Sb but not for Mo and W. Such complexes may help to explain their mobility under reducing conditions.

Concentrations of Sb and Mo tend to track with As, with the highest concentrations occurring with the highest Cl concentrations but there is much more scatter in the data. For the Gibbon and Firehole Rivers, Sb and Mo concentration profiles are strikingly similar showing no attenuation. One anomaly occurs in the Gibbon River profile. A substantial inflow of Mo enters from Terrace Spring just before the convergence of the Gibbon with the Firehole. These trace elements are indicative of the deep geothermal reservoir composition and not greatly affected during transport to the surface.

Concentrations of V behave very differently from the other oxyanions; they are below 10 µg/L for nearly all Cl concentrations above 200 mg/L. Higher concentrations are only found in acid waters of low Cl concentration, regardless of temperature. These results suggest that V is dominantly derived from acid weathering of near surface rocks. Furthermore, V is the element in this group that forms a cation under reduced conditions which also helps to explain its higher concentration in acidic waters.

Both similar and dissimilar trends in these trace elements can be demonstrated. The biggest dissimilarity is the lack of any correlation for V with the other elements. The other elements generally behave similarly with the exception of some local anomalies. When thermal overflows enter river systems there is little to no attenuation likely because of continual silica precipitation and the lack of hydrated iron oxides.

Natural pyrite weathering rate in a small catchment compared with mined catchments and lab rates

D. Kirk Nordstrom[1*]

[1]US Geological Survey, Boulder, USA, dkn@usgs.gov (* presenting author)

As part of the USGS background study of the Questa mine in northern New Mexico, a small catchment (Straight Creek) of about 2.67 km^2, was studied to determine the hydrogeochemical processes that naturally generate acidic, metal-rich surface waters and groundwaters. The predominant reaction is pyrite oxidation because there is excess pyrite (2-10 wt.%) in quartz-sericite alteration. A mass–balance calculation was performed reacting pure water to the median composition of 14 water analyses from 2000-2003 with median pH of 2.98 and median sulfate concentration of 2,030 mg/L. The most likely mass–balance model consistent with mineralogical analyses, assuming that rates are unaffected by solid/solution ratio or by evaporation, indicates oxidative dissolution of 8.66 mmol pyrite/kg_{H_2O}. When combined with a median discharge of 37.85 L/min measured simultaneously, the weathering rate was 5.46 mmol pyrite/h. This value is larger than batch abiotic laboratory rates, about 0.01 mmol/h for Fe(III) oxidation with pH close to 2, or microbial laboratory rates, about 0.22 mmol/h based on an interlab comparison. Evaporation effects or a "pooling effect" might be the main sources of discrepancy between apparent field rates based on mass balances and laboratory rates. Similar calculations for effluent water at the Leviathan Mine, CA (pH = 1.8) result in an apparent pyrite weathering rate of 40 mmol/h, 200 times higher than expected from laboratory rates; this result could be explained by the extremely fine-grained pyrite that occurs there as well as evaporation effects.

Calculations for Iron Mountain, CA a massive sulphide copper deposit that has been extensively mined and exposed to air and water, result in an apparent pyrite weathering rate of 17,100 mol/h, five orders of magnitude higher than laboratory rates. At Iron Mountain pyrite weathering has produced enormous amounts of efflorescent salts that periodically dissolve and reprecipitate in the underground workings. When the mass–balance is modified in terms of dissolving soluble salts, removal of some iron as goethite is required and the weathering rate becomes 24,800 moles soluble sulfates/h.

Regardless of how mass–balances are calculated, the field rate for pyrite oxidation is much faster than the laboratory rate suggesting that evaporation, pooling, or possibly surface areas, strongly influence these calculations for most mined sites. The pyrite weathering rate might be a guide to whether the mechanism is dominated by pyrite weathering or by precipitation/dissolution of soluble salts. Another conclusion dictated by the mass balance is that large amounts of iron and silica must precipitate. This conclusion is also supported by the saturation indices having reached saturation for silica in many of these waters.

Geochemical signatures of IOCG mineralization and alteration in till

Philippe X. Normandeau[1*], Isabelle McMartin[2], Jeanne Paquette[1], Louise Corriveau[2] and Jean-François Montreauil[3]

[1]Dept. of Earth and Planetary Sciences, McGill University, Montreal, Quebec, Canada philippe.normandeau@mail.mcgill.ca (*presenting author), jeanne.paquette@mcgill.ca

[2]Geological Survey of Canada, Natural Resources Canada, Ottawa, Ontario, Canada, isabelle.mcmartin@nrcan-rncan.gc.ca, louise.corriveau@nrcan-rncan.gc.ca

[3]INRS-ETE, Québec, Canada, jmontreu@nrcan.gc.ca

Introduction

As part of Canada's Geomapping for Energy and Minerals (GEM) Program, an applied Quaternary research activity under the IOCG-Great Bear Project was undertaken in the Great Bear magmatic zone (Northwest Territories, Canada) to provide a practical guide for geochemical and indicator mineral exploration targeting iron oxide copper-gold (IOCG) and affiliated deposits in glaciated terrain. Detailed till sampling (n=111) was completed in the vicinity of the NICO Au- Co-Bi-Cu magnetite-group IOCG deposit as well as the Sue-Dianne Cu-Ag-Au magnetite- to hematite-group IOCG deposit, and near showings hosted within other IOCG-type alteration systems in the GBmz. Samples were collected up-ice, proximal to, and down-ice from mineralization, hydrothermally-altered host rocks and least-altered bedrock. Extensive lihogeochemical data set (n=1243) was available within the IOCG-Great Bear Project.

Results and conclusion

Lithogeochemical signatures of mineralization and/or alteration are reflected in the till matrix (K, Na, Ca, Mg, Ti, Cu, Ba, Cr, Co, Th, Bi, Mo, U, As) despite variable degrees of post-glacial weathering and textural differences. Possible IOCG deposit pathfinder elements in till (<2 and/or <63 µm fraction) include Cu, Mo, Bi and Co (enrichments), as well as Ti (depletion). However, given the high variability of IOCG and affiliated mineralization, a multivariate statistical approach was also applied to see if their associated, and more characteristic, alteration types left a clear signal. A principal component analysis (PCA) was performed on combined data sets of till geochemistry and lithogeochemistry. This innovative approach helps to isolate the role of hydrothermal processes from surface processes such as glacial communition and post glacial weathering in the internal variability of the till geochemistry. Results so far show: 1) grouping of till samples by the first 3 principal components, based on their related IOCG showings; 2) discrimination between anomalous till samples based on multi-enrichments of alteration related elements (K, Ca, Na), and 3) potential to identify the type of bedrock IOCG alteration in overlying till samples.

Understanding biogeochemical mechanisms for heavy metal removal in SuDS

M. J. Norris[1*], H. L. Haynes[2], C. C. Dorea[3], I.D. Pulford[1], and V.R. Phoenix[1]

[1]University of Glasgow College of Science and Engineering, Glasgow, Scotland G12 8QQ (* m.norris.1@research.gla.ac.uk)
[2]Heriot-Watt University Institute for Infrastructure & Environment, Edinburgh, Scotland EH14 4AS
[3]Université Laval Département de génie civil et génie des eaux, Québec, QC, Canada G1V 0A6

With urbanization on the rise, there has become a growing need for sustainable approaches to cope with increased pollutant load and reduced land available for stormwater infiltration. A type of Sustainable urban Drainage System (SuDS) of particular interest is a filter drain, which utilizes gravel media to filter and treat road runoff laden with pollutants. While the simple concept is known to remove suspended solids and heavy metals typical in road runoff, the design of such systems is based on limited scientific input. This study aims to characterize the biogeochemical mechanisms responsible for pollutant removal, specifically heavy metals, to help improve design and efficiency in SuDS systems.

While metal immobilization in filter drains may be biologically mediated and a subject of future research, initial experimentation explored removal processes by the gravel itself and with the addition of a mineral amendment. Enhancing heavy metal removal with an iron oxide coating has been explored due to the the vast literature evidence of iron oxide minerals sequestering metals [1]. Kinetic batch and flow-through column experiments demonstrated that an iron oxide coated gravel removed similar concentrations of zinc to a locally sourced uncoated microgabbro gravel. Since coated gravel also buffered solution pH away from neutral, it was concluded that the difficult, costly coating process would not be suitable for use in an environmental setting.

Specifically, kinetic batch experiments showed typical adsorption curves and removal rates of zinc by uncoated microgabbro at 80% removal up to 8 hours and nearly 100% after 48 hours. Whereas other types of gravel such as dolomite, sandstone and granite removed between 10-50% less zinc overall than microgabbro. Scanning electron microscope (SEM) images of microgabbro show a rough, high surface area and mineral components of microgabbro have the ability to weather to clay minerals, which also have a high affinity for heavy metals. Further experimentation has proven the weathered surface in fact accelerates zinc immobilization by about 20% compared to an unweathered surface.

The SuDS Manual, which is used in construction and design of new SuDS systems, indicates that filter drain material should be a locally sourced graded stone/rock [2]. While this implies that the geology of the type of rock utilized in such systems does not affect pollutant removal mechanisms, kinetic batch experiments of different rock types indicates otherwise.

Conservative behavior of Uranium vs. salinity in sea ice and brine

Christelle Not[1*], Kristina Brown[2], Bassam Ghaleb[3] and Claude Hillaire-Marcel[4]

[1]GEOTOP-UQAM, Montréal, Canada and AORI-Tokyo University, Kashiwa, Japan, christelle.not@aori.u-tokyo.ac.jp (* presenting author)
[2]University of British Columbia, Department of Earth and Ocean Sciences, Vancouver, Canada, kbrown@eos.ubc.ca
[3]GEOTOP-UQAM, Montréal, Canada, ghaleb.bassam@uqam.ca
[4]GEOTOP-UQAM, Montréal, Canada, hillaire-marcel.claude@uqam.ca

Since studies by Ku et al [1] and Chen et al [2], it is widely accepted that uranium (U) behaves conservatively with respect to salinity (S) in seawater over the salinty range of 30 to 36. However, in low salinity environments, such as estuaries, its behavior seems more variable. Freezing in the Arctic Ocean provides a natural mechanism to concentrate dissovled seawater constituants into high salinitity brine through the formation of sea ice, and reintroduce low salinity water to the surface through melt.

Here we compare U concentration and isotopic composition from samples of low-salinity sea ice, underlying surface seawater, and high salinity brine, covering a salinity range of 0 to 135. Based on these samples, we found that U behaves conservatively across a wide salinity range, producing a U-S relationship slightly different than the one described in previous studies [1] (Figure 1). The isotopic ratio $^{234}U/^{238}U$ from melted sea ice, under-ice seawater, and sea ice brine samples were not statisically different from mean ocean values, within our statistical uncertainties.

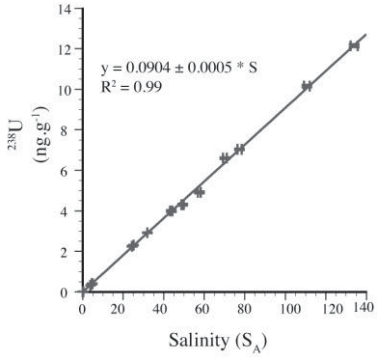

Figure 1: U-Salinity relationship in sea ice, surface sea water, and brine samples [3].

Nitrogen mobility in freshwater peat

MARTIN NOVAK[1*], IVANA JACKOVA[1], FRANTISEK BUZEK[1], LUCIE ERBANOVA[1] AND MARKETA STEPANOVA[1]

[1] Czech Geological Survey, Prague, Czech Republic, martin.novak@geology.cz (* presenting author), ivana.jackova@geology.cz, frantisek.buzek@geology.cz, lucie.erbanova@geology.cz, marketa.stepanova@geology.cz

Peatlands cover less than 5 % of the Earth's land surface, yet they store as much as 15 % of the world's soil N, and 30 % of the world's soil C. Vile et al. [1] have recently reported that ^{210}Pb dated peat in pristine high-latitude bogs contains 20 times more N than could be explained by inputs of atmospheric N. Vile et al. [1] have suggested that the "excess" N in peat is a result of *in-situ* N_2 fixation from cyanobacteria, a process that has been largely overlooked. It is unclear whether in N-polluted areas, where N is not a limiting nutrient, the symbiosis between *Sphagnum* and N-fixing microorganisms is lost. Still, it appears that a major gap in the global biogeochemical cycling of N has been identified.

Here we report a field experiment that might provide an insight into the retention of atmogenic N in peat. We hypothesized that vertical N profiles in peat do not directly reflect historical trends in N deposition and that N is mobile after its burial in peat. We selected two Central European peat bogs, differing in present-day atmospheric N inputs by a factor of 2, and collected 10 peat cores per site. Trends in N deposition since the beginning of the Industrial Revolution have been extremely well documented in the area [2]. The more polluted site VJ exhibited a clear-cut N concentration peak in layers dating from 1950. The less polluted site CB showed a N concentration minimum in layers dating from 1940. In actual fact, the atmospheric N input increased smoothly until 1980, and dropped thereafter [2]. We suggest that N in peat profiles does not record past N deposition levels. We conducted an 18-month reciprocal peat transplant experiment between VJ and CB, using 5 cores as transplants and 5 cores as controls per site. At the end of the experiment, at both sites, bulk N to a depth of 10 cm changed its δ^{15}N value by 3 per mil, converging to that of the host site. Again, the bulk N isotope change indicated a measurable degree of N mobility in peat.

Development of a process-based chemical weathering model with consideration of the effective surface area

TAICHI NOZU[1*] AND EIICHI TAJIKA[1,2]

[1]The University of Tokyo, Earth and Planetary Science, tnozu@eps.s.u-tokyo.ac.jp (* presenting author)
[2]The University of Tokyo, Complexity Science and Engineering, tajika@k.u-tokyo.ac.jp

Feedback mechanism between climate and chemical weathering is one of the most important aspects of the Earth system. Despite a significant number of studies for understanding the rate of chemical weathering quantitatively by observational, experimental, and numerical methods, the global chemical weathering rate has not been estimated straightforwardly owing to a significant discrepancy between field and laboratory studies. The discrepancy may be explained as a sum effect of several phenomena such as increase in surface roughness with time and difference in reaction affinities between natural and experimental conditions [1].

We are developing a process-based chemical weathering model to study behaviours of the geochemical cycle system in response to changes in modern- and palaeo-environment. This model is similar to "WITCH" model [2], but the originality of our approach lies on integration of simple soil physics (i.e. heat and moisture transport) and consideration of soil biological activity in the weathering model. The model has been applied to different small (< 10 km^2) watersheds such as Strengbach in France and Lac Clair in Canada to verify the model to reproduce major ion concentrations of modern streams. We introduced a free parameter which represents a ratio of field-scale weathering rate to mineralogical dissolution rate to fit the results to the observational data. Sensitivity analyses show that riverine ionic concentrations of base cations are well reproduced from the model only by tuning this parameter alone. We interpret that this parameter may represent the erosional effect which, in turn, controls the age of the weathering environment. That is, the time dependency of silicate weathering [1] can explain the difference in this parameter. The obtained parameter is also comparable with the ratio of the effective surface area to the BET surface area estimated in previous studies.

Our results imply that the chemical weathering process can be modelled by considering the difference in the effective surface area controlled by lithology and erosion.

Trichodesmium is a globally important nitrogen-fixing, filamentous cyanobacterium. In the present study, we collected *Trichodesmium* colonies from the Sargasso Sea and investigated their elemental signature. Element concentrations and spatial distributions in colonies were compared using inductively coupled plasma mass spectrometry (ICPMS), CHN analysis, and synchrotron x-ray fluorescence (SXRF) mapping. *Trichodesmium*'s cellular stoichiometry of 647C:111N:1P deviated significantly from the canonical Redfield ratio and illustrates the P-limiting condition at the time of sampling. Additionally, ICPMS and SXRF analysis confirmed that the metallome of *Trichodesmium* is enriched in V, Fe and Ni in comparison to other phytoplankton. Surprisingly, V was the most abundant metal in *Trichodesmium*, and the V quota was up to 4-fold higher than the corresponding Fe quota. Furthermore, SXRF mapping revealed the presence of V and Fe hotspots. These hotspots typically spanned over several contiguous cells. The spatial distribution of Ni differed from V and Fe and was enriched in transverse walls between attached cells. As hotspots of V, Fe, or Ni were spatially decoupled from each other, we conclude that external adsorption of aerosol particles on *Trichodesmium* trichomes did not contribute to the elevated element quotas. Fe hotspots were found in only ca. 10% of analysed trichome sections, and Fe enrichment in contiguous cells may be linked to diazocytes as zones of nitrogen fixation in *Trichodesmium*. In contrast, genomic analyses indicated that V is not directly associated with nitrogenase in *Trichodesmium*. V maybe used in V-dependent haloperoxidases to protect the oxygen susceptible nitrogen fixing enzyme nitrogenase from reactive oxygen species (ROS) such as hydrogen peroxide, but genomic evidence for such an enzymatic role of V is also currently lacking. The presence of Ni in transverse walls is in agreement with genomic evidence for the presence of Ni-superoxide dismutase and/or NiFe hydrogenase. Both Ni-containing enzymes are beneficial for nitrogen fixation by either inactivation of the ROS species superoxide or the catalyzation of hydrogen, respectively. We conclude that the enrichment of these metals is directly or indirectly linked to nitrogen fixation in *Trichodesmium*.

Zooming on Heinrich layers H2 to H0 through geochemical and sedimentological analysis of a core raised off Hudson Strait

LAURENCE NUTTIN[1] AND CLAUDE HILLAIRE-MARCEL[1]

1GEOTOP-UQAM, Montréal, Canada, lanuttin@gmail.com

The ~ 9 m-long core (HU08-029-004; 2674 m water-depth; 61°27'N, 58°2'W) was raised from the lower slope of the Labrador Sea, approximately 100 nm off the Hudson Strait shelf edge. It provides a high resolution record of recent detrital carbonate sedimentary pulses through Hudson Strait assigned to "Heinrich events" H2, H1, H0, thus the means to constrain the age and depositional mechanism of the corresponding "Heinrich layers" at near proximity of sediment source. Some special attention is given to depositional mechanisms of fine glacial flour reworked by meltwater vs ice-rafted debris (IRD). Analysis includes, at ~ 10 cm-intervals, uranium and thorium series measurements (^{238}U, ^{234}U, ^{230}Th and ^{232}Th), at 4 cm intervals, semi-quantitative analyses of mineralogical assemblages (XRD), inorganic and organic carbon ($C_{inorg.}$, $C_{org.}$) contents and $C_{org.}$/N data, coarse fraction abundance (>106 μm), which we associate with IRD, CAT-scan images; nine layers provided enough Neogloboquadrina pachyderma (l) shells for ^{14}C measurements. Calibrated ^{14}C ages indicate a mean sedimentation rate of ~ 27 cm/ka, Heinrich-layers included, and of ~ 25 cm/ka when they are assigned a duration from literature data then excluded from the sediment inventory (i.e., "background" sedimentation rate). ^{230}Th-excesses ($^{230}Th_{xs}$) over supported fraction are estimated following Veiga-Pires & Hillaire-Marcel (1999). Preliminary results show that the Heinrich layers contain up to 60% fine detrital carbonates (mostly calcite) and are highlighted by low $^{230}Th_{xs}$ (nearly 0 dpm/g) indicating an extremely fast depositional mechanism of the fine fraction. Coarse fraction peaks highlight intense IRD on both sides of the fine detrital carbonate layer, i.e., from the very beginning until a "late" H-event phase. They likely correlate with the H-layers as observed in more distal North Atlantic sites. $^{230}Th_{xs}$ inventories and background sedimentation rate calculated as above, suggest much higher Holocene $^{230}Th_{xs}$ fluxes at the study site, in comparision to late glacial fluxes, resulting from $^{230}Th_{xs}$-advection by an enhanced Western Boundary Undercurrent.

Introduction

The high monetary and energy costs associated with the production of pure CO_2, for storage has necessitated the need for consideration of waste stream with some impurities (e.g. H_2S, SO_x, NO_x). However, little knowledge exists on the geochemical impact of these gas mixtures when injected into geological formations for the long term geological storage of CO_2. We report results from initial experiments that have been conducted with pure CO_2 as base cases with which to compare subsequent experiments involving impurities. The experiments investigated the reaction of Permo-Triassic sandstones (the on-shore equivalent of a North Sea reservoir rock) with brine in the presence of supercritical CO_2. Experiments were conducted over 3-6 months using 0.5 M NaCl solution at 70°C and 200 bar pressure, conditions typical of many potential CO_2 geologic storage sites. Modelling of the experimental systems was also carried out using PHREEQC. Figure 1 below shows the schematic content of pressure vessel used for laboratory batch experiments.

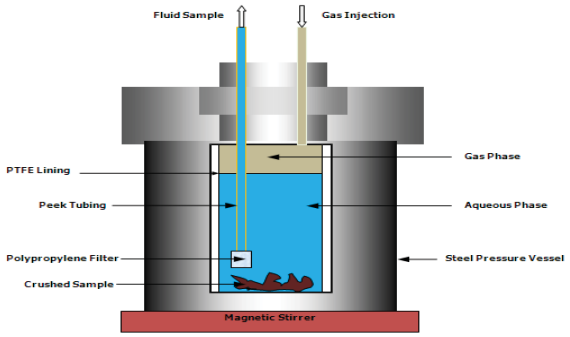

Figure 1: Schematic of pressure vessel

Results and Conclusions

Increasing concentrations of Mg, Ca and K were observed in the experiments over time. Mineralogical analyses and mass balance calculations for reacted and un-reacted rock samples, indicate that increases of Mg and Ca may be explained by dissolution of carbonate minerals such as calcite and dolomite, possibly followed by slight dissolution or ion-exchange with clay minerals. K concentrations are possibly governed by dissolution of trace halide minerals. In non-reactive 'control' experiments representing only the fluid-rock system equilibration using N_2 gas as the pressurising fluid, concentrations of the same elements were much lower.

PHREEQC modelling utilised rates of mineral dissolution and precipitation from the literature. Longer-term trends in observed solution chemistry could be modelled, if some assumptions about reactive surface areas were made. However, the model could not account for observed decreases in concentration of dissolved elements such as Al and Fe. Work is in progress to account for these changes and will be presented at the conference. Preliminary results from on-going experiments involving fluid-rock-CO_2 reaction in the presence of impurities (particularly H_2S) will also be presented.

Use of vegetation, soil, and radiometric survey to locate areas of concealed uranium mineralization at the Jacques Lake area, Labrador.

Abstract

We applied biogeochemical analysis of black spruce twigs, bark, and Labrador tea shoots with soil geochemistry, and an air-borne magnetic and radiometric survey to delineate areas of uranium enrichment at the Jacques Lake prospect of the Central Mineral Belt, Labrador, Canada. This area is overlain by thick layers of glacial till and peat which effectively obscure the direct observation of mineralized outcrops and accompanying alteration haloes. The topography is rugged with dense coniferous forest cover, lacks access roads, and is characterized by long and extreme winter weather conditions with very high precipitation. Biogeochemical signatures from black spruce twigs show elevated concentrations of U and pathfinder elements Be, Ag, Pb, and Sb over mineralized areas. A PCA plot of the data discriminated the bedrock mineralization with good anomaly contrast for uranium and related pathfinder elements (Be, Ag, Sb, V and Pb). Bark samples of black spruce generally showed weak to moderate anomaly contrasts. Labrador Tea leaves and stems defined very low anomalies or none at all; and possibly attributable to the shallow root system of the shrub. There is metal enrichment and an expression of the bedrock mineralization in the B-horizon soil. The distribution of U, Sb, Cu, Pb and to a less extent V in the soil exhibit anomalous signatures that may reflect a primary mineralized halo associated with the Jacque's Lake U prospect. Uranium concentrations (mixed acid digest) in soil ranged from 0.01 – 867 ppm. Areas of anomalous U concentration in B-horizon soils coincide with the airborne magnetic and radiometric and black spruce twig uranium anomalies that defined the Jacque's Lake deposit.

Concerning the composition of the Earth's core and mantle, iron is one of the most interesting elements for applications in geosciences. Investigation of its electronic structure is essential to understand the origin of physical properties of different iron containing minerals existing in the Earth's interior. E.g. Fe^{2+}/Fe^{3+} ratios, the spin state as well as the oxygen fugacity can vary significantly at relevant conditions, i.e. pressures up to 1 Mbar and temperatures up to 3000°C [1-2]. Thus, experimental determination of such parameters in situ is crucial to understand the thermodynamic properties of these minerals [3].

X-ray Raman scattering (XRS) provides a possibility to measure electronic excitations by inelastic x-ray scattering which yields similar information like measurement of x-ray absorption edges by x-ray absorption spectroscopy (XAFS) or electron energy loss spectroscopy (EELS) [4]. Because XRS is an energy loss technique and the energy of the incident radiation does not depend on the binding energy of an atom, in contrast to XAFS and EELS, measurments of absorption edges of low Z elements in soft x-ray regime are possible using hard x-rays which allows measurements even in highly absorbing sample environments like diamond anvil cells with resistive or laser heating.

In this study, Fe $L_{2/3}$ and $M_{2/3}$-edges of different iron oxides and iron containing minerals measured by x-ray Raman scattering are presented in comparison with XAFS and EELS results. Furthermore, the momentum transfer dependency of the Fe $M_{2/3}$-edge is discussed. Possible applications in geosciences are pressure induced electronic transitions in iron containing minerals.

Unravelling Plio-Pleistocene sea surface temperature signals: a multi-proxy latitudinal approach from the South China Sea

CHARLOTTE L. O'BRIEN[1]*, RICHARD D. PANCOST[1] AND GAVIN L. FOSTER[2]

[1]Organic Geochemistry Unit, School of Chemistry, University of Bristol, UK, c.l.obrien@bristol.ac.uk (* presenting author)

[2]School of Ocean and Earth Science, National Oceanography Centre, University of Southampton, UK

The tropical oceans are thought to have played a major role in the evolution of the Earth's climate since the Pliocene, such that accurately reconstructing tropical sea surface temperatures (SSTs) is an essential part of investigating how the global climate system has evolved over the past 5 Ma. Marine sediments from the tropical South China Sea (SCS) have yielded numerous paleotemperature records, however disagreement among different proxies and the potential causes of these differences may be hindering our understanding of the climate system. Using sediments from ODP Sites 1148 and 1143 located in the northern and southern SCS, respectively, we have applied three independent paleo-proxies to examine variations in SST for the past 5 Ma. Specifically, we have generated comparable SST records using the alkenone $U^{K'}_{37}$ index, TEX_{86} and Mg/Ca ratios in planktic foraminifer, *G. sacculifer*.

Our Pliocene TEX_{86}-derived temperatures for both sites indicate SSTs continuously higher than 27°C, exceeding modern mean annual SSTs. The southern SCS is generally warmer (28.0-32.5°C) than the northern SCS (27.0-31.0°C), with ODP Site 1143 displaying both greater variability (4.5°C) and a long-term decrease from 4 to 2 Ma. In contrast, the northern ODP Site 1148 exhibits lower variability (3.5°C) and no apparent trend such that the two records converge to similar values in the Pleistocene. Our Mg/Ca-SSTs show a similar trend to Mg/Ca SSTs at ODP Site 806 in the western equatorial Pacific [1], remaining generally stable (25.5-31.5°C) throughout the last 5 Ma with no indication of any global cooling. Alkenones are abundant in our samples. However, during the Pliocene, concentrations of tri-unsaturated alkenones are below detection limits indicating that SSTs in the SCS were above the limits of the $U^{K'}_{37}$ proxy (27.0-29.0°C) during this time.

The high $U^{K'}_{37}$ indices are consistent with the high SSTs in our TEX_{86} records, implying that SCS SSTs in the Pliocene and early Pleistocene exceeded modern mean annual SSTs. In contrast, our Mg/Ca SSTs (25.5-30.5°C) during this same period are offset from our TEX_{86}-SSTs (27.0-32.5°C) by, on average, >2°C at both SCS sites. Furthermore, our alkenone SSTs for ODP Site 1148 show that the northern SCS has cooled over the last 2 Ma, but this cooling is not seen in our Mg/Ca records. Higher TEX_{86}-derived temperatures may be in part due to TEX_{86}-SST estimates corresponding to warm season SSTs, as reported for a SCS core top sample [2], but it is unclear if such a bias can explain the high $U^{K'}_{37}$-derived SSTs. With these data we shall discuss reconstructing past tropical warmth and the application of various SST proxies in the Pliocene.

[4] Perilya Limited, Broken Hill, Australia, dean.rogers@perilya.com.au

Gahnite-bearing rocks ($ZnAl_2O_4$) are volumetrically abundant throughout the Proterozoic Broken Hill Domain, New South Wales, Australia, where they are associated with Broken Hill-type (BHT) Pb-Zn-Ag mineralization (including the supergiant, 200 Mt, Broken Hill deposit). Historically, the presence of gahnite has been utilized as an exploration guide for ores of this type, but has led to relatively limited sulfide discoveries. Major element chemistry has been used successfully to define a compositional range of gahnite associated with metamorphosed massive sulphides deposits, but it fails to distinguish sulfide-rich from sulfide-poor occurrences.

Major and trace element data from LA-ICP-MS and electron microprobe analyses provide valuable insight both into the origin of gahnite at Broken Hill, and its use as an exploration guide. Samples from 12 BHT deposits were analysed to determine whether or not prospective BHT deposits can be compositionally distinguished from non-prospective occurrences based on trace element content. Data were discriminated using a Principal Component Analysis to distinguish gahnite associated with the main ore lode from that associated with unmineralized lode pegmatites and sillimanite gneiss. Gahnite from the main ore bodies at Broken Hill have a relatively restricted compositional range that, based on a series of bivariate plot with density ellipses, overlap with the compositions of gahnite from several minor BHT occurrences. Based on contour maps of ore grade (wt. % Pb + Zn) associated with each gahnite locality, gahnite associated with the highest grades from the minor BHT deposits, have compositions that plot within the field for gahnite from the main ore bodies suggesting that trace element chemistry (e.g., Co: 60-80 ppm, and Cr+V+Mn+Ga: 1,100-2,200 ppm) may be used as an exploration guide for high-grade ore.

Ground water contamination with As is an environmental problem affecting human health [1]. Sorption of As to Fe(III)-(oxyhydr)oxides, is one of the most efficient mechanisms for immobilizing As in the environment. Fe(II)-oxidizing bacteria have recently been identified as possible contributors to As immobilization [2]. The objective of this study was to map the partitioning of As at various stages of precipitation [3] and to clarify the detoxification mechanisms.

The nitrate-reducing, Fe(II)-oxidizing *Acidovorax* strain BoFeN1 was cultured in presence of 0.2-1 mM arsenate. Samples were prepared anoxically for spectromicroscopic identification and mapping of the of cell-mineral aggregates formed during biogenic Fe(II) oxidation. Chemical speciation of As was measured at sub-100 nm spatial resolution by scanning transmission (soft) X-ray microscopy (STXM) using X-ray fluorescence (XRF) detection at beamline 11.0.2, Advanced Light Source (ALS), Berkeley USA.

Biogenic Fe-precipitates formed at different stages of microbial Fe(II) oxidation were found to vary significantly in their affinity for arsenate sorption/coprecipitation. The cytoplasm and the periplasm of cells cultured in the absence of Fe as well as periplasmatic Fe(III) precipitates formed when cultivated with Fe(II)) were highly depleted in As(V). No reduction of arsenate to arsenite was detected, which would be an essential step in the conventional As-detoxification systems. These results together indicate a yet unknown, efficient mechanism of either hindering As(V) from entering the cytoplasm through the phosphate transport mechanisms, or an arsenate-specific efflux pump. Although present in the genome of BoFeN1, the arsC, arsA and the ARR3 genes which are involved in the conventional detoxification, seemed not to play a role in the As depletion of the cells. In contrast, cell-associated extracellular precipitates of mineral-filled cell-residues of late stages of Fe(II) oxidation were enriched in their As(V)-content.

15f. Organic sulfur in the Earth System

There is overwhelming hypothesis about the importance of sulfur mass-independent isotopic (MIF) signatures $\Delta^{33}S$, $\delta^{34}S$, and $\Delta^{36}S$ observed in the early Earth's history[1]. The accumulation of MIF signals in ancient rocks has been linked to UV photolysis of SO_2 that penetrated deep in the Earth's atmosphere during the Archean[2]. Recently, it has been argued that thermochemical sulfate reduction (TSR) produce anomalous sulfur-33 compositions[3], but the source of this anomalous isotope signature have been suggested to result from a magnetic isotope effects (MIE) and the anomaly is limited to the magnetic isotope ^{33}S and not on ^{36}S[4].

In order to elucidate the mechanisms and differentiate between the sulfur isotope anomalies produced by photochemical and thermochemical reactions. We carried out a series of UV photolysis experiments of SO_2 with methane (CH_4), acetylene (C_2H_2), and ethylene (C_2H_4). The photolysis produced a number of methylated sulfoxide aerosol species (such as dimethylsulfone - DSO and methanesulfonic acids -MSA). The different isotope patterns are observed for the radiation under 190 to 220 and 250 to 330 nm UV absorption bands. But all shows anomaly in both S-33 and S-36. New thermochemical experiments of model organosulfur compounds demonstrate that thermolysis of terminal thiyl (such as glutathionine) and aromatic thiane (1,3,5-trithiane) compounds can also produce significant $\Delta^{33}S$ anomalies. These ^{33}S enrichments are attributed to a magnetic isotope effect (MIE) that affects only odd isotopes via the formation of thiyl-disulfide ion-radical pairs.

The findings in this thermal experiment are not consistent with multiple sulfur isotope trends of extracted methylated sulfoxide compounds observed in SO_2-CH_4-C_2H_2-C_2H_4 photochemical experiments, which exhibit significant ^{36}S anomalies and further the assertion that the early Archean record does not reflect this thermally induced radical sulfur chemistry. Detailed reaction mechanisms and processes leading to photochemical and thermochemical S-MIF signals will be presented.

Direct evidence for isotopic fractionation during congruent dissolution, precipitation and at equilibrium

ERIC H. OELKERS[1*], CHRISTOPHER R. PEARCE[2], GIUSEPPE D. SALDI[3], AND JACQUES SCHOTT[1]

[1]Géosciences Environnement Toulouse, (GET/ CNRS UMR 5563, 14 Avenue Edourd Belin, 31400 Toulouse, France, oelkers@get.obs-mip.fr (* presenting author)

[3] Earth Sciences Division, Lawrence Berkeley Laboratory, 1 Cyclotron Road, Berkeley, CA 94720, USA

This study provides direct experimental evidence of magnesium (Mg) isotope fractionation between an aqueous fluid and magnesite during its congruent dissolution, precipitation, and at equilibrium. Closed-system batch reactor experiments were performed at temperatures from 120 to 200 ºC and at 15 to 30 bars CO_2 pressure. During congruent magnesite dissolution the fluid became enriched in isotopically heavy Mg, with a steady state $\delta^{26}Mg_{fluid}$ composition 0.4 ‰ higher than the dissolving magnesite at 15 bars of CO_2 pressure, and 0.15 ‰ higher at 30 bars of CO_2 pressure. Equilibrium $^{26}Mg/^{24}Mg$ fractionation factors (α_{eqm}) for the were found to be 0.99881 at 150 °C and 0.99912 at 200 °C, close to those predicted by density-functional electronic structure models Magnesite precipitation was provoked by increasing the reactor temperature after equilibrium had been attained via dissolution. Kinetic isotope fractionation effects consistent with Rayleigh fractionation were observed immediately after the reactor temperature was increased and rapid magnesite precipitation occurred. However, isotopic exchange continued as the system equilibrated, eradicating the kinetic signal in the precipitated solid. As most natural systems fail to sustain rapid precipitation rates long-term, this observation suggests that kinetic fractionation effects in precipitated minerals will not be preserved in most geological systems.

The results of this study confirm the concept of dynamic equilibrium during water-mineral processes. Dynamic equilibrium also means that minerals and fluids will continue to equilibrate isotopically long after equilibrium is attained. This conclusion likely has significant consequences for the use of mineral isotopic compositions to illuminate chemical weathering processes, water-rock interaction in the crust, and past environmental conditions.

.

On the competition between kinetic and equilibrium isotope fractionation during low-T silica precipitation

M. OELZE[1*], F. VON BLANCKENBURG[1], D. HÖLLEN[2], M. DIETZEL[2], J. BOUCHEZ[1]

[1] GFZ German Centre for Geosciences, Potsdam, Germany, Oelze@gfz-potsdam.de(* presenting author)
[2]Institute of Applied Geosciences, Graz University of Technology, Austria

Formation of Si-bearing phases due to precipitation or adsorption always favors incorporation of light isotopes (apparent fractionation factor $\Delta_{solid\text{-}fluid} < 0$‰), which is usually explained by kinetic isotope fractionation. We challenge this assumption by conducting two sets of laboratory experiments.

First, Si-adsorption experiments (exp. #1) onto suspended gibbsite were performed at different initial monosilicic acid concentrations ($[Si]_{aq}$= 10, 20 and 40 ppm) at pH 7. Adsorption of silicic acid results in an increase of $\delta^{30}Si_{aq}$ values and a chemical steady state is reached after ~ 300 h of experimental runtime. These experiments confirm that $\Delta_{solid\text{-}fluid} < 0$‰, but also show that the magnitude of $\Delta_{solid\text{-}fluid}$ depends on the initial Si concentration. We show that Si concentrations affect the precipitation rate, but there is no obvious reason why isotope fractionation should depend on precipitation rate in a well-mixed system where no isotope fractionation due to diffusion in the solution should occur.

However, according to DePaolo[1], the fractionation of isotopes between solution and forming solids depends on the ratio of net precipitation rate R_p to the backward reaction rate R_b. When $R_p \approx R_b$, a competition between equilibrium and kinetic fractionation is expected. To test this hypothesis, a second set of experiments (exp. #2) were conducted, where solutions were frozen and thawed within 24 hours up to 130 days and sampled at regular intervals, during which amorphous silica was repeatedly precipitated/adsorbed and redissolved. In this special setup, $R_p << R_b$ might be achieved, a condition for isotope fractionation to reflect equilibrium[1]. Several sets of these experiments were performed at pH 4.5 and 7, with solutions initially containing $[Si]_{aq}$ = 45 ppm and $[Al]_{aq}$ = 2.7 or 27 ppm. We suggest precipitation of an Al-O-OH phase and subsequent adsorption of Si and/or coprecipitation of Si and Al. Experiments with high initial Al concentration show changing $\delta^{30}Si_{aq}$ values with experimental runtime. The $\delta^{30}Si_{aq}$ values increased during the first 20 days to up to 2.4‰ and then shows a decline to almost starting values of 0‰ after 130 days. This setup allows that R_p shifts from values $>> R_b$ to values $R_p << R_b$, which results in a change from kinetically- to equilibrium-dominated isotope fractionation.

In the first set of adsorption experiments (exp. #1), where $R_p > R_b$, kinetic isotope fractionation is assumed as Si rarely exchanges with the solution.

To conclude, the withdrawal of Si in natural systems due to precipitation or adsorption is not necessarily dominated by kinetic isotope fractionation. Instead, isotope fractionation might approach $\Delta_{solid\text{-}fluid} \geq 0$ if $R_p << R_b$, which can then be interpreted as equilibrium isotope fractionation.

This communication presents results of the investigation of the distribution and speciation of mercury (Hg) in deep-sea waters of the Mediterranean Sea during oceanographic cruise on board the Italian research vessel URANIA as a part of GMOS project. The study includes deep water profiles of dissolved gaseous Hg (DGM), reactive Hg (RHg), total (THg), monomethyl Hg (MeHg) and dimethyl Hg (DMeHg) in open ocean waters. A special attention is paid on the distribution of DGM, which plays the major role in the exchange of Hg between water and atmosphere. Average concentrations of measured Hg species were characterized by seasonal and spatial variations. Overall average THg concentrations ranged between 0.41 to 2.65 pM (1.32 ± 0.48 pM) and were comparable to those obtained in previous studies for the Mediterranean Sea [1,2]. Generally, average THg concentration was higher in W and E Mediteranean Deep Waters (WMDW and EMDW) and Leavantine Intermediate Water (LIW) than overlaying Modified Atlantic Water (MAW). High concentrations and portions of DGM and MeHg indicate high reactivity of Hg in open ocean waters. DGM was present in surface waters mainly as Hg^0 as no DMHg was detected at the surface, while towards the bottom a noticeable, but relatively small portion of DMeHg is present. DGM represents a considerable proportion of total Hg (average 20%, 0.23 ± 0.11 pM). The portion of DGM typically increased towards the bottom, especially in areas with strong tectonic activity (Alboran Sea, Strait of Sicily, Tyrrhenian Sea), indicating its bacterial and/or geotectonic origin. This is also confirmed by the fact that average DGM concentration was the highest in deep water masses (WMDW and EMDW). The percentage of MeHg (0.22 ± 0.12 pM) was on average approximately the same as for DGM. The observed increase of MeHg towards the bottom could be the consequence of photochemical degradation and/or microbial actions in surface and microbiologically mediated methylation in deeper waters [3,4].

Results will be also compared to the results obtained in the last GEOTRACES Atlantic Ocean cruise.

Hydrochemistry of shallow groundwater in areas affected by livestock burial

JUN-SEOP OH[1*], SEONG-TAEK YUN[1], JEONG-HO LEE[1], KYOUNG-HO KIM[1], KWANG-JUN CHOI[2], DONG-HO KIM[3], TAE-SEUNG KIM[3], JIN-SEOK HAN[3], AND BERNHARD MAYER[4]

[4]University of Calgary, Geoscience, Canada

As a result of an outbreak of foot and mouth disease (FMD) between late 2010 and early 2011 in South Korea, a large number of livestock carcasses (> 3.4 million) were buried in ~4,400 pits (usually 5 m deep) throughout the country. As a result, there is concern about the potential impacts of leachates from livestock burial sites on shallow groundwater. In addition, there are debates about the origin of groundwater contamination around livestock burial sites, as groundwater in agricultural areas is also usually contaminated by nitrogen-bearing compounds and chlorine from preexisting non-point and point sources. Therefore, we conducted hydrochemical surveys of groundwater in a few areas potentially affected by livestock burial, with the main purpose of assessing the potential impacts on groundwater quality. An additional objective was to identify geochemical indicators which can be used for differentiating contamination from agricultural areas and livestock burial sites. We collected hydrochemical (i.e., major cations and anions and trace metals) and isotopic data for nitrate ($\delta^{15}N$ and $\delta^{18}O$) for groundwater from domestic and agricultural wells (< 300 m away from burial sites) as well as leachate samples from burial sites. The obtained data were interpreted using factor analysis to reveal the relationships between variables and to cluster the samples based on hydrochemical processes.

The results show that only a few monitoring wells at distances of < 5 m from the burial sites were impacted by leachate from burial sites yielding groundwater that was strongly anoxic and high in ammonium and other solutes such as HCO_3, Ca, Cl, Mg, Na, K, SO_4, Br, Fe, Mn and B. The leachates and groundwaters affected by burial sites were hydrochemically a Ca-HCO_3 type, while unaffected groundwater was mostly Ca-Cl(NO_3) type due to pervasive impacts from agrochemicals. The isotopic composition of traces of nitrate in leachate and groundwater affected by burial sites were variable and inconsistent with values known for diverse nitrate sources such as fertilizers, manure and sewage, possibly due to nitrification under isotopic disequilibrium or due to other nitrogen transformation processes. We propose the use of following geochemical parameters for differentiating groundwater contamination from leachate of livestock burial sites and from agricultural areas: 1) redox-sensitive parameters such as ammonium, Fe and DO (especially, the occurrence of ammonium ion) and 2) hydrochemical water types in conjunction with (Na+K)/∑cations versus (SO_4+Cl) relationship.

Evidence for the O_2 and CO_2 rich Archean atmosphere

H. OHMOTO[1*], Y. WATANABE[1], K.E. YAMAGUCHI[2], H. HAMASAKI, J. BRAINARD[1], AND A.P. CHORNEY[1]

[1]NASA Astrobiology Institute and Department of Geosciences, Penn State University, University Park, USA, hqo@psu.edu; yxw129@psu.edu; hzh114@psu.edu; jlb5156@psu.edu; apc5060@psu.edu

[2]Toho University, Chiba, Japan, kosei@chem.sci.toho-u.ac.jp

In the oxygenated world, the CO_2 and O_2 contents of the atmosphere and oceans are regulated at steady-state levels by the balance between the forward and backward reactions of: $CO_2 + H_2O = CH_2O + O_2$. Today, ~100% of the CH_2O formed on land and ~99.7% of the CH_2O formed in the oceans by oxygenic photosynthesis are recycled back to CO_2 in <10 yrs by aerobic oxidation. Burial of the ~0.3% of marine organic matter as kerogen in sediments has been responsible for the long-term (>1,000 yrs) production of O_2 in the atmosphere and oceans. Oxidation of the kerogen during soil formation has been the main pathway for the long-term consumption of O_2.

In the anaerobic world, such as the one postulated by many for the Archean, organic synthesis is carried out by anoxygenic photosynthesis (e.g., $CO_2 + 2H_2 \rightarrow CH_2O + H_2O$). Fresh organic matter decomposes by fermentation (e.g., $CH_2O \rightarrow CO + H_2$ and $3CH_2O \rightarrow 2CO + CH_4 + H_2O$, c.f., Hoeler et al., 2001), but kerogen is not decomposed. In such a world, the atmospheric CO_2 is continuously converted to reduced C compounds (CH_2O, CO, CH_4 and C) and not completely recycled back to CO_2. Thus, the atmospheric CO_2 continuously decreases, even with continuous supplies of CO_2 by volcanic gas and weathering of carbonates, and disappears in <~100 Ma since the emergence of photoautotrophs, creating an icy, dead planet (Ohmoto and Lasaga, 2001). However, the abundances of carbonates and organic C-rich shales, and their $\delta^{13}C$ values, in Archean sedimentary rocks are essentially the same as those in younger ones (Ohmoto, 2004), suggesting that since ~3.8 Ga, the atmosphere and oceans have remained O_2- and CO_2 rich and the modern-styled redox cycle of C has operated.

Black shales with high pyrite contents, which positively correlate with organic C contents, and sulfate-rich sediments are not uncommon in Archean rocks (Ohmoto, 2004). $\delta^{34}S$ values of the pyrites and sulfates show large variations, from -20 to +35‰ and from +2 to +27‰, respectively (Ohmoto, 1992, 2004; Kiyokawa et al., in prep.). The common $\delta^{15}N$ values for kerogen in Archean shales (0 to +15‰) are essentially the same as those in Phanerozoic ones (Yamaguchi, 2004; Kerrich et al., 2006). These data suggest that since >3.5 Ga, the oceans have been rich in SO_4^{2-} and NO_3^-. Researchers have interpreted the isotopic records of S, Fe, Mo and Cr in sedimentary rocks based on anoxic Archean atmosphere models. However, we can better explain these isotopic data, as well as the Pb isotope data and the variations in the Fe^{III}-, Mo-, Ce, and U contents, of Archean rocks with the model of a fully-oxygenated Archean world. The isotopic variations in the 2.7-2.5 Ga Hamersley sediments can be explained by combinations of biological-, diagenetic- and hydrothermal processes in a nearly-closed euxinic basin, which episodically hosted matalliferous brine pools and/or opened to the O_2-, S-, Mo- and U rich oceans.

Many researchers have cited the presence of AIF-S (or MIF-S) and detrital grains of uraninite and pyrite in some Archean-aged sedimentary rocks as strong evidence for an anoxic Archean atmosphere. But such arguments are invalid, as AIF-S and these detrital minerals have also been found in much younger-aged materials (Ohmoto, 2004; Watanabe et al., Goldschmidt 2012).

Trace element composition of size-fractionated particulates in the North Atlantic U.S. GEOTRACES section

DANIEL C. OHNEMUS[1,2*], PHOEBE J. LAM[2]

[1]MIT/WHOI Joint Program in Oceanography, Woods Hole, USA (*dan@whoi.edu)

[2]Department of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Inst., Woods Hole, USA, pjlam@whoi.edu

Sinking (>51μm) and suspended (<51μm) marine particulates were collected via *in situ* filtration during the US GEOTRACES North Atlantic Zonal Transect cruises on the *R/V Knorr* in 2010 and 2011. Total and acetic acid-leachable compositional profiles for key trace elements and isotopes (TEIs—Fe, Al, Zn, Mn, Cd, Cu) and other TEIs of interest (Co, Ti, Ba, V, Ni, Mo) are presented, allowing a first look at particulate composition for a full ocean transect, in sixteen-point depth resolution.

This transect explores a diverse array of sites—the Saharan African and North American continental margins, a mid-ocean ridge hydrothermal plume, several benthic boundary layers, as well as open-ocean sites—which significantly expands our knowledge of the highly-variable and dynamic marine particulate world. Common behaviors are observed for several groups of elements, highlighting differences between lithogenic and biogenic particulate pools, and the dynamics that exchange material between different size-fractions. Acetic acid-leachable particulate data furthermore provides constraints on exchangeable and/or bioavailable elemental pools, and also explores the behaviors of redox-sensitive metals in oxygen minimum zones, benthic boundary layers, and in surface waters. Combination of this dataset with other, forthcoming GEOTRACES results (e.g. ^{234}Th export, dissolved TEI parameters) will be an exciting product of the worldwide GEOTRACES program.

Bio-mineralization of rare earth elements

T. OHNUKI[1*], M. JIANG[1,2], S. UTSUNOMIYA[2], K. TANAKA[1,3]

[1] Advanced Science Research Center, Japan Atomic Energy Agency, Tokai, Ibaraki, 319-1195 Japan
(*correspondence: ohnuki.toshihiko@jaea.go.jp)
[2] Department of Chemistry, Kyushu University, Fukuoka-shi, Fukuoka-ken, 812-8581 Japan
[3] Department of Earth and Planetary Systems Science, Hiroshima University, Higashi-Hiroshima, Hiroshima, 739-8526Japan

Geochemical behaviors of rare earth elements (REEs) are important to understand the migration of trivalent actinides and fission genic REEs from nuclear power plants and high level radioactive waste. When REEs migrates in environemnts, their chemical states may change by the interaction with inorganic and organic materials. Many researchers have studied the interaction of REEs with inorganic materials. However, the biotransformation of REEs have not fully understood. We have conducted the research on the effects of microorganisms on chemical states change of REEs.

We found that Sm(III) phosphate minerals were formed on the cells surface of gram negative bacterium *Pseudomonas fluorescens* after exposure of Sm(III) solution with the resting cells, even though no phosphate is added. TEM-SAED analysis showed that Sm-monazite was developed directly from the surface of cells. Sm(III) ions were first adsorbed by the functional groups of cells surface, followed by the chemical states change by the reaction with phosphate ions released from inside the yeast cells.

When phosphate is provided in the solution as glycerol phosphate-Ca, Yb concentration decreased abruptly with time after *P. fluorescens* exposed to the solution containing Yb(III) and lactic acid. TEM and XAFS analyses showed the nanoprecipitates containing Yb and P were formed directly from the cells surface. Interestingly, precipitates containing Ca and P, but no Yb were observed on the cells. On the contary, without glycerol phosphate, Yb concentration in the solution slightly decreased with time by the formation of Yb-lactate complex in the solution.

These findings strongly indicate that Yb phosphate mineralization was occurred on the cells surface, even when P was provided from inside and outside cells. Thus, cell surface of microorganisms functions as specific reaction environment for biotransportation of REEs.

Speciation study of copper in stream sediments and soils

ATSUYUKI OHTA[1*], HIROYUKI KAGI2

[1]Geological Suervey of Japan, Tsukuba, Japan, aohta@aist.go.jp
[2] The University of Tokyo, Tokyo, Japan, kagi@eqchem.s.u-tokyo.ac.jp

A sequential extraction method has been used widely to elucidate its chemical binding forms in sediments including soil. However, the method might give misleading results due to alteration of the samples during the individual steps of the extraction [1]. We applied a X-ray absorption fine structure (XAFS) spectroscopy to identify the Cu species in the residues after each step of the sequential extraction. The Cu in 7 geo-standard materials (JSd-1~5: stream sediments, JSO-1 and 3: soils) was extracted using a modified three-step extraction developed by the Community Bureau of Reference (BCR) [2]. The steps and extractants are as follows;

(1) Step1: CH_3COOH (0.11 mol/L).
(2) Step 2: $NH_2OH{\cdot}HCl$ (0.5 mol/L).
(3) Step 3: H_2O_2 (8.8 mol/L) and CH_3COONH_4 (1 mol/L).

The residues after each step of extraction were filtrated by a membrane filter. The $Cu^{3+}_{(aq)}$, $Cu(NO_3)_2$, Cu doped FeOOH (or MnO_2), Cu doped humic materials, and JCu-1 (a geochemical reference material of CuS ores) were prepared As a reference compounds. The Cu K-edge XANES spectra were recorded in a fluoresce mode at the BL-12C of KEK-PF. The fluorescence X-ray was measured by a 19 element pure-Ge SSD.

Figure 1 shows the Cu K-edge XANES spectra of JSd-2 and reference materials and its fitting results. The JSd-2 is a stream sediment reference material collected from the drainage basin having Cu mine. The speciation of Cu in JSd-2 is expected to be a mixture of Cu weakly adsorbed on materials (step 1), Cu bound to Fe-Mn hydroxides (step 2), chalcopyrite (step 3) and silicate materials (residue). The linear fitting result was roughly comparable to the results from the BCR scheme, although the relative amount of Cu extracted at step 3 is underestimated. Thus, the method using XAFS spectroscopy combined with BCR scheme is effective to accurately identify and quantify Cu species in sediment samples.

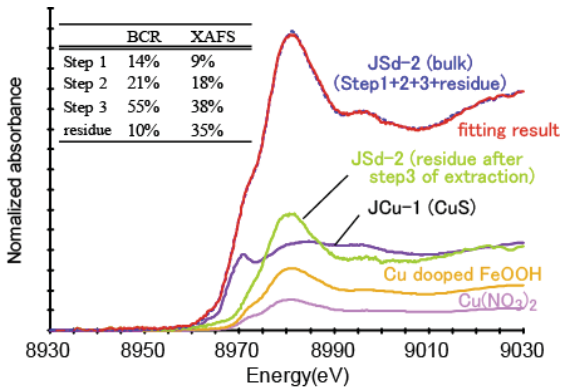

Figure 1. The Cu K-edge XANES spectra of JSd-2 and the residue of JSd-2 after third step in the BCR scheme, and reference materials.

Iron isotopic signature of Fe-Ni metals in ordinary chondrites using LAL-MC-ICPMS technique

SATOKI OKABAYASHI[1*], TETSUYA YOKOYAMA[2], AND TAKAFUMI HIRATA[1]

[1]Laboratory for Planetary Sciences, Kyoto University, Kyoto, Japan, okabayashi-s-aa@kueps.kyoto-u.ac.jp (* presenting author)
[2]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan

Introduction

The ordinary chondrite is the most abundant and primitive meteorite in the solar system. It is widely believed that the formation sequence of the ordinary chondrites tell us details of the early solar system history. Among the various minerals or components found in the ordinary chondrites, the Fe-Ni metal is one of the characteristic materials of ordinary chondrite. Despite the major components, the formation processes of Fe-Ni metals have still been veiled. The Fe isotopic signature is one of the key information to derive the formation processes of Fe-Ni metals in the ordinary chondrites, because (a) Fe is ubiquitously distributed in various minerals or phases in the meteorites, and (b) Fe isotope composition can vary through the formation processes. In this study, the Fe isotopic ratios of Fe-Ni grains in ordinary chondrites were measured. In order to derive inherent and reliable Fe isotopic data from complex Fe-Ni phases, we have developed a new sampling technique described below.

Experimental

In this study, Fe-Ni metals in ordinary chondrites were collected using laser ablation in liquid (LAL) technique [1, 2]. The sample surface was polished and the metal phase was ablated in the deionized water using the femtosecond laser (λ=780 nm). Unlike with the conventional micro-drilling technique, the LAL technique can provide minimum risk of contamination of Fe from equipments. After the LAL sampling procedure, the resulting sample suspension was collected using micropipette and was then subsidized to acid digestion using conc. HCl and conc. H_2O_2. The sample solution was heated until dryness and the resulting sample cake was re-dissolved in 0.1% HCl, and then used for the isotopic analysis of Fe using MC-ICPMS connected to the desolvating nebulizer system.

Results and Conclusion

Total 15 ordinary chondrite metals were analyzed in this study. The δ^{56}Fe data for L chondrites did not vary with the δ^{56}Fe data for LL chondrites. In contrast, Fe in the H chondrites was isotopically lighter than those for L or LL chondrites. These Fe isotopic variations between H, L and LL chondrites are consistent with the data obtained by Theis et al. (2008) [3]. However, these Fe isotopic ratios within the metallic phase in the H, L and LL chondrites cannot be explained by the simple redox reaction suggested by Theis et al. (2008). Possible cause of the present variation of Fe isotopic ratios will be discussed in this presentation.

Vertical distributions of ^{230}Th in the Pacific Ocean and their relation to advection and diffusion

AYAKO OKUBO[1*], HAJIME OBATA[2], TOSHITAKA GAMO[3], MASATOSHI YAMADA[4]

[1]Research Group for Radiochemistry, Japan Atomic Energy Agency, Ibaraki, Japan, okubo.ayako@jaea.go.jp (* presenting author)
[2]Atmosphere and Ocean Research Institute, the University of Tokyo, Chiba, Japan obata@aori.u-tokyo.ac.jp
[3]Atmosphere and Ocean Research Institute, the University of Tokyo, Chiba, Japan gamo@aori.u-tokyo.ac.jp
[4]Institute of Radiation Emergency Medicine, Hirosaki University, Aomori, Japan, myamada@cc.hirosaki-u.ac.jp

In the central Pacific Ocean, which is remote from all the continents, the distributions of trace elements expectedly show the typical vertical profiles of open oceans.

Vertical distributions of ^{230}Th in the Pacific Ocean have been well-described by the reversible scavenging model [1]-[5]. On the basis of the assumption of no lateral ^{230}Th transport in this model, in-situ produced ^{230}Th is scavenged within the basin. In contrast, the effect of lateral advection on Th distribution have been shown in the Southern Ocean and Atlantic Ocean[6]-[8] and using a model caluculation the effect of isopynal diffusion have been discussed [9].

We investigated the vertical distribution of total ^{230}Th in mid-latitudes of the Pacific Ocean. Because of low biogenic particle flux, high ^{230}Th activity in deep water is exhibited in the central gyre. The west–east section (20°N) of ^{230}Th shows a strong gradient in the deep waters around 170°E and 110°W. At depths of 2000–4000 m and 4000 m–bottom, within the time-scale of scavenging residence time of ^{230}Th, the horizontal eddy diffusion could reach 1100–1400 km and 400–700 km, respectively. The horizontal eddy diffusion transport is too weak to affect Th distribution in the deep layers between each station in this study area. We observed the depletion of total ^{230}Th compared with a reversible scavenging model prediction for the deep layers in the mid-latitudes of the North Pacific Ocean. The observed depletion is partly explained by lateral advection, adopting the scavenging-mixing model. Additionally, a bottom scavenging process above the seafloor and a diffusion process are considered to explain the ^{230}Th deficit.

In the Eastern Subtropical Pacific, advection and diffusion of low-^{230}Th water in the high particle flux region could affect the distributions of ^{230}Th. At the station on the East Pacific Rise, we observed exceptionaly depleted ^{230}Th in deep layers. The ^{230}Th depletion would be attributed to the active hydro-thermal activity in this area.

Characterization of microbial activity by petroleum compositional changes using ultra-high resolution mass spectrometry techniques (FT-ICR-MS)

THOMAS B.P. OLDENBURG[1*], KEN CHANTHAMONTRI[1], ANDREW P. STOPFORD[1], HAIPING HUANG[1], MAN-LING WONG[2], GERRIT VOORDOUW[2], STEVE R. LARTER[1]

[1]Petroleum Reservoir Group, Department of Geoscience, University of Calgary, Calgary, Alberta, Canada, toldenbu@ucalgary.ca (* presenting author), ckchanth@ucalgary.ca, andrew.stopford@ucalgary.ca, huah@ucalgary.ca, slarter@ucalgary.ca

[2]Petroleum Microbiology Research Group, Department of Biological Science, University of Calgary, Alberta, Canada, mlwong@ucalgary.ca, voordouw@ucalgary.ca

Introduction & Methods

Most of the world petroleum reserves are biodegraded with the largest oil reserves being found on the flanks of foreland basins in Canada and Venezuela. Coal as another essential energy source is also known to being partially biodegraded yielding to biogenic gas.

In this study, the compositional changes of fossil fuels during biodegradation in lab experiments and in natural reservoir profiles under aerobic and anaerobic conditions will be shown as well as indicators of microbiological activity.

The fossil fuel compositions were analyzed using an ultra-high resolution Fourier Transform-Ion Cyclotron Resonance-Mass Spectrometry (Bruker12T FT-ICR-MS) and GC-MS techniques. For FT-ICR-MS the ionization methods used include Electrospray (ESI) in positive and negative ion mode as well as Atmospheric Pressure Photoionization (APPI) in positive ion mode.

Results & Discussion

One example of compositional changes during biodegradation of bitumen and assessment of microbial activity is shown in Fig. 1.

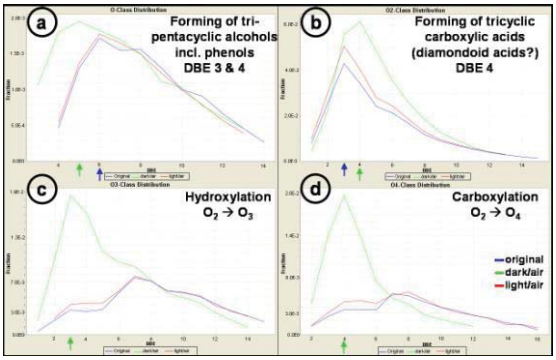

Figure 1: Changes in oxygen compound systematics of aerobic biodegradation lab experiments of oil sands bitumen: a. alcohols, b. carboxylic acids, c. hydroxy-carboxylic acids, d. dicarboxylic acids. All oxygen compound classes (O1-4) are becoming strongly enriched in the absence of light whereas under light no or only minor changes are observed.

Thermodynamic properties of carbonate liquids: required for models of carbonate stability in the mantle

MARY CATHERINE O'LEARY[1*] AND REBECCA A. LANGE[1], AND YUHUI AI[1]

[1] Department of Earth and Environmental Sciences, University of Michigan, Ann Arbor, mcolear@umich.edu (*presenting author)

Not only is mantle carbonate an important reservoir in the global carbon cycle, it also plays a key role in mantle melting processes. Mantle carbonate, of which $MgCO_3$ and $CaCO_3$ are the most important components, has been shown to have a major effect on both the depth of melting and the resultant magma composition (e.g., Dasgupta et al., 2006). In order to fully explore under what T-P conditions mantle carbonate can be subducted into the lower mantle, as well as to examine all possible temperature, pressure, and composition conditions where mantle carbonate influences melting, the number of phase equilibrium experiments needed is prohibitive. Therefore, thermodynamic models of mantle melting that incorporate carbonate are of considerable interest. In order to achieve this, thermodynamic data on $CaCO_3$ and $MgCO_3$ liquids are needed, including their heat capacity, enthalpy, volume, and compressibility. By mixing the alkaline earth carbonates with the alkali carbonates, liquidus temperatures are lowered to those below decomposition (< 1300K), permitting measurement of various thermodynamic properties to be made. This method also tests whether the molar volume, compressibility, and heat capacity of carbonate liquids mix ideally with respect to composition, allowing the partial molar liquid properties for $CaCO_3$ and $MgCO_3$ to be derived. Previous work in the system Li_2CO_3-Na_2CO_3-K_2CO_3-$CaCO_3$ by Liu and Lange (2003) has shown that the volume and thermal expansion mix ideally. In this study, we show that the compressibility and heat capacity of Li_2CO3-Na_2CO_3-K_2CO_3-$CaCO_3$ liquids also mix ideally with respect to composition at one bar. Compressibility measurements were made on eleven liquids (four containing ≤ 50 mol% $CaCO_3$) using frequency-sweep acoustic interferometery at one bar between 800 and 1300 K. When the ideal mixing model for compressibility is applied,

$$\beta_T(X) = \sum X_i \frac{\overline{V}_{i,T}}{\overline{V}_T}\left(\overline{\beta}_{i,T_{1100K}} + \frac{\partial \overline{B}_i}{\partial T}(T - 1100\,K)\right)$$

fitted partial molar compressibilities are acquired (Table 1).

Carbonate Component	$\beta_{T,1100K} \pm 1\sigma$ (10^{-2} GPa^{-1})	$\partial\beta_T/\partial T \pm 1\sigma$ (10^{-2} GPa^{-1})
$CaCO_3$	5.36 ± 0.13	0.0061 ± 0.0010
Li_2CO_3	8.09 ± 0.06	0.0044 ± 0.0008
Na_2CO_3	10.62 ± 0.07	0.0103 ± 0.0006
K_2CO_3	14.09 ± 0.06	0.0135 ± 0.0004

Table 1. Partial molar compressibilities for the carbonates.

A Perkin-Elmer Diamond differential scanning calorimeter is being used to measure liquid heat capacities. We have applied our results to a thermodynamic analysis of the fusion curve of $CaCO_3$ in order to constrain its one-bar enthalpy and entropy of fusion in addition to the pressure dependence of the compressibility (bulk modulus) of $CaCO_3$ liquid (K_0'), using a 3rd-order Birch-Murnaghan equation of state. Currently, our best estimate for the K_0' of $CaCO_3$ liquid is 4.5 ± 0.5. Though DSC measurements are ongoing, our preliminary estimate for the enthalpy of fusion for $CaCO_3$ at one bar is 67.5 ± 0.5 kJ/mol for a one-bar metastable melting temperature of 1295°C.

Fossil Corals as an archive of Phanerozoic seawater chemistry

ANNE M. O'LEARY[1*], MICHAEL L. BENDER[1], JAROSŁAW STOLARSKI[2], JESS. F. ADKINS[3], KATE J. DENNIS[1], DANIEL P. SCHRAG[4]

[1]Princeton University, Geosciences, Princeton, NJ, aoleary@princeton.edu (*presenting author)
[2]Instytut Paleobiologii, Polska Akademia Nauk, Warszawa, Poland, stolacy@twarda.pan.pl
[3]California Institute of Technology, Geological and Planetary Sciences, Pasadena, CA, jess@gps.caltech.edu
[4]Harvard University, Earth and Planetary Sciences, Cambridge, MA, schrag@eps.harvard.edu

Numerous observations indicate that the composition of seawater has not remained constant through time. It has been hypothesized that such variability is linked to changes in geologic processes such as continental weathering, sea-floor spreading, and continental onlap. Fossil corals may be suitable candidates for studying seawater chemistry. Although there is evidence that incorporation of some elements into the coral skeleton is biologically mediated[1], other elements seem to accurately record certain chemical properties of the seawater from which the corals grow.

We studied a suite of ~12 well-preserved fossil corals dating back to the Triassic. The primary objective of this work was to assemble a collection of fossil corals that have been meticulously tested and shown to be diagenetically unaltered with respect to their original structure and mineralogy. X-ray diffraction, micro-Raman spectroscopy, and cathodoluminescence analyses suggest that these specimens contain little to no secondary calcite. Electron and optical microscopy studies reveal crystal structures consistent with modern coral aragonite. Clumped isotope data for 6 specimens give temperatures that seem either appropriate for what we understand about the time and location at which each coral grew or they appear too low, similar to some modern corals.[2] However, secondary ion mass spectrometry (SIMS) analyses suggest there is some micron-scale alteration indicated by high Mn/Ca, high Mg/Ca, and low Sr/Ca ratios. In fossils with low Mn/Ca, we observe a positive correlation between Na/Ca and S/Ca, as in modern corals.[3] We sometimes observe a negative relation between Sr/Ca and Mg/Ca, also similar to some modern corals.[4]

The second objective of this study is to analyze properties such as Sr/Ca and Mg/Ca in corals to supplement existing records of global seawater chemistry since the Triassic. Initial results from SIMS measurements of Sr/Ca ratios are consistent with some existing records of Sr/Ca in seawater through time; Sr/Ca is relatively constant from the modern to the Triassic. These results are supportive of using corals as archives of paleo-seawater chemistry. Additionally, we find that Mg/Ca ratios in fossil corals decrease with age, but because of possible vital effects, the implications for seawater chemistry are uncertain.

Transport and deposition of engineered nanoparticles (NPs) in saturated porous media (schist): role of interactions between NPs and the rock matrix

PATRICK OLLIVIER*, HÉLÈNE PAUWELS, GUILLAUME WILLE, GILLES BRAIBANT AND GÉRALDINE PICOT-COLBEAUX

BRGM, Water Division, p.ollivier@brgm.fr (* presenting author)

The increasing use of engineered nanoparticles for industrial and household purposes (cosmetics, clothing, electronic, automotive, medical products…) will inevitably lead to their introduction into different environmental compartments, including groundwater. Assessing the risk of groundwater contamination by nanoparticles is worth studying but requires the knowledge of their mobility and environmental reactivity. How far these nanoparticles will travel in waters? A number of studies addressed the processes driving mobility of nanoparticles in simple waters and conditions (clean Quartz sand, bare silica surfaces, uniform and spherical glass beads…). They highlight nanoparticles dispersion in water is highly dependent on physical and chemical key parameters of nanoparticles (solubility, pH_{zpc}, which may vary with chemical composition, crystallinity, size and eventual coating…), and on the overall groundwater composition (pH, ionic strength, major element concentration, e.g. Ca or Na, organic matter contents…). The present study conducted in the frame of the AquaNano project aims at characterising metal oxide nanoparticles (TiO_2 and CeO_2) behaviour and reactivity during transport in schist (heterogeneous medium). Transport (flushing) experiments of nanoparticles suspension through 10 cm long rock column under pressure (up to 5 bars) have been conducted in laboratory. After the experiments, NPs retained in column have been mapped using scanning electron microscopy (SEM). Chemical and physical interactions between NPs and the rock matrix have been constrained using Raman spectroscopy associated with SEM. Results show that NPs deposition and aggregation occurred during their transfer while favorable (repulsive and low ionic strength) transfer conditions were applied in column. Also, it appears a more rapid transfer of NPs concomitant with an increase of NPs retention (by a factor 40) by rock matrix after successives NPs inputs in the column separated by NPs-free water circulation. Experiments conclusively demonstrate that physical and chemical properties of NPs and rock matrix (biotite, quartz…) govern the mobility of NPs. We suggest a rearrangement of NPs (adsorption/desorption processes) in column during NPs-free water circulation and modifications to preferential pathways for NPs circulation while aggregation enhanced NPs deposition.

Dissimilatory iron reduction and the redox cycling of green rust

EDWARD J. O'LOUGHLIN[1]*, MAXIM I. BOYANOV[1], CHRISTOPHER A. GORSKI[2], MICHAEL L. MCCORMICK[3], MICHELLE M. SCHERER[4], AND KENNETH M.. KEMNER[1]

[1]Argonne National Laboratory, Argonne, IL, USA, oloughlin@anl.gov (* presenting author)

[4]The University of Iowa, Iowa City, IA, USA

Introduction

Green rusts (mixed Fe^{II}/Fe^{III} layered double hydroxides) have been identified in Fe^{III}/Fe^{II} transition zones in a variety of natural and engineered subsurface environments including groundwater, soils, and sediments, and among corrosion products in zero valent iron permeable reactive barriers. Many of these environments are characterized by periodic or seasonal cycling of redox conditions (e.g., redoximorphic soils in areas with seasonal flooding) that create the opportunity for cycling of Fe between oxidized and reduced forms. In recent years evidence has been building that suggests that the green rust mineral fougerite plays a central role in Fe redox cycling in these environments.

Experimental Methodology

Carbonate green rust was produced in anoxic defined mineral medium containing 75 mM formate and 80 mM Fe^{III}, in the form of phosphate doped (0.7 mass % P) lepidocrocite, inoculated with *Shewanella putrefaciens* CN32. The green rust was then oxidized by introducing sterile air into the headspace. After 24 h the suspensions were sparged with sterile Ar and re-inoculated with *S. putrefaciens* CN32. Samples were collected for measurement of Fe^{II} and characterization of the secondary mineralization products by powder X-ray diffraction, scanning electron microscopy, and ^{57}Fe Mössbauer spectroscopy.

Discussion of Results

Results of the analysis of the product of green rust oxidation were consistent with ferric green rust. In our experiment, the oxidation of green rust by O_2 to ferric green rust occurred over a period of 24 h without the formation of other Fe^{III} oxide phases. However, the initial green rust was formed in the presence of phosphate and sorption of phosphate or silicate by green rust has been shown to promote oxidation of green rust to ferric green rust by suppressing the dissolution of green rust, a prerequisite for the formation of other ferric phases such as lepidocrocite or goethite. After re-inoculation, total Fe^{II} concentrations rebounded to pre-oxidation concentrations and green rust was observed as the dominant secondary mineralization product. Since phosphate and silicate are typically available in soils and sediments, similar conditions may be encountered in-situ. Thus, our results indicate the potential for cycling of green rust between reduced and oxidized forms under redox dynamics similar to those encountered in environments that alternate between iron-reducing and oxic conditions and are consistent with the identification of green rust in soils/sediments with seasonal redox cycling.

Using laboratory-derived mineral dissolution rates to test biogeochemical weathering in the field

Chemical weathering controls the long-term carbon cycle over million year timescales. Accurate modeling of atmospheric CO_2 requires an understanding of the feedbacks between weathering and CO_2 in natural waters and the atmosphere. However, field-based chemical weathering rates are notoriously hard to measure. Conversely, laboratory-derived mineral dissolution rates are generally two to five orders of magnitude faster than those measured in the field (see [1] and cited references). Additionally, biology plays a critical role in weathering that is very difficult to simulate in the lab or measure in natural environments.

We measured serpentinite dissolution in both laboratory dissolution experiments and in field weathering experiments and modeled our results using the reactive transport code CrunchFlow to try to quantitatively interpret field weathering of serpentinite at two recently glaciated sites in Maine and California. Serpentinites exert a strong control on the ecosystyems that form on them due to the bulk chemistry of serpentinite rocks, high in Mg and trace elements, and low in nutrients such as Ca, K, P, and N, which causes an extreme and stressful environment for biota. Laboratory dissolution studies showed that lizardite dissolves six times times faster in the presence of oxalate, a biological exudate, than in inorganic acids at pH 5. Field samples of a deep profile of the Pine Hill Serpentinite on Little Deer Isle, Maine, show that Ca and other major elements are depleted from the bedrock at depths of up to 1 m, most likely due to the weathering of Ca-rich pyroxenes. Conversely, some trace metals including Cu and Zn show enrichment in the upper meter of the profile. Ongoing reactive transport modeling will allow us to quantitatively interpret the processes contributing to these observed profiles.

Experimental study of stibnite solubility and antimony complexation in aqueous sulfide solutions from 20 to 95˚C

NELLIE J. OLSEN[1, 2*], BRUCE W. MOUNTAIN[1], AND TERRY M. SEWARD[2]

[1]GNS Science, Wairakei Research Centre, Taupo, New Zealand, n.olsen@gns.cri.nz (*presenting author), b.mountain@gns.cri.nz
[2]Victoria University, Wellington, New Zealand, terry.seward@vuw.ac.nz

Modeling antimony transport and mobility in natural hydrothermal systems and mitigation of stibnite (Sb_2S_3) scaling in geothermal power stations require precise data on changes in stibnite solubility in response to small changes in pH, sulfide concentration, pressure and temperatures between 20˚C and 350˚C. There is some uncertainty in stability and stoichiometry of antimony(III) sulfide and hydrosulfide species (i.e. thioantimonites and oxythoantimonites) at 25˚C and at higher temperatures, the nature of the thioantimony(III) stoichiometry is poorly constrained.

We have conducted flow-through solubility experiments with natural stibnite to detemine the solubility of stibnite in aqueous sulfide solutions from pH 6.1 to 12.7 and sulfide contents from 0.01 to 0.06 molal S_{total} at 22˚C. Higher temperature experiments up to 60˚C have been completed at pH 11.1 and 0.006 molal S_{total} and experiments up to 95˚C and at variable pH are on-going. Our experimental results are similar to the solubilities found at 25˚C by [1]. Krupp(1988) concluded that $H_xSb_2S_4^{2-x}$ species are dominant between pH 3 to 12. We note that for arsenic(III)-sulfide/hydrosulfide interactions, the dominant thioarsenite stoichiometry is apparently as the $As(HS)_3$ moiety [2], [3], [4]. At 60˚C, our solubilities are also similar to solubilities extrapolated to higher pH and temperature from [1] but predict lower solubilities at 90˚C. Our measurements will provide a complete set of stibnite solubility data from 22˚ to 95˚C in reduced, sulfide-containing fluids and permit a new evaluation of the stoichiometry and stability of thioantimonite species over this temperature range.

Regional Erosion Surfaces and Climatic Readjustments, Midwest USA: Clues from late Pleistocene loess and paleosols (OIS 5e-2)

CAROLYN OLSON*

U.S. Department of Agriculture, Washington, DC, USDA carolyn.olson@wdc.usda.gov

Background

In the Midwestern, USA, early Wisconsinan time was marked by a series of events that until recently were not clearly linked to post-glacial climatic readjustment on a regional scale. Areas outside the Wisconsinan glacial border and adjacent to major river divides in several Midwestern states were examined in an attempt to locate similar adjacent regions on a scale comparable to continental glaciations.

Studies in the early 20th Century in northeastern Iowa identified an extensive erosion surface [1]. Buried by late Wisconsin loess, this surface cut the entire stratigraphic section from the Wisconsin till to the pre-Illinoian till and thus established its relative age as younger than Wisconsin till and older than late Wisconsin loess deposition. Radiocarbon dates for basal Wisconsinan soils, the uppermost unit truncated by the erosion surface, indicated an age of generally greater than 18000 BP. That age indicates its development was a direct response to shifts in climate associated with glacial retreat.

Wisconsin glaciation extended through much of the upper Midwest but at that time, there was no evidence that the surface in Iowa had parallels in adjacent regions. In the 1980's, we began studies of the Ohio/Wabash stream divides in southeastern Indiana traditionally known as "Illinoian till plain' stratigraphically, late Wisconsin loess overlying Illinoian till. From the investigations, it was determined that although the loess was present in a uniformly continuous blanket across these areas, there was little or no Illinoian till beneath. The late Wisconsin loess lay directly on bedrock, pedisediment, or older tills. Borings on subdued highs revealed that these erosional outliers contained complete stratigraphic sections that had been sequentially truncated by an erosions surface [2, 3]. Hidden beneath loess, this erosion surface had cut the slopes that descend in all directions from the remnant outliers to form the floor of the 'till' plain.

Recent Regional Evidence

The Mississippi/Ohio divide in southern Illinois within the Illinoian drift border and well south of the Wisconsinan drift border were examined most recently. Multiple coring sites and soil pits were located near the divides of tributaries to the Big Muddy River drainage. Here, as in Indiana and Iowa, undisturbed thicknesses of late Wisconsin loess directly overlie bedrock, pedisediment or older drift revealing erosional surfaces. Illinoian till is present only in protected coves of the subsurface landscape.

Conclusions

During the waning phases of the last glaciation in North America, a period of significant subaerial erosion occurred that remained largely unknown and undocumented, in part because of a lack of exposures and the difficulty in developing subsurface stratigraphic landscapes. The relative synchroneity, extent, and number of erosion surfaces outside the Wisconsinan drift border suggest a subaerial response to shifts in climatic events occurring during and immediately following the withdrawal of the last glacial ice sheet.

Nacre as a proxy for water-temperature and hydrostatic-pressure

IAN C. OLSON[1], AND PUPA U. P. A. GILBERT[1*]
[1]Department of Physics, University of Wisconsin, Madison, WI 53706, USA. pupa@physics.wisc.edu (* presenting author)

Many proxies of chemistry, temperature, salinity and pH are based on chemical measurement of mollusk shells, including elemental ratios, and isotopic ratios. These are chemical proxies. Here we present the first evidence of a structural proxy: mollusk shell nacre, or mother-of-pearl, and specifically the angle spread and thickness of aragonite ($CaCO_3$) tablets in modern nacre.

With 20-nm resolution, Polarization-dependent Imaging Contrast (PIC)-mapping [1-4] displays in grayscale the orientation of the aragonite crystal axes in mollusk shell nacre, and it also shows the tablet layer thickness (Fig. 1). Both parameters are species-specific [5]. Furthermore, we found a strong correlation between nacre crystal mis-orientations and environmental temperature, and between nacre tablet thickness and hydrostatic pressure [5]. These observations have far-reaching implications: Nacre tablet thickness may provide insight into the depth at which extinct mollusk species lived, whereas crystal orientations may be used as a paleothermometer of ancient climate, spanning 450 Myr of Earth history.

Thus far we only tested the "nacre as a proxy" hypothesis on modern nacre. Once validated on fossil nacre, e.g. from ammonites, this hypothesis will be put to a test.

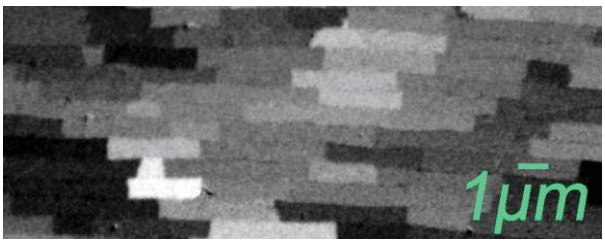

Figure 1: Polarization-dependent Imaging Contrast (PIC) maps of nacre from the fresh-water mussel shell of *Lasmigona complanata*. Different aragonite tablet crystal orientations are shown as different gray levels.

Dissolved elements released by the Grímsvötn volcanic ash, 2011

J. OLSSON[1,2*], S.L.S.STIPP[1], AND S.R.GISLASON[2]
[1]Nano-Science Center, Chemistry Department, University of Copenhagen, Denmark, jolsson@nano.ku.dk, stipp@nano.ku.dk
[2]Nordic Volcanological Centre, Institute of Earth Sciences, University of Iceland, Iceland, sigrg@raunvis.hi.is

During the evening of the 21st of May, 2011, the Grímsvötn volcano, located in southeast Iceland, began its strongest eruption in more than 100 years. The ash plume rose to 20 km and spread over Europe and the North Atlantic. The total amount of ash released was estimated by the Icelandic Meteorological Office to be more than 120 million tons and over 90% of it was released during the first 24 hours [1]. The purpose of this study was to measure the release rate of various elements during ash-water interaction and to assess the environmental impacts of the Grímsvötn ash.

Magmatic gases condense onto the surface of ash particles during a volcanic eruption. As the particles react with air and water vapour, the condensed gases form sulphuric and halogen acids and the ash surfaces dissolve [2]. The acid leaches cations from the bulk ash and secondary minerals can precipitate as a thin coating [3]. This material can be highly soluble in water, leading to rapid dispersal of possible harmful elements and/or nutrients into the enviroment when the ash comes into contact with rain or surface waters [e.g. 4].

In the present study, nanopure water (pH 5.9) was pumped through Teflon columns filled with ash of known surface area to monitor change in pH and the release of 70 elements, as a function of time. Initially, release rates were dominated by dissolution of surface salts, then after hours or days, by dissolution of the bulk volcanic ash. Within the first 10 minutes, the concentrations of most measured elements decreased by more than an order of magnitude, including some rare earth elements. Initially, S, Na, Ca, Mg and Cl dominated in the leachate, but after 12 hours, the most abundant element released was Si. The first water exiting the ash filled column had a pH of 7.3 and the pH gradually increased until it reached 9.7 at about 160 minutes. Over the next 4 weeks, pH slowly decreased to 6.5. The total release (mol/g ash) was determined for all harmful elements and compared with the World Health Organization (WHO) guidelines for safe drinking water [5]. The amount of Grímsvötn ash needed per litre of water, to exceed the WHO threshold values for As, Cd, Cr, F, Hg, and Pb, is 3.9, 35, 2.1, 0.10, 720, and 3.0 kg ash/l, respectively. Measured nutrients were P, Fe, V, Mo, and NO_3.

Our study provides valuable information for assessing the environmental impact of ash from volcanic eruptions on vegetation, livestock, and people.

High Arctic perennial spring activity and associated minerals: their value to Mars analogue studies

CHRISTOPHER R. OMELON[1]*, WAYNE H. POLLARD[2], DALE T. ANDERSEN[3], MARCOS ZENTILLI[4]

[1]Department of Geological Sciences, The University of Texas at Austin, Austin, Texas, USA, omelon@jsg.utexas.edu (*presenting author)

[4]Department of Earth Sciences, Dalhousie University, Halifax, Nova Scotia, Canada, marcos.zentilli@dal.ca

Saline spring discharge in cold environments is of specific relevance to ongoing interest in the search for the presence of water on other planets such as Mars [1]. Inherent to this search is the goal of finding morphological or geochemical evidence that life once existed on these planets. To better understand what these biosignatures may look like, current work aims to understand both how life survives in analogous environments on Earth and how such life interacts with their surroundings to produce biosignatures that may be preserved over geologic timescales.

Saline perennial springs in the Canadian high Arctic are a unique target for such studies. The brines emerge from the subsurface at constant temperatures and flow rates despite extremes in seasonal climate conditions. Mineral precipitates associated with spring discharge include carbonates, sulfates, and chlorides, however the majority of mineral growth occurs during winter months when cold temperatures drive freezing fractionation of salts within the waters to produce large amounts of ice and ice-rich minerals including ikaite ($CaCO_3 \cdot 6H_2O$), mirabilite ($Na_2SO_4 \cdot 10H_2O$), and hydrohalite ($NaCl \cdot 2H_2O$). Halotolerant bacteria inhabit springs at several sites including Gypsum Hill Diapir, Colour Peak Diapir, and Wolf Diapir, but they are restricted to spring outlets where chemical energy such as sulfide and methane are present and temperatures remain near 0˚C. In contrast, it is hypothesized that a lack of energy source coupled with extremely high meaured salinities in waters emanating from Stolz Diapir limits microbial colonization of this habitat.

Examination of mineral precipitates from these sites by microscopy and synchrotron radiation show variations in mineralogies due to differences in source water geochemistry. There is scant evidence of microbial colonization of mineral surfaces or creation of biosignatures at Gypsum Hill and Wolf Diapirs due to low accumulations of mineral precipitates or the souble nature of minerals at near-freezing temperatures. At Colour Peak, however, bacterial sulfate reduction in the deep subsurface is recorded in carbonate precipitates as interbedded FeS_2 laminations, which may be distantly comparable to mineral precipitation associated with a nearby inactive fossil spring adjacent to the White Glacier that formed ancient deposits. Independent data suggests the fossil spring may have been active for several million years and involved warm brines originating at depth, a habitat that could have provided restricted ecological niches for microbial evolution.

Lead Incorporation within Biological Apatite May Occur through a Polyphosphte Precursor

SIDNEY OMELON*[1]

[1]University of Ottawa, Toronto, Canada, somelon@uottawa.ca (* presenting author)

Introduction

Elevated levels of lead in seawater close to a lead and zinc mine in Greenland has been positivly correlated to lead levels in seaweed, mussels, prawns, and in the liver and bone of wolf-fish and sculpin [1]. Although environmental lead is known to report to bone, the pathway between lead injection and transport to bone mineral has not been elucidated. A new bone mineral nucleation theory suggests that a precursor to biological apatite is calcium polyphosphate. Polyphosphate chelates strongly to calcium, and other divalent cations such as lead [2]. It is possible that polyphosphate chelation to lead could be one of many biological strategies to immobilize lead and prevent it from reacting with other species. A lead-calcium-polyphosphate complex could also be a precursor to biological apatite.

Alkaline phosphatase has been associated with apatite biomineralization [3]; tissue-nonspecific alkaline phosphatase was shown to break down polyphosphate ions into orthophosphate ions [4]. It is proposed that breaking down a calcium polyphosphate complex into orthophosphates increases the apatite saturation and allows for apatite nucleation.

To determine if a lead-calcium-polyphospahte complex could be transformed into biological apatite containing lead, calcium-lead complexes were formed in neutral pH solutions, and exposed to alkaline phosphatase under basic pH conditions.

Figure 1 shows the powder x-ray diffraction of the reaction products.

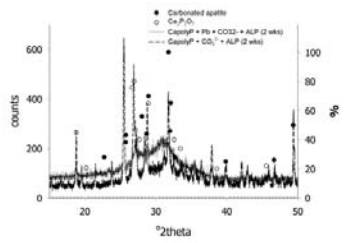

Figure 1: Powder x-ray diffraction of the products of exposing calcium- or lead-calcium polyphosphate to alkaline phosphatase for 2 weeks at 37 °C.

Results and Conclusion

Crystalline materials that have not yet been identified are the product of these in vitro experiments, however, this demonstrates that lead-calcium polyphosphate is a substrate for alkaline phosphatase. With further work on the experimental conditions, lead might be incorporated into biological apatite formed from the degradation products of lead, calcium, and polyphosphate.

Millions of people globally are exposed to groundwaters that exceed the World Health Organization (WHO) safe guideline value of 10 ppb (or 0.13 μM) for arsenic in groundwater [1-3]. In this study we used microcosms containing sediment from an aquifer in Cambodia with naturally elevated levels of arsenic (As) in the associated groundwater to evaluate the effectiveness of microbially-mediated production of iron minerals for *in situ* As remediation. The microcosms were initially incubated without amendments to allow the microbial release of As, and other geogenic chemicals from the sediments into the aqueous phase. Following this period, either nitrate, or a mixture of sulfate and lactate were then added to stimulate biological Fe(II) oxidation and sulfate reduction, respectively.

Without treatment, soluble As concentrations in the microcosms reached 3.9 (±0.9) μM at the end of the 143 day experiment. However, As levels had decreased to 0.01 and 0.41(±0.13) μM in the nitrate, and in the sulfate with lactate treated microcosms, respectively by the end of the experiment. Analyses using a range of biogeochemical and mineralogical tools, indicated that sorption onto freshly formed hydrous ferric oxide (HFO) and ferrous iron monosulfide (FeS) are the likely mechanisms for As removal in the respective treatments. Incorporation of the experimental results into a one-dimensional transport-reaction model suggests that, under conditions representative of the Cambodian aquifer, the *in situ* precipitation of HFO would be effective in bringing groundwaters into compliance with the World Health Organization (WHO) safe water limit for As, although soluble Mn release accompanying biogenic HFO generation presents a potential health concern. In contrast, production of biogenic iron sulfide minerals would not remediate the groundwater As concentration below the recommended WHO limit.

Geochemical and isotopic characteristics of Earth's early mafic crust: a comparison between Nuvvuagittuq and Isua greenstone belt metavolcanic rocks

J. O'NEIL[1*], H. RIZO[1], M. BOYET[1], R.W. CARLSON[2] AND M. ROSING[3]

[1] Laboratoire Magmas et Volcans, Clermont-Ferrand, France (*J.Oneil@opgc.univ-bpclermont.fr)
[2] Carnegie Institution of Washington, Washington DC, USA
[3] University of Copenhagen, Copenhagen, Denmark

Investigation of Earth's primitive crust largely has focused on felsic rocks because they are the most likely host rocks of zircons, providing robust geochronological constraints. However, these felsic rocks cannot be directly produced from melting of the mantle but instead originate by melting of an older mafic precursor. Despite the scarcity of preserved early mafic crusts, the Isua and Nuvvuagittuq greenstone belts are dominated by basaltic metavolcanic rocks. The Isua greenstone belt includes geochemically distinct subterranes dominated by tholeiites and boninite-like rocks (Garbenschiefer) interpreted to have been produced in an arc setting. Similarly, the Nuvvuagittuq belt is mainly composed of a succession of tholeiitic, boninitic and calc-alkaline rocks (Ujaraaluk unit) also sharing geochemical characteristics with suprasubduction related rocks. Both greenstone belts comprise rocks with ^{142}Nd anomalies compared to modern terrestrial Nd. Because ^{142}Nd anomalies can only be produced while ^{146}Sm decay was active, i.e. before 4 Ga, both suites of rocks acquired their ^{142}Nd isotopic composition in the Hadean. The Isua metavolcanic rocks were formed between 3.7-3.8 Ga. Therefore, their elevated ^{142}Nd isotopic composition is consistent with their Eoarchean derivation from an incompatible-element depleted Hadean mantle source. Consequently, they show no correlation between their ^{142}Nd/^{144}Nd and Sm/Nd ratios. However, the Nuvvuagittuq mafic rocks display a positive correlation between their ^{142}Nd/^{144}Nd and Sm/Nd ratios consistent with them being formed in the Hadean, between 4.3 and 4.4 Ga, from a "normal" depleted mantle. The Nuvvuagittuq rocks with the strongest arc-like signature have larger ^{142}Nd anomalies compared to the tholeiitic rocks. However, most Isua mafic rocks analyzed so far for their ^{142}Nd isotopic composition are tholeiites. Here we present a ^{146,147}Sm-^{142,143}Nd isotopic study of the Garbenschiefer which has the strongest arc-like signature in the Isua greenstone belt, allowing comparisons between the different groups of Isua mafic rocks. The studied set of Garbenschiefer rocks covers a relatively wide range of ^{147}Sm/^{144}Nd ratios (0.1650–0.2610) and preliminary analyses suggest that they also yield ^{142}Nd anomalies. The Isua and Nuvvuagittuq greenstone belts represent the oldest preserved mantle-derived suites of rocks and despite the fact that they were most likely formed ~500 million years apart, they share striking geochemical similarities. A geochemical and isotopic comparison between these greenstone belts will allow us to better understand the evolution of Earth's early crust through time and the geological processes responsible for its formation.

Pressure effects on sulfur mass-independent fractionation during SO_2 photolysis and its implication to the Archean atmospheric chemistry

SHUHEI ONO[1*] AND ANDREW WHITEHILL[2]

[1]Massachusetts Institute of Technology, Cambridge MA, USA, sono@mit.edu (*presenting author)

[2]Massachusetts Institute of Technology, Cambridge MA, USA, arwhite@mit.edu

Large $\Delta^{33}S$ values are measured in pyrite sulfur in rocks deposited before 3.2 Ga and between 2.7 Ga and 2.4 Ga, whereas those between 3.2 and 2.7 Ga yield relatively small $\Delta^{33}S$ values [1,2]. This apparent structure in the Archean $\Delta^{33}S$ signal may reflect changes in the atmospheric chemistry such as an incipient, transient rise of oxygen before the great oxidation event (i.e., *whiff of oxygen*) [1,3], the formation of organic haze aerosols [4], or a change in the redox state of volcanic gases [5].

In order to test various hypotheses, we performed laboratory SO_2 photolysis experiments using a flow through photochemical reactor with a Xe arc lamp as the light source. We will report the results of experiments to test the effect of pSO_2 and pN_2 on the pattern of multiple sulfur isotope fractionation. A new experimental system allows us to experiment at lower pSO_2 (i.e., low SO_2 column density) than using static photochemical cells. The results show that the $\delta^{34}S$, $\Delta^{33}S$ and $\Delta^{36}S$ signatures of the elemetnal sulfur product are a strong function of the SO_2 pressure under the tested range of pSO_2 (0.1 mbar and above), decreasing with decreasing pSO_2. The effect of bath gas pressure was also tested between 250 and 1000 mbar. The results of these experiments suggest that the change in the S-MIF pattern can be linked to the volcanic SO_2 loading in the atmosphere. The implications of this model will be discussed in the context of the early evolution of oxygenic photosynthesis and the resulting effect on the chemistry of the early atmosphere.

Trace-element control on near IR transmittance of pyrite

M. ORTELLI [1*], K. KOUZMANOV[1], N. UBRIG[2]

[1] Earth and Environmental Sciences, University of Geneva, Switzerland (*correspondence: melissa.ortelli@unige.ch)

[2] Département de Physique de la Matière Condensée (DPMC), University of Geneva, Switzerland

Pyrite, which commonly occurs intergrown with economic ore minerals in a variety of hydrothermal deposits, can be transparent to near-infrared (NIR) light and has been therefore studied by NIR microscopy to observe internal features, such as growth zoning or fluid inclusions. The main limitation of the NIR petrography and microthermometric studies on pyrite is the transmittance of the mineral, which depends on its trace element content, the thickness and the crystallographic orientation of the section used [1].

In this study, we investigate growth zoning in pyrites from two different localities: i) the Toromocho porphyry Cu-Mo deposit, Peru, and ii) the Butte district, USA, by NIR microscopy, electron microprobe (EMP) analysis and FTIR spectroscopy to quantify the effect of minor and trace element substitutions on the NIR light transmittance of the mineral.

Pyrite samples from Toromocho exhibit growth zoning pattern controlled by trace amounts of Co and As. Both elements were often below the detection limit of the EMP, 75 and 470 ppm, respectively. However, As reaches 0.49 wt.% in IR-opaque growth bands (no transmittance detected by FTIR spectroscopy from 0.7 to 5 μm), while the presence of Co was revealed by FTIR transmitted spectrum with its characteristic IR absorption peak at 2 μm [2]. In pyrite samples from the Leonard Mine at Butte, oscillatory growth and sector zoning, observed in NIR light, is controlled by a high Cu content, reaching up to 2500 ppm in some growth bands (Figure 1).

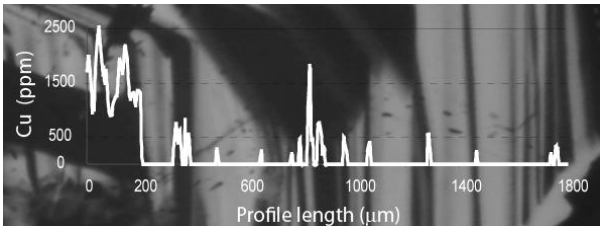

Figure 1 : IR transmitted-light photomicrograph of pyrite (Butte district) superposed to the electron microprobe line scan for Cu. The profile is 1800 μm long and is located along the X-axis.

Trace concentrations of As, Co and Cu decrease significantly the infrared transmittance in pyrite, which is the main limitation for a successful fluid inclusion study. Often trace element content is at the ppm level, thus requiring the use of more sensitive analytical technique, such as LA-ICP-MS, to correctly quantify trace amounts of these elements in the pyrite structure. Correlation between trace element content and quantitative FTIR transmittance spectroscopy allows preselection of samples potentially suitable for fluid inclusion studies.

Structure and dynamics of ions and water at mineral-water interfaces: Insights from experimental and computational studies

The dynamic behaviour of water within nanometres of the solid interface and or under confinement has particularly interesting properties. One among many interests lies in the various geochemical applications [1]. Here, we present Atomic Force Microscope (AFM) force spectroscopy experiments which simultaneously capture the normal (structural) forces and lateral (viscous) forces as a function of tip-sample distance. To link the lateral force and interfacial viscosity, we modify the definition of Newtonian viscosity. When two plates are separated by d, the shear force required to slide one plate parallel to is proportional to the gradient of the fluid velocity, v_x, in the direction perpendicular to the plates.

$$F_L/A = \eta\,(\mathrm{d}v_x/\mathrm{d}z) \qquad (1)$$

The proportionality factor, η, is the viscosity of the liquid and A is the area of the shear. With substitution, we can relate the viscosity on a wetting surface Fig. 1(a), to that of a non-wetting surface, Fig. 1(b) to solve for the slip length, b [2]

$$\eta_{eff} = \eta^{b=0}\, v_{shear}/(d + b) \qquad (2)$$

Where $\eta^{b=0}$ is the interfacial viscosity of water, measured on a surface with zero slippage, and η_{eff} is the interfacial viscosity of water on a surface with slippage. This suggests the boundary viscosity of water strongly depends on the wetting properties of the surface.

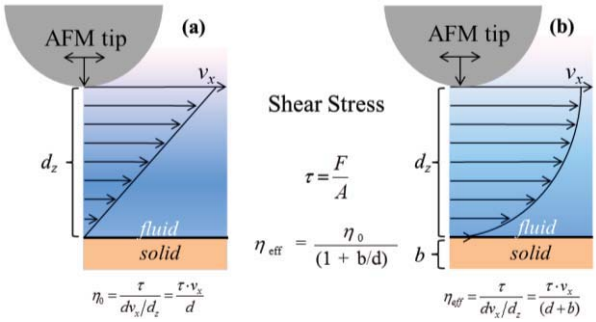

Figure 1. **Schematic of slip length from a shearing an AFM tip.** The wetting case is conveyed in (a) and non-wetting in (b).

We investigated the boundary viscosity and slip length as a function of gap size for mineral, crystalline and other carbon and carbon like surfaces. The slip length values will be discussed relative to surface properties, as well as surface wettability (contact angle), and viscosity.

The Pliocene closure of the Central American Seaway: reconstructing surface-, intermediate- and deep-water connections.

A. H. OSBORNE[1*], M. FRANK[1], R. TIEDEMANN[2]

[1]GEOMAR | Helmholtz-Zentrum für Ozeanforschung Kiel, Germany, aosborne@geomar.de (* presenting author)
[2]AWI, Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany.

Timing of Gateway Closure

The shoaling of the Isthmus of Panama and the associated reorganisation of deep-ocean circulation have been controversially reported as contributing to both a warming and a cooling of global climate. A resulting increase in moisture supply to the northern hemisphere, through the initiation or strengthening of the Gulf Stream, may have been an important precondition for Northern Hemisphere Glaciation. A robust timeframe for the closure of this major ocean gateway is essential for understanding its direct and indirect effects on global climate.

Method

We use radiogenic isotopes of Nd and Pb to reconstruct the history of shallow, intermediate and deep water connections between the Caribbean Sea and the eastern Equatorial Pacific Ocean from 5.0 to 2.0 million years ago. Surface water exchange is characterised using the Nd isotope composition of planktonic foraminiferal calcite. The Nd and Pb isotope compositions of early diagenetic ferromanganese coatings of the same sediment samples are employed to reconstruct intermediate and deep water exchange.

Results and Conclusion

Our results indicate that Caribbean Intermediate Water continued to diverge from a relatively constant Pacific deepwater Nd composition from 5.0 to 2.0 Ma. Comparison with published stable isotope and Mg/Ca records from the same ODP Sites 999, 1000 and 1241 suggest that Caribbean Intermediate Water composition continued to change even after a decrease in surface water exchange with the Pacific (4.5 Ma onwards [1]). A more rapid restriction of mixing between the Pacific and Caribbean at intermediate depths from 4 to 3.5 Ma clearly preceeded the major increase in ice-rafted-debris north of Iceland [2].

Reduction of jarosite by *Shewanella oneidensis* MR-1 and its geochemical implication

BINGJIE OUYANG[1]*, XIANCAI LU[1], HUAN LIU[1], JIANJUN LU[1], JUAN LI[1], RUCHENG WANG[1]

[1] Nanjing University, School of Earth Sciences and Engineering, jessicaoy89@gmail.com (* presenting author)

Jarosite is a common mineral in acidic, sulfate-rich environments formed by the oxidation of sulfide in mining area. Decomposition of jarosite by dissimilatory iron reducing bacteria (DIRB) under acidic conditions has been well proved previously [1], and this process influences the mobility of many heavy metals accommodated in jarosite. However, the effects of DIRB on the stability of jarosite under neutral pH conditions have been seldom studied. This study aims to evaluate these effects, and provide a more comprehensive understanding of the geochemical mechanism.

Jarosite was synthesized by microbial oxidation of ferrous ion at 30 °C. The used bacteria strain was Shewanella oneidensis MR-1. We designed a series of batch experiments to study the microbial reduction process of jarosite under anaerobic, aerobic, and no inoculation conditions for 20 days. Lactate was added to the solution as electron donor for MR-1. Temporal evolution of Fe(II) and total dissolved Fe in solution was monitored everyday by using o-phenanthroline method. The concentrations of sulfate, lactate and acetate were determined by ion chromatography (IC). The content of K+ was examined by inductively coupled plasma optical emission spectrometer (ICP-OES). The compositions of the secondary minerals were analyzed by X-ray diffraction and scanning electron microscopy coupled with energy dispersive spectrometer. Diffuse reflection spectroscopy was employed to investigate the component of Fe-bearing minerals. Transformations of jarosite in 40 days and 80 days were also investigated to confirm the reduction process.

Results and conclusions

Our results indicate that jarosite can be reduced by MR-1 under anaerobic condition, and secondary mineralization accompanies the reduction process. Increases in Fe(II), K+, sulfate and acetate concentrations, and a decrease in lactate were observed for the biotic experiment. The release rate of Fe(II) was constant in the beginning period. Microscopic results demonstrated bacterial attachment to the surface of jarosite, which can be regarded as evidence of bacterial absorption. The formation of new minerals as goethite and some green rust was identified. Compared to anaerobic treatment, the concentrations of Fe(II), K+, and sulfate in aerobic treatment and no inoculation treatment were undetectable at first, and tremendously lower than anaerobic treatment after 40 days of reaction. However, reduction of jarosite in aerobic treatment and no inoculation treatment was severely limited, and secondary minerals were either not produced or undetectable.

Dating zircons from volcanic ash beds in sedimentary successions: magmatic crystallization vs. ash deposition

M. OVTCHAROVA[1*], U. SCHALTEGGER[1], N. GOUDEMAND[2], AND H. BUCHER[2]

[1]Earth and Environmental Sciences, University of Geneva, Switzerland, maria.ovtcharova@unige.ch (*presenting author)
[2]Institute and Museum of Paleontology, Zurich, Switzerland

Detailed calibration of the Late-Middle Triassic time-scale requires precise and accurate age determinations from volcanic ash beds within biostratigraphically well dated marine sedimentary sections. High precision CA-ID-TIMS U-Pb zircon dates of volcanic ash beds have been used to quantify and calibrate the stratigraphic column across the Early-Middle Triassic boundary in South China. Despite an optimal control on the continuity of the stratigraphic record and on the accuracy of analytical procedures, some single ash-beds from the Monggan Wantuo section (Luolou Fm., NW Guangxi, S. China) yield ages that are too old and contradict the stratigraphic succession. How can we improve the confidence in the interpretation of zircon dates as proxies for the age of deposition of these ash beds?

We dated 15 samples of ash beds (four thereof with signs of sedimentary reworking) within the 15m Wantuo Mongan section, applying CA-ID-TIMS techniques on a number of single grains for each sample. In 13 out of 15 ash beds zircon dates are following the stratigraphic succession within analytical uncertainty (from the late Early Triassic Luolou Formation – 248.08 ± 0.12 Ma to the Middle Anisian Transition Beds – 246.43 ± 0.17 Ma). The zircons from two intermediate volcanic ash beds within the Transition Beds at the Early/Middle Anisian boundary yield well clustering $^{206}Pb/^{238}U$ dates at 247.10 ± 0.15 and 247.35 ± 0.11 Ma, clearly indicating that the zircons in this magma batch were crystallizing over a long period of time or remobilized from deeper levels within the same magmatic system. The problem of recurrent zircon dates in a sedimentary succession is common and can only be discovered by sufficiently dense sampling and a sufficient number of data for each ash bed.

We have to keep in mind that for the correct interpretation of dates in stratigraphic sections interlayered with fossil-bearing rocks we need: i) at least one single well preserved stratigraphic section with sufficient absolute or relative chronological control (biochronology, chemostratigraphy, astrochronology) to guarantee that the stratigraphic succession is accurately known; ii) volcanic ash beds that are as much undisturbed as possible (no volcaniclastic material, no sedimentary reworking); iii) sufficient sample and data density to be able to distinguish between magmatic and sedimentary signals coded in the crystallization ages of zircon.

Enhanced delivery of bioavailable Fe through glacial processes in Kongsfjorden, Svalbard

JEREMY D. OWENS[1*], LAURA M. WEHRMANN[1], ROBERT RAISWELL[2] AND TIMOTHY W. LYONS[1]

[1]University of California- Riverside, Riverside, CA, USA, jowens@student.ucr.edu, laura.wehrmann@ucr.edu, timothyl@ucr.edu (* presenting author)

[2]Leeds University, Leeds, UK, r.raiswell@earth.leeds.ac.uk

Primary production in large portions of the world's ocean is iron-limited, and the supply of bioavailable iron is not well understood. Only recently have glacially derived iron sources been considered a potential major contributor, particularly to high latitude regions. Past workers considered glacial iron to be non-bioavailable or non-reactive more generally. However, we now know that increased delivery of reactive iron to the ocean, as driven by enhanced glacial runoff, has the capacity to increase primary production and concomitant CO_2 uptake. Understanding the role of glaciers in the delivery of bioavailable iron to the ocean has become a priority, and the concentration and reactivity of glacial iron is likely controlled by chemical weathering processes tied to pyrite oxidation and bedrock type within the subglacial environment.

To better understand the factors controlling the delivery of bioavailable iron to glacial fjord environments, we sampled three proglacial streams in the Kongsfjorden region of Svalbard. The streams differed dramatically in the characters of their adjacent glaciers, in their suspended loads and the local bedrock. We quantified the amount of dissolved iron in the glacial meltwaters, determined the reactivity of the iron associated with the fine glacial flour of the streams, and constrained the iron properties of the source bedrock. Here, we present iron data (Fe_{Total}/Al and $Fe_{Highly\ Reactive}/Fe_{Total}$) from each sample type, along with riverine sulfate and bedrock sulfide isotope data ($\delta^{34}S$). The average dissolved iron concentrations varied from glacier to glacier between 4 ppb and 13 ppb, which is only 2 to 3 times higher than in seawater. However, highly reactive iron was enriched in the glacial flour samples at highly variable levels. The overarching suggestion is that the Kongsfjorden glacial systems could deposit large amounts of reactive iron into the fjords via the discharge of glacial flour. The three sampled meltwater streams have comparable and relatively stable pH (~8) coupled with $\delta^{34}S$ values of dissolved sulfate near +10‰, suggesting that the iron is from a source other than just pyrite oxidation. These initial data and specifically the observed variability indicate that bedrock type and other still unknown variables affecting diverse glacial processes control the delivery of bioavailable iron to the ocean in high latitude regions.

Modeling ocean acidification and de-oxygenation: Testing the linkage between large igneous province and Ocean Anoxic Event.

KAZUMI OZAKI [1*], EIICHI TAJIKA[2]

[1]University of Tokyo, Earth and Planetary Science, Tokyo, Japan, ozaki@eps.s.u-tokyo.ac.jp (* presenting author)

[2]University of Tokyo, Complexity Science and Engineering, Chiba-ken, Japan, tajika@k.u-tokyo.ac.jp

Recent geochemical data and chronology enable us to explore biogeochemical dynamics in geological past. The causal linkage between ocean anoxic events and activity of large igeneous provinces has been discussed based on the geochemical imformation, such as the rapid disturbances of osmium isotopic records or metal abundance anomalies before and during ocean anoxic events. It has been discussed that the abundance of nannoconid is rapidly decreased at the initiation of OAE1a, implying the oceanic acidification in sea surface environment. Considering the compensation mechanism of oceanic carbonate system, this must indicate drastic disturbances of Earth's surface environment.

We developed a new atmosphere-ocean biogeochemical cycle model in order to explore the biogeochemical consequences of the activity of large igneous province, and a systematic model sensitivity study is performed with respect to an injection scenario of CO_2 into the terrestrial environment. Examined characteristic timescale of the CO_2 injecation scenarios ranges from 100 year to several hundreds of thoushands of years and the total amount of injection ranges in three orders of magnitudes (0.01-10 EmolC).

Systematic examination shows that (1) the required CO_2 amount for the maximum carbon isotopic anomaly of +1 to 4 permil is approximately from 0.4 to 1.0 Emol (10^{18} mol), providing the theoretical requirements for the carbon isotopic anomaly accompanied with OAE2, and (2) such scenarios result in the global ocean de-oxygenation of approximately 40-80 % (depending on the degassing flux). Our simulation results also indicate that the rapid (less than 10 kyr) and drastic (greater than 100 TmolC/yr) CO_2 injection would be required to explain the strong acidification of sea surface waters and widespread carbonate gap. We conclude that the many characteristic features of OAEs can be explained by the short, rapid and frequent activity of large igneous province.

In-situ U-Pb dating of baddeleyite in Shergotty and a chassignite: Implications for Martian chronology

SHIN OZAWA[1*], TREVOR R. IRELAND[2], AHMED EL GORESY[3], EIJI OHTANI[1], MASAAKI MIYAHARA[1], AND YOSHINORI ITO[1].

[1] TohokuUniversity, Department of Earth Science, Sendai, Japan, shin.ozawa@s.tohoku.ac.jp (* presenting author)

[3] Universität Bayreuth, Bayerisches Geoinstitut, Bayreuth, Germany, ahmed.elgoresy@uni-bayreuth.de

Introduction

There is a long-standing debate on the crystallization ages of SNC meteorites, which are considered to be of Martian origin. As to shergottites, young ages of 165–475 Ma have been reported using various radiometric methods [1]. However, Bouvier et al. (2005, 2008) [2, 3] reported old Pb-Pb ages (~4.1 Ga) for basaltic shergottites Shergotty and Zagami, as well as young Rb-Sr, Sm-Nd and Lu-Hf ages (150–180 Ma) for the same meteorites. They concluded that the old ages are their crystallization ages, and the young ages correspond to the timing of shock metamorphism or aqueous alteration. Two different ages were reported for the chassignite NWA 2737. Misawa et al. (2005) [4] reported a whole rock Sm-Nd age of NWA 2737 chassignite as ~1.4 Ga, while Bogard et al. (2008) [5] obtained an ^{40}Ar-^{39}Ar age of 160–190 Ma for the same meteorite. We conducted *in-situ* U-Pb dating of baddeleyite (ZrO_2) in these meteorites using SHRIMP-II and -RG in order to clarify the crystallization ages of Shergotty and NWA 2737 chassignite.

Results and Discussions

We found seven baddeleyite in Shergotty and one baddeleyite in NWA 2737, which can be used for SHRIMP analyses. Before SHRIMP analyses, each baddeleyite was carefully characterized by using FE-SEM, micro-Raman spectrometry and EPMA. The size of the baddeleyite grains range from 3×5 μm to 11×24μm. Baddeleyite usually occurs with ilmenite, titanomagnetite and pyrrhotite.

SHRIMP U-Pb measurements of the seven baddeleyite in Shergotty revealed three clusters of data points on the Concordia diagram, corresponding to ages of ~230, ~400 and older than 3000 Ma, respectively. This result could indicate an old crystallization age of this rock (in excess of 3000 Ma) and recent partial age resetting due to shock-induced melting.

Three U-Pb measurements on the one baddeleyite in NWA 2737 chassignite revealed a U-Pb age of 1640 ± 70 Ma. This is consistent with, but slightly older, than the Sm-Nd age of 1420 ± 70 Ma reported by [4]. It suggests that NWA 2737 chassignite crystallized at 1.4–1.6 Ga and experienced a thermal event, probably by impact, at 160–190 Ma.

For a better understanding of the origin and history of these baddeleyite, FIB-TEM studies are in progress.

Combining U and Sr isotope tracers to evaluate water sources and mixing relations in freshwater and estuarine wetlands

J.B. PACES[1*], J.Z. DREXLER[2], F. WURSTER[3], L.A. NEYMARK[1]

[1]U.S. Geological Survey, Denver, CO, USA, jbpaces@usgs.gov (*presenting author), lneymark@usgs.gov
[2] U.S. Geological Survey, Sacramento, CA, USA, jdrexler@usgs.gov
[3]U.S. Fish & Wildlife Service, Suffolk, VA, fred_wurster@fws.gov

Understanding wetland water supplies is important for managing these resources and determining habitat impacts due to climate change or other anthropogenic activities. However, identifying multiple sources and contributions is often difficult due to complex hydrologic, biologic, and chemical processes. Combined $\delta^{87}Sr$ and $^{234}U/^{238}U$ data from wetlands in NV and CA identified 3-component mixing patterns that were not easily recognized by other chemical approaches. Isotopes of Sr and U are particularly useful because they are relatively abundant, can be analyzed with high precision, may have large differences between sources, and remain unchanged by geochemical processes such as evaporation and mineral precipitation or biological fractionation. Mixing models form distorted triangular nets that bound the data and allow contributions from each source to be estimated.

Sources of water in wetlands on the Pahranagat National Wildlife Refuge (PNWR), NV consist of surface flow from high-volume springs from the regional carbonate aquifer and groundwater from local volcanic aquifers. Major ions and H-O-S isotopes are affected by evapotranspiration, mineral precipitation, and sulfate reduction. However, $\delta^{87}Sr$ and $^{234}U/^{238}U$ are unaffected and indicate a 70:20:10 mixture for the irrigation source and a range of mixtures depending on location and water management practices (fig. 1A).

Variations in river water and tidal influence in the Sacramento-San Joaquin Delta, CA, over the last 6,000 years were recorded by $\delta^{87}Sr$ and $^{234}U/^{238}U$ in peat cores. Plants take up substantial dissolved Sr during growth, whereas redox reactions at the peat-water interface causes immobilization of U dissolved in the water column. Analyses of peat cores show coherent changes in space and time, reflecting evolving mixtures of fluvial and seawater sources (fig. 1B). Contributions from hydraulic mine sediment with $\delta^{87}Sr$ >0.0 and $^{234}U/^{238}U$ activities ~1.0 are also apparent in peat-poor samples deposited between 1850 and 1963.

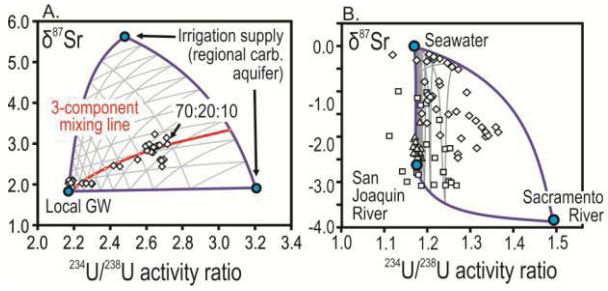

Figure 1: Three-component mixing models showing 10% intervals for water in the PNWR (A) and peat in the Sacramento-San Joaquin Delta (B).

Elucidating the complex thermal and fluid history of Austurhorn Intrusive Complex: zircon elemental and isotopic geochemistry

The Austurhorn Intrusive Complex (AIC), comprising large bodies of granophyre, gabbro, and a mafic-felsic composite zone, is Iceland's best-studied intrusion (Blake 1966; Furman et al 1992a,b; Thorarinsson & Tegner 2009). However, despite widespread recognition of the value of zircon as a tracer of history and evolution of its parental magma(s), zircon studies are notably lacking for the AIC and other Icelandic plutons. Here, we present the first detailed chronologic, elemental, and isotopic Icelandic plutonic zircon study.

The elemental compositions of AIC zircons generally form a broad but coherent array which, for the most part, overlaps with that of zircons from Icelandic silicic volcanic rocks (Carley et al 2011). With some exceptions (see below), Ti concentrations range from 6-25 ppm (Ti_{zirc} temperatures ~ 730-870°C), and Hf concentrations are low (<10,000 ppm, typical of Icelandic zircon). Epsilon-Hf values are constrained to +13±1, falling between ε_{Hf} for Icelandic basalts from rift and off-rift settings. Similarly, $\delta^{18}O$ values are generally well-constrained at +3 to +4‰, consistent with Icelandic magmatic zircon (Bindeman et al 2012) and suggesting contributions from hydrothermally-altered crust to the petrogenesis of the parental silicic magmas. Zircons from a high-silica granophyre are notable exceptions to the trends described above: a large portion fall well outside of the AIC elemental array, distinguished primarily by extreme Hf concentrations ranging upward to 24,000 ppm (far higher than other analyzed Icelandic zircon), along with generally higher U and Th and lower Ti (down to 2 ppm [~630°C], lowest for Iceland). Their $\delta^{18}O$ values range from "normal" (+4) to extremely low (-6‰). Most of the elementally and isotopically unusual analyses are from CL-dark zones that display convolute and/or irregular zoning. We interpret these zones to reflect hydrothermal crystallization or recrystallization.

Zircon U-Pb geochronology reveals that the AIC was constructed by two distinct major intrusive events, the first at 6.45±0.04 Ma (MSWD=1.3) and a second at 5.99±0.06 Ma (MSWD=1.17). Most ages in the older population are from silicic rocks, while most ages in the younger populations are from a dominantly mafic zone. We interpret the younger age to represent the intrusion of voluminous basalt, which partially reactivated and remobilized the host silicic material ~500k.y. after initial emplacement of the AIC.

Tracking the Parental Melt of Chromite Using Trace Elements from LA-ICP-MS: an Effective Tool for Chromite Provenance

PAGÉ, PHILIPPE[1]*, BARNES SARAH-JANE[1]

[1] Canada Research Chair in Magmatic Metallogeny, Université du Québec à Chicoutimi, Québec, Canada, G7H 2B1; (Philippe_Page@uqac.ca); (Sarah-Jane_Barnes@uqac.ca)

Chromite is one of the first phases to crystallize in ultramafic - mafic silicate melts, and can thus be used to study early magmatic processes in volcanic and plutonic environments. A better understanding of chromite crystallization is also of economic interest, since it constitutes the only source of primary Cr, and massive chromitites can host important Platinum-Group Element (PGE) concentrations (e.g. UG2, Bushveld Complex).

In our ongoing work, we are studying the composition of chromites, obtained by EMPA and LA-ICP-MS, to i) constrain it's role in the fractionation of certain elements (e.g. Os, Ir, Ru, Sc, Ga, Ni, Co, …) during early magmatic processes (i.e. fractionation of Ru by komatiitic chromite [2, 3]) and ii) investigate the nature of the parental melt involved in the formation of chromitite in both oceanic and continental settings. Using this approach, we have shown a clear similarity between the geochemical signature of chromite from ophiolitic podiform chromitites and chromite from the primitive boninites [1]. This study aims to constrain the nature of the primitive melt involved in the formation of the Stillwater Complex chromitites which have a distinctive geochemical signature compared to chromites from various primitive ultramafic - mafic melts (Fig. 1) suggesting that none of these primitive magmas are involved in their formation. Also, these dissimilarities between the geochemical signature of chromite from the various lavas and from the Stillwater Complex chromitites can be used to discriminate them from one another and thus be used as a provenance mineral.

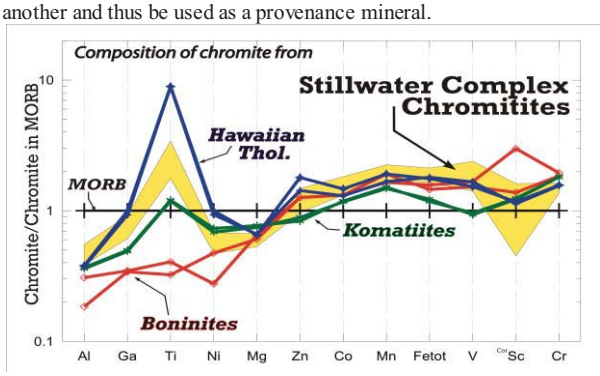

Figure 1: Composition of chromites from the Stillwater Complex chromitites compared to chromite from ultramafic-mafic volcanic rocks, including komatiite, boninite, and Hawaiian tholeiite, all of which have been normalised to the composition of the chromite from the MORB [1].

Neodymium isotopic composition of South Pacific bottom water

KATHARINA PAHNKE[1]*, CHANDRANATH BASAK[1] AND RAINER GERSONDE[2]

[1]Max Planck Research Group for Marine Isotope Geochemistry, Oldenburg, Germany (kpahnke@mpi-bremen.de)
[2]Alfred Wegener Institute, Bremerhaven, Germany

Neodymium isotope ratios in seawater are a useful tracer of water masses and marine biogeochemical processes, but our current knowledge of the distribution of Nd isotopes in the ocean is limited by the number of available data. Large areas, particularly in the Southern Ocean, remain unstudied. The international effort of the GEOTRACES program to map the global distributions of trace elements and isotopes in the ocean [1] is improving the basis for the use of Nd isotopes as tracers of present and past processes and changes.

Here we present water column and surface sediment Nd isotope ratios ($^{143}Nd/^{144}Nd$, expressed in ε_{Nd} notation) from the Pacific sector of the Southern Ocean collected during *R/V Polarstern* expedition ANTXXVI-2. Deep and bottom waters in the southwest Pacific within the Antarctic Circumpolar Current (ACC) have an isotopic composition of ε_{Nd} = -9, the characteristic isotope signature of the ACC in the South Pacific and Atlantic [2, 3]. At a station south of the ACC and just north of the Ross Sea (69°S), bottom waters with the temperature-salinity properties of Antarctic Bottom Water formed in the Ross Sea (RSBW), are more radiogenic (ε_{Nd} = -7). These values are consistent with the Nd isotopic composition of sediments and tills in the Ross Sea [4-6]), suggesting an imprint of the Ross Sea signal on RSBW.

We find similar ε_{Nd} values in the authigenic ferromanganese oxide fraction of surface sediments in the southeast Pacific at depths bathed by RSBW, suggesting the northward transport of the Ross Sea ε_{Nd} signal into the southeast Pacific. Our results show a clear contribution of Antarctic Nd sources on the isotopic composition of South Pacific bottom water and suggest that ε_{Nd} can be used to trace the northward flow of RSBW into the southeast Pacific.

Controls on the formation and crystallization of Mg^{2+}-Fe^{3+}-SO_4^{2-} type layered double hydroxides

SUSANTA PAIKARAY* AND M. JIM HENDRY

Department of Geological Sciences, University of Saskatchewan, Saskatoon, SK, S7N5E2 Canada
Email-sup394@mail.usask.ca

Introduction

Layered double hydroxides (LDH) can play an important role in remediation of hazardous contaminants. Hydrotalcite-like (HTlc) LDH, also known as anionic clays, can be precipitated from numerous divalent (M^{2+}) and trivalent (M^{3+}) cations along with interlayer anions (A^{n-}) where the nature, M^{2+}/M^{3+} ratio and concentation of ions, hydrothermal conditions, aqueous pH can strongly control their formation and crystallization and, as such, their applicability to act as sorbents, catalysts, pharmaceuticals, etc. This study address such aspects using geochemical, spectroscopic, microscopic and diffractogram techniques.

Materials and Methods

HTlc formation was monitored using the coprecipitation synthesis method [1] at ambient temperature and pressure conditions and by varying the pH (7-13), M^{2+}/M^{3+} ratio (0.5-2.5), cation addition rate (2-100 ml h^{-1}), and cation concentrations (0.1-1.0 M) at a constant M^{2+}/M^{3+} ratio (1.0), while assessing the degree of crystallinity over 30 days at three temperatures (22, 65 and 95 °C) and two drying temperatures (100 and 200 °C). The resultant solid phases were studied using X-ray diffraction, Raman and ATR-Infrared spectroscopy, and SEM and thermogravimetric analysis.

Results and Discussion

Formation of HTlc was favored at pH ≥ 9 and $M^{2+}/M^{3+} \geq 0.75$ with both CO_3^{2-} and SO_4^{2-} as interlayer anions. The latttice parameters c and a determined at pH 13 and M^{2+}/M^{3+}=2.5 was ~23.5 Å and ~3.1 Å, respectively. Although HTlc formation was not greatly influenced by the reagent addition rate and M^{2+}-M^{3+} concentrations, slow addition appeared to inhibit development of $d_{(110)}$ plane representing poor 'a' crystallographic development, while slow addition and lower M^{2+}-M^{3+} concentrations facilitated slightly better crystallization. This may be explained by better nucleation and the lack of availability of elevated concentrations of cations [2].

The degree of crystallinity was observed to increase after ageing for 30 days at room temperature (RT, 22±2 °C), increasing the hydrothermal temperature to 95 °C within 1 day and increasing the drying temperature to 200 °C. The crystallization started lowering after 5 days and 1 day at 65 and 95 °C hydrothermal treatment, respectively.

Conclusions

Preliminary observations suggest increasing pH, M^{2+}/M^{3+} ratio, low M^{2+}-M^{3+} concentrations, and a slow mixing rate facilitate HTlc formation and enhance its crystallinity. Although HTlc is likely to develop crystallinity at RT upon prolonged exposure, elevated hydrothermal temperatures may adversely impact its structure.

Boron contamination at the McIntyre tailings, Timmins, Ontario

CORY PALIEWICZ[1]*, MONA-LIZA C. SIRBESCU[1], EDMOND H. VAN HEES[2], AND THOMAS SULATYCKY[3]

[1]Central Michigan University, Earth and Atmospheric Sciences, Mt. Pleasant, MI, USA palie1cc@cmich.edu (* presenting author)
[2]Wayne State University, Dept. of Geology, Detroit, MI, USA
[3]Goldcorp Inc., Timmins, Ontario, Canada

Anomalous concentrations of soluble boron of uncertain origin occur in >40 year old mine tailings of the McIntyre-Hollinger mesothermal gold deposit. We seek to understand 1) the distribution and movement of B in the tailings and 2) sources of soluble B including: the wall-rock of the mineralization, the gangue minerals, and anthropogenic borax that might have been used to smelt the gold ore.

To explore the distribution of boron within an area of about 100,000 m^2, eight boreholes (e.g. H1) were drilled manually to a depth of ~9 m and sampled at ~0.15 or ~1 m intervals. The samples were leached with deionized water at a sediment:water ratio of 1:3 and the filtered leachate was analyzed by ion chromatography. Boron is distributed heterogeneously with depth and distance from the edge of the tailings dam (Fig. 1). Boron contents correlate positively with the ≤38 µm grain size fraction, indicating that absorbtion onto silt-clay particles and/or low permeability result in B build-up. Tailings near surface and at the margin of the dams are coarser and depleted in B. Ephemeral, efflorescent hydrous Mg-borate found along the dam edge is consistent with an outflow of B along paths of high permeability.

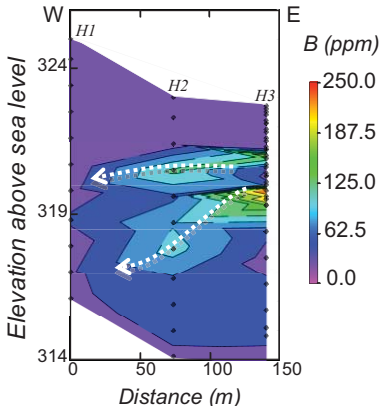

Figure 1: W-E cross-section of B (ppm) distribution and proposed discharge paths to edge of the dam ~20 m west of H1.

The unusual B contents in the McIntyre tailings might originate from altered basaltic wall-rock with B contents <3000 ppm. However, the erratic character of the anomaly suggests that the release of B from the disposal of crushed, borax-fluxed slag into the tailings is also possible. Fresh tourmaline in the tailings sediment and relatively soluble gangue minerals (anhydrite, calcite, siderite, etc.) with <6 ppm B (via laser ablation ICP-MS) cannot account for the amount of soluble B encountered.

Nature of fluids in the deep mantle (>300km) inferred from a carbon and nitrogen micro-analytical study of a single ultra-deep diamond from Kankan, Guinea

M. PALOT[1*], D.G PEARSON[1], R. STERN[1], T. STACHEL[1]

[1]Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Canada, palot@ualberta.ca (* presenting author).

The nature of the deep mantle, especially the transition-zone, is a topic of very broad interest to solid Earth geochemists and geophysicists. Data on actual samples from this region are extremely scarce. Diamonds are derived from the base of the lithosphere down to the lower mantle (>660km) and provide a unique opportunity to sample this region of critical rheological and chemical changes in the Earth. In order to evaluate the nature of fluids percolating through the transition zone, we present the first carbon and nitrogen isotope micro-analytical study of a deep-diamond (Kankan, Guinea) by Secondary Ion Mass Spectrometry (SIMS). This diamond contains a single $CaSiO_3$-walstromite inclusion, presumed to represent retrogressed former $CaSiO_3$-perovskite and hence indicative of an ultra-deep (lowermost transition zone to lower mantle) paragenesis. The large size of the diamond allows to investigate variability in the diamond growth medium along detailed traverses. Combined C-N isotope and N abundance measurements allow us, for the first time, to place strong constraints on the nature of the parental fluid for an ultra-deep diamond.

Carbon isotopic compositions show a small but systematic decrease of $\delta^{13}C$ values from the core to the rim of the diamond. $\delta^{15}N$ is negatively correlated with $\delta^{13}C$, whereas nitrogen abundances show a positive correlation. These co-variations in $\delta^{13}C$-$\delta^{15}N$-[N] are consistent with open system isotopic fractionation where the isotopic and elemental evolution of the fluid is related to diamond crystallisation. The speciation of carbon and nitrogen of the fluid precursor of this deep diamond may be constrained through modelling of these co-variations. Such modelling indicates diamond growth from a reduced, CH_4-bearing fluid, with nitrogen behaving compatibly. Due to uncertainities in $\delta^{15}N$, we cannot constrain whether nitrogen was present in the fluid phase as N_2 or the NH_4^+. Although the origin of the diamond forming fluid (subducted or mantle material) is still a matter of debate, these results have fundamental implications for the fO_2 in the deep mantle and the deep volatile cycle of the Earth.

A critical evaluation of TEX_{86} derived sea surface temperatures in the Paleogene

RICHARD D. PANCOST[1*], KYLE TAYLOR[1] AND CHRIS HOLLIS[2]

[1]Organic Geochemistry Unit, School of Chemistry, The Cabot Institute, University of Bristol, UK, r.d.pancost@bristol.ac.uk (* presenting author)

[2] GNS Science, Lower Hutt, New Zealand

The application of glycerol dialkyl glycerol tetraether (GDGT) based sea surface temperature proxies (e.g. TEX_{86}) has brought about major advances in our understanding of Cenozoic climate. However, TEX_{86} approaches yield very high temperatures at high latitudes during Paleogene hyperthermals, and the resulting low latitudinal temperature gradients challenge our understanding of the physical climate system. Here, we examine existing TEX_{86} data and revisit the modern calibration dataset. A comparison of TEX_{86} SST estimates to those derived from oxygen isotopes or Mg/Ca ratios of well preserved 'glassy' planktonic foraminifera reveals a strong correlation between foraminiferal and GDGT-based approaches, but the latter are 4-6°C warmer. We have also compared TEX_{86} SST estimates from shelf sea settings to associated continental mean air temperatures (MAT) derived from soil bacterial GDGTs (the MBT/CBT index). Again, the two approaches exhibit a strong correlation but with the former yielding 4-6°C warmer temperatures. Intriguingly, SSTs derived from the recently proposed TEX_{86}^L approach are lower and consistent with foraminifera-based approaches and MBT/CBT derived MATs.

We also developed SST records from multiple sites in the SW Pacific, in order to place hyperthermal SST estimates into a longer-term Paleogene context. Our estimates indicate that sea floor and sea surface temperatures increased by 10°C or more from late Paleocene (18 to 23°C) to early Eocene times (30-32°C). MBT/CBT-derived MATs broadly parallel the SST trends, but with 4-6°C lower values throughout the entire sequence. These records suggest that elevated high southern latitude SSTs are reproducible at multiple sites and do document the relative long-term Paleogene climate evolution recorded by benthic foraminifera and inferred from faunal and floral assemblages.

Combined, these two lines of evidence indicate that high latitude EECO temperatures were indeed significantly higher than those of today, but they also suggest that the specific estimates could be as much as 4-6°C too warm. There are multiple explanations for this, but one possibility is an oceanographic and/or ecological control on the GDGT assemblages exported to sediments, an explanation that could also explain the unexpected offset between SSTs derived from TEX_{86}^L compared to other calibrations. Specifically, the offset in both ancient and modern settings is associated with low GDGT-2 to GDGT-3 ratios. In contrast to previous inferences, those low ratios are not limited to cold regions and in fact are associated with shallow water settings and upwelling zones. We propose that this reflects depth-dependant differences in GDGT distributions that are manifested differently in the various TEX_{86} calibrations, with some reflecting primarily shallow water signatures and others reflecting integration over a greater depth range.

Zinc isotopic variations among ordinary chondrites

RANDAL C. PANIELLO[1,*], FREDERIC MOYNIER[1], JEAN-GABRIEL FRABOULET[1]

[1]Dept of Earth and Planetary Sciences, Washington University, St. Louis, MO, USA, paniellor@wustl.edu (* presenting author)

Zinc is a moderately volatile element that may be capable of movement among minerals or even volatization during thermal metamorphism, despite the absence of partial melts. We obtained high-precision isotopic measurements of zinc by MC-ICP-MS 1,2] from a suite of 70 ordinary chondrites (OCs), in order to study their variation across the metamorphic range. The samples included 23 LL-, 26 L-, and 21 H-chondrites; 26 of the 70 were non-Antarctic falls, 3 were non-Antarctic finds, and 41 were Antarctic finds. Serial leachates were obtained from the LL3.0 Semarkona, and magnetic (metal), silicate and sulfide fractions were separated in three samples in order to determine the contributions of each phase to the total zinc budget. Three whole rock samples were broken into several smaller pieces and each was measured in order to determine the small scale homogeneity of the zinc isotopes.

The $\delta^{66/64}$Zn (reported against the JMC-Lyon standard) for the entire suite, combined with previous data [3,4] generally fell within a narrow range, with a mean of -0.04±0.13 (2se). There was no significant difference measured between Antarctic and Non-Antarctic samples. Isotopic fractionation showed a slight trend across OC subtypes LL<L<H, and unequilibrated OCs were lighter than equilibrated OCs in each subgroup, but these effects were modest. There was also a general trend across petrologicic grade, with the highest subtypes (5-7) heavier than the less metamorphosed subtypes (3-4), by 0.35‰ for LL to 0.68‰ for H. However, zinc concentration did not vary with metamorphic grade, but instead averaged 43-52ppm for all petrologic grades. Leachates and separates show that a large portion of the zinc in OCs is found in sulfide phases. On a small scall, these OCs exhibited a high degree of homogeneity.

The similar zinc content of all OCs rules out significant volatization with increasing metamorphism. Variations in zinc isotopic ratios may reflect pre-accretion nebular processes, or may represent closed-system metamorphic changes in which the zinc moves between phases in a mass-dependent process.

Carbonaceous material associated with apatite in the Chassigny meteorite from Mars

DOMINIC PAPINEAU[1,2*]

[1] Department of Earth and Environmental Sciences, Boston College, Chestnut Hill, United States, dominic.papineau@bc.edu

[2] Geophysical Laboratory, Carnegie Institution of Washington, Washington DC, United States.

Following the biologically important elements is key for the search for life beyond Earth. Carbon and Phosphorous are two fundamental biological elements for all life on Earth, and are found throughout Earth's geological record in minerals like graphite and apatite. Associations between disordered carbonaceous material and apatite are reported here for the first time in an extraterrestrial sample. These mineral-pairs were found in the Chassigny meteorite which is an olivine cumulate rock from the Martian mantle. Raman spectra and microspectroscopic images show the presence of disordered carbonaceous material associated with hydroxylapatite-maskelynite inclusions in olivine grains. Optical and electron microscopy suggest that there is a petrogenetic connection between carbonaceous material, hydroxylapatite, maskelynite, Ni-rich pyrrhotite, Cr-rich spinel, orthopyroxene, and olivine. Carbonaceous material is often associated with hydroxylapatite in fields of dozens of 2-30 micron-sized maskelynite inclusions in olivine, which is interpreted here, on the basis of the Raman D- and G-bands, to represent precipitation from low-temperature hydrothermal fluids.

Focused Ion Beam (FIB) was performed to micro-fabricate targets of these mineral associations. Analyses by TEM-EDS show that hydroxylated apatite grains a few microns in size are embedded as inclusions in maskelynite, which was also observed by Raman spectroscopic imaging. In addition, we also found numerous Ni-rich pyrrhotite grains (with up to 4%wt Ni). Cr-rich spinels also occur throughout the olivine cumulates. Such a petrographic context is important because Fischer-Tropsch synthesis produces short-chain alkanes from the reduction of carbon monoxide by dihydrogen and catalyzed by metals such as Ni and Cr.

It is here proposed that apatite acted as a template for aromatic and aliphatic carbonaceous material to condense because apatite and graphite both have an hexagonal structure and there is a near-integer factor of 3.85 difference between their unit cell sizes. The discovery reported here is thus also relevant to the possibility of life on Mars, to the production of organic molecules on Mars (including traces of atmospheric methane), and also to yield a natural example of an early stage of non-biological organic synthesis for the transition from a prebiotic to a biological world.

Calcrete on Everglades tree islands: human occupation or tree growth?

JEANNE PAQUETTE[1*], MARIE GRAF[2], GAIL L. CHMURA[3], CAMERON BUTLER[4]

[1]Earth & Planetary Sciences, McGill University, Montreal, Canada, jeanne.paquette@mcgill.ca (* presenting author)
[2]Montreal, Canada, graf_marie@hotmail.com
[3]McGill University and Global Environmental and Climate Change Centre, Montreal, Canada, gail.chmura@mcgill.ca
[4]Bioresources Engineering, McGill University, Ste-Anne-de-Bellevue, Canada, cameron.butler@mail.mcgill.ca

New geochemical and petrographic analyses shed light on the origin of the "enigmatic" carbonate layer perched within the soil of some Everglades tree islands. For some time, archaeologists [1, 2] have noticed the presence a 45-70 cm thick calcareous layer in the islands of terrestrial vegetation perched just a meter above the flooded wetlands of the Everglades. This layer, impenetrable without heavy equipment, had been interpreted as a topographic high in the underlying karst platform. Schwadron's archeological excavations of selected islands revealed soil and artifacts below the carbonate layer and a midden just above the karst platform [3]. As Schwadron had not observed artifacts in the layer, she interpreted it as a hiatus in midden/peat deposition. The cultural age of artifacts above and below the layer suggested that it formed ~3800-2700 cal yr BP, a period corresponding to a broad scale climate change recognized in the southeast U.S. and associated with cultural changes from the Late Archaic (Archaic = 9k to 3.5k BP) to Early Woodland culture [4].

Another model [5] proposed for the development of the calcrete layer required no major climate perturbation, only the occurrence of distinct wet and dry seasons where evapotranspiration from vegetation might result in the reprecipitation of calcium carbonate around roots within the soil profile.

Our most recent investigations indicate that a major component of the hardened layer is detrital rather than pedogenic. Most calcareous fragments show textures of an oolitic limestone with isopachous meteoric cements. Their oomoldic porosity is typical of the local underlying Pleistocene bedrock (Miami Limestone). Pedogenic features (needle-fiber calcite, root casts) in the surrounding soil indicate that the limestone fragments have been dissolving in the peaty soil profile. Phreatic acicular calcite cements fill pores in phosphatic bone fragments throughout the layer, enhancing their preservation and fixing phosphorus within the tree island soil.

This provides evidence for layer development that requires neither abandonment nor climate change. The question remains as to whether these limestone fragments were pulled up from a karstic, rubble-covered bedrock by fallen trees or if they were left by human occupants. If vegetation simply enhanced the pedogenic cementation into cohesive calcrete layers of limestone fragments left by early human occupants, these layers might have value as stratigraphic markers.

How large is the subducted water flux? New constraints on mantle regassing rates

RITA PARAI[1*] AND SUJOY MUKHOPADHYAY[1]

[1]Harvard University, Cambridge, MA, USA, *parai@fas.harvard.edu

Constraints on the long-term cycling of water between the mantle and exosphere (i.e., the atmosphere, oceans and crust) are critical to our understanding of mantle rheology, the structure and style of mantle convection [1], and the volatile budget of our planet. Volcanic water output from the mantle is offset by input at subduction zones in the form of chemically-bound water in subducting slabs. Water released from subducting slabs at high pressures and temperatures is outgassed to the exosphere by arc and back-arc volcanism. Any water entrained in the mantle wedge or retained in the slab beyond depths of magma generation constitutes a return flux of water to the interior, often referred to as the post-arc subducted water flux. Estimates of the magnitude of the total input flux of water at subduction zones and the magnitude of the return flux beyond arcs into the deep mantle have been used to discuss long-term regassing of the mantle [2-5]. However, these estimates vary widely, and some are large enough to have reduced the volume of water in the global ocean by a factor of two over the Phanerozoic.

In light of uncertainties in the initial hydration state of subducting slabs, magma production rates and mantle source water contents, we use a Monte Carlo simulation of the deep Earth water cycle to set limits on long-term mantle regassing. The simulation is constrained by reconstructions of Phanerozoic sea level change, which suggest that ocean volume is near steady-state, though a sea level decrease of up to 360 m may be supported [6-8]. We find that previous estimates of both the input flux of water into subduction zones and the return flux beyond depths of magma generation are frequently too large to reflect long-term water cycling. Our results [9] suggest a limited extent of serpentinization in subducting lithospheric mantle. For a near steady-state exosphere (0-100 m sea level decrease), we find an average return flux of 1.4–2.0 x 10^{13} moles/yr, corresponding to 2-3% serpentinization in 10 km of lithospheric mantle. For a maximum sea level decrease of 360 m, the average return flux is 3.5 x 10^{13} moles/yr, corresponding to 5% serpentinization in 10 km of lithospheric mantle. Our estimates of the return flux of water past arcs are up to 7 times lower than previously suggested [2-5; 9]. The net imbalance between our estimates of the return flux and the mantle-derived output flux gives an upper limit bulk mantle regassing rate of 24 ppm/Ga. Furthermore, our results indicate that while water in the mid-ocean ridge basalt source may be accounted for by recycling of water carried in subducted slabs, recycled slab water contents may not be high enough to account for the water contents of the ocean island basalt (OIB) source, such that some fraction of OIB source water appears to be juvenile.

Role of Syntrophy in the Microbial Reduction of Crystalline Iron Oxides

MADHAVI PARIKH[1,*], TAMAR BARKAY[1], NATHAN YEE[1]

[1]School of Environmental and Biological Sciences, Rutgers University, New Brunswick, NJ, USA
(*correspondence: madhavi@eden.rutgers.edu)

Background

Syntrophic microbial consortia composed of anaerobic bacteria are able to catalyze electron transfer reactions that a single organism cannot [1]. Syntrophy is a community-level process that involves interspecies exchange of metabolites between organisms. Cooperative exchange of electrons and hydrogen in microbial communities is known to play an important role in the fermenation of complex natural organic matter to CO_2 and CH_4. Currently, the role of syntrophy in the the reduction of crystalline iron oxides is poorly understood. Here we examined the reduction of crystalline iron oxides by an anaerobic microbial consortium during fermentative growth. We present evidence that the rapid iron reduction rates are enabled by syntrophic interactions between the bacteria that form this consortium.

Materials and Methods

A consortium composed of two microorganisms was cultivated from a sediment core collected from the United States Department of Energy Field Research Center (FRC) in Oak Ridge Tennessee. The consortium consists of a fermenting *Clostridium* species and a hydrogen-oxidizing bacterium belonging to the family *Vellionellaceae*. Iron reduction experiments were conducted to evaluate the ability of this consortium and pure culture to reduce goethite, hematite and ferrihydrite during fermentation of peptone. At periodic time points, samples were collected and analysed for Fe(II) and hydrogen production by ferrozine assay and gas chromatography, respectively. PCR amplification of the 16S rRNA genes and denaturing gradient gel electrophoresis (DGGE) analysis were performed to determine the dominant member of the microbial community.

Results and Discussion

When grown on fermentable substrates, the microbial consortium reduced goethite (α-FeOOH) and hematite (Fe_2O_3) with specific log reduction rates of -3.1 and -3.3 pmol m^{-2} h^{-1} $cell^{-1}$, respectively. DGGE analyses indicated that the *Clostridium* species was the dominant member in the consortium during the reductive dissolution of crystalline iron oxides. In pure culture, the *Clostridium* species was able to reduce ferrihydrite, but it reduced goethite and hematite at 4 to 5 times lower rates than the intact consortium. Finally, we show that the *Clostridium* species produces hydrogen during fermentation, and that the growth of the *Vellionellaceae* partner is stimulated by the presence of H_2 gas. These results suggest that interspecies hydrogen transfer may play a key role in controlling the rates of crystalline iron oxide reduction by fermentative microbial communities.

Profile of sulfate isotopic composition of Lake Matano, Indonesia

G. PARIS[1*], J.F. ADKINS[1], A.L. SESSIONS[1], S.A. CROWE[2], C. JONES[2], D.A. FOWLE[3], D.E. CANFIELD[2]

*corresponding author: gparis@caltech.edu

Lake Matano, Indonesia, is one of the ten deepest lakes in the world and the largest modern ferruginous basin [1,2]. Despite a low thermal gradient, a persistent chemocline at 100 m isolates surface waters with low sulfate concentrations (<25 µmol.l^{-1}) and sulfate-free deep waters [1]. The chemical properties of Lake Matano make it a prospective analogue for the ferruginous Archean ocean and it has been used to study the potential role of anoxygenic phototrophic Fe(II)-oxidizing bacteria in the synthesis of Banded Iron Formations [1] as well as carbon cycling in ferruginous settings [2]. Dissolved sulfate is completely removed between 100 and 150 m by sulfate reduction. However, very low concentrations of sulfide are observed in the Fe(II)-rich chemocline because of efficient removal by precipitation of FeS [2].

To explore the biogeochemical cycling of sulfur in Lake Matano, we investigate the isotopic composition of sulfur in sulfate ($\delta^{34}S_{SO_4}$) from a water profile spanning the surface and chemocline of the lake. Because of the low concentrations of sulfate make the analysis of the sulfur isotopic composition of SO_4 with conventional $BaSO_4$ precipitation is nearly impossible because it would require a huge amount of sample. Here, we use a recently developed method for $\delta^{34}S_{SO_4}$ analysis using the ThermoScientific 'Neptune' multicollector inductively-coupled plasma mass spectrometer (MC-ICPMS). This method allows us to measure the isotopic composition of sulfur from trace sulfates in natural samples. Sulfate was extracted from lake waters using a cation-exchange resin (Dionex AG50X8) and analyzed on the Neptune as Na_2SO_4. Furthermore, using a Cetac 'Aridus' as an introduction system decreases isobaric interference due to O_2 isotopologues on the isotopes ^{32}S, ^{33}S and ^{34}S and ^{32}S-H on ^{33}S. We will also explore the triple isotope variability of this unique system using our new MC-ICPMS method.

Reproducibility of $\delta^{34}S$ better than 0.2 ‰ (1σ) is achieved by running 5 to 20 nmol of sulfate (1 to 10 ml of waters from Lake Matano). Results will provide new constraints on the fractionation of sulfur isotopes in sulfate-poor water, thus helping to constrain our understanding of sulfur cycling during Archean times in a ferruginous ocean.

A biogeochemical orientation study in Mo skarn deposits, Jecheon distict, Korea

JI-YOUNG PARK[1*], JONG-NAM KIM[1, 2], AND HYO-TAEK CHON[1]

[1]Seoul National University, Department of Energy Resources Engineering, Seoul, Republic of Korea, jypakr05@snu.ac.kr (*presenting author), chon@snu.ac.kr

[2]Korea Resources Coportation, Seoul, Republic of Korea, kimjn@kores.or.kr

A biogeochemical orientation survey was conducted in the vicinity of Mo skarn deposits in Jecheon district in Korea. A skarn zone of over 600 m length is hosted in Ordovician carbonate sediments and is adjacent to both Jurrassic and Cretaceous felsic intrusives. Molybedenum occurs in fracture zones within the skarn and in disseminated form. The skarn ore minerals consist mainly of scheelite, molybdenite, galena, and chalcopyrite. The total samples of rocks, soils, and plants – daimyo oak leaves/branches (*Q. dentata*) and sargent cherry leaves (*P. sargentii*) – were collected from the target area and barren control area, and analyzed by ICP-MS. Each of three sampling lines was designed to cross the orebody at 30 m spacing intervals. The soil samples (n=36/10, target/control) collected from the target area show higher values of Mo (<0.1~38.7 ppm) compared with those from the control area (<0.1~3.2 ppm Mo). In all of the plant samples (n=108/30, target/control), Mo concentration from the target area (2.7~95 ppm in *Q. dentata* leaves, 0.2~99.1 ppm in *Q. dentata* branches, and 1.7~69 ppm in *P. sargentii* leaves) is 3~7 times higher than that from the control area (1.9~10.3 ppm in *Q. dentata* leaves, 0.9~6.3 ppm in *Q. dentata* branches, and 2~5 ppm in *P. sargentii* leaves). The variation patterns of Mo in plants are similar to those in soils, suggesting a corresponding Mo anomaly and contrast between soils and plants. The values of Mo in soils and plants are strongly correlated. The biological absorption coefficient (BAC) of Mo in the plants is generally high (*Q. dentata leaves* = 15 and *Q. dentata* branches/*P. sargentii* leaves = 9.1). The three plant organs have high possibilities to be used as indicators for the biogeochemical prospecting of Mo.

Delamination of subcontinental lithosphere beneath the Korean Peninsula: evidence from ultramafic xenoliths in Cenozoic basalts

KYE-HUN PARK[1*], YONG-SUN SONG[2]

[1]Pukyong National University, Earth Environmental Sciences, Busan, Korea, khpark@pknu.ac.kr (* presenting author)

[2]Pukyong National University, Earth Environmental Sciences, Busan, Korea, yssong@pknu.ac.kr

The Cenozoic alkali basalts are widely scattered over Korea and often carry spinel lherzolite xenoliths, indicating that the lithospheric thickness beneath Korea does not reach deep enough to the garnet lherzolite stability field. Interestingly enough, the spinel peridotite xenoliths from Korean peninsula can be divided into two groups based on their geochemical and Sr, Nd, Hf and Pb radiogenic isotopic compositions, i.e. enriched group and depleted group. The former xenoliths have enriched isotopic compositions very similar to their host basalts but show refractory nature of major element compositions with quite low CaO and Al_2O_3 contents indicating their derivation from the old Paleoproterozoic subcontinental lithospheric mantle beneath the Korean peninsula. In contrast, the latter have depleted isotopic compositions similar to mid-oceanic ridge basalts with apparently fertile major element compositions of relatively high CaO and Al_2O_3 contents similar to present day asthenospheric mantle indicating that such asthenosphere-derived materials may have replaced the lithosphere quite recently. In general, the host basalts show isotopic compositions similar to the enriched xenoliths, indicating genetic link between them.

Simple geobarometric calculations indicate that the depths of origination of the xenoliths are in average of ca. 75 km, suggesting that the maximum thickness of the subcontinental lithosphere would not exceed such depth quite much. On the contrary, the crustal evolution of the Korean peninsula seemingly started since the Archean, at least some part of it, suggesting normal lithospheric thickness of 150 km or greater. Such lithospheric thickness of the Korean peninsula significantly thinner than expected is quite similar to the case of North China Craton having lithospheric thickness of ca. 80 km in average, suggesting significant delamination of the lithospheric mantle in a depth scale of a few tens of kilometers during the past geologic time. Such delaminations may have occurred after the continental collisional events of Paleoproterozoic and early Mesozoic, suggested by wide occurrences of igneous and metamorphic events during the 1.9-2.0 Ga and also during the early Mesozoic throughout the Korean peninsula.

Adsorption of organics and nanoparticles at mineral-water interfaces.

STEPHEN C. PARKER[1*], THOMAS V. SHAPLEY[1], RUNLIANG ZHU[1,2], AND MARCO MOLINARI[1]

[1]Department of Chemistry, University of Bath, Bath BA2 7AY, United Kingdom, s.c.parker@bath.ac.uk (* presenting author)
[2]Key Laboratory of Mineralogy and Metallogeny, Guangzhou Institute of Geochemistry, Chinese Academy of Science, Guangzhou, 510640, China

We present our recent work, developing and applying complementary computational methods to gain atomistic insights into systems comprising mineral-organic-water interfaces. The research scheme involves the use of *ab initio* including van der Waals interactions and experimental data to validate rigid-ion or polarizable potential models which are then applied within energy minimization (EM) and classical molecular dynamics (MD) techniques. This robust approach covers the evolution of systems of different sizes and for different lengths of time allowing the evaluation of structures and dynamic properties.

The focus of our attention is on layered minerals including metal hydroxides, clay minerals and organo-clays interacting in the aqueous environment. The presence of organo-compounds (OCs) and nanoparticles (NPs) which can impact on the environment by entering the food chain, can also disrupt the mineral/water interfaces affecting the physico-chemistry of aqueous systems.

Several examples are discussed including adsorption and transport of OCs on montmorillonite and pyrophyllite and of fullerene on brucite in the presence of water capturing their atomistic features and helping to interpret experiments. The CLAYFF [1] and GAFF [2] or CVFF [3] force fields are applied to the clay surfaces and OCs and NPs respectively. Flexible TIP3P [4] and shell models of water are used in solvated systems. Interatomic potentials are tested against DFT calculations using VASP [5]. EM and MD employ the METADISE [6] and DL_POLY [7] codes.

Our results indicate that the interplay between the adsorption, which is surface-site as well as counter-ion-site dependent, and the transport of OCs and NPs on soil clay significantly disrupts the structure of the mineral-water interface [8,9] which has previously been shown to extend well above both mineral and nanoparticle surfaces [10]. Finally we find that the energy of adsorption is strongly affected by the inclusion of the van der Waals interactions within the DFT simulations and of the polarizability terms in the potential models within classical techniques.

Magnesium is the eight most abundant element in the Earths crust, and the fourth most abundant species in seawater. As such it is an essential component of life, with pivotal roles in the generation of cellular energy as well as in plant chlorophyll[1]. The bio-geochemical cycling of Mg is associated with mass dependant fractionation (MDF) of the three stable Mg isotopes, ^{24}Mg, ^{25}Mg and ^{26}Mg[1]. The largest MDF of Mg isotopes has been recorded in carbonates, with foraminiferal tests displaying the lowest $\delta^{25}Mg$ and $\delta^{26}Mg$ compositions[2].

Bacterial carbonate precipitation is known to have occurred in modern and ancient Earth surface environments[3,4], with cyanobacteria having a dominat role in carbonate formation during the Archean. In this study, we aim to better constrain the extent to which Mg isotope fractionation occurs during cellular processes, and to identify when, and how, this signal is transferred to carbonates. To quantify these effects we have performed biologically-induced carbonate precipitation experiments using several bacteria strains. The organisms are grown under defined organic and Ca/Mg ratios in artificial seawater, and under temperature controlled conditions that promote carbonate formation. Carbonate spheres of ~100 microns diameter are produced, which are amenable to SEM, EMP and Mg isotopic analysis by MC-ICP-MS. In order to compare our experimental data to natural samples we will present Mg isotope data for modern and ancient stromatolites, which are laminated carbonates produced by micro-organisms. Our new data will shed light on tracing bacterial signals in the geological record.

Frontiers in Computational Geochemistry

The experimental study of systems under condition of high temperature and pressure provide a considerable challenge. Accurate and reliable computer simulations could be of great help in this area of science. However to reach this goal considerable technical difficulties need to be overcome. We present a number of methods developed in our laboratory that greatly help towards reaching this goal. We apply these techniquese to study the phase diagram of materials, structural phase transition and the nucleation of crystals from solution.

Fluctuations in Precambrian atmospheric and oceanic oxygen levels: a new Precambrian paradigm emerging?

The Precambrian atmosphere and oceans are traditionally thought to have undergone a progressive, gradual increase in oxygen content after ~2.4 Ga [1]. This gradual transition from anoxic to oxidizing conditions is assumed to have occurred in two incremental steps, one at the beginning, and one at the end of the Proterozoic Eon. Emerging data require a change to this paradigm. Enrichments of the redox-sensitive element uranium in organic matter-rich shales through time shows that the Earth's surface oxidation had a more dynamic and unexpected history. Archean shales show very low [U] (<10 ppm, average of 3.8 ppm), consistent with a large U sink in anoxic oceans. The Great Oxidation Event (GOE) is accompanied by a rapid increase in maximum [U], up to 60 ppm, which likely reflects the onset of strong oxidative continental weathering releasing soluble U and expansion of oxygenated environments in the oceans. The initial rise of atmospheric oxygen ~2.4-2.32 billion years ago was followed by a dramatic decline to less oxidizing conditions during the Middle Proterozoic, beginning after the cessation of the Lomagundi carbon isotope excursion at ~2.05 Ga, when [U] in shales returned to near-to-crustal levels (average of 3.2 ppm). The subsequently established, steady-state low-oxygen mode persisted for nearly one billion years, terminating with a second oxygenation event in the latest Neoproterozoic, when [U] in shales demonstrate a dramatic increase, up to 94 ppm, by 551 Ma. Utilizing the ubiquitous geological shale record, U concentrations reveal Earth's dynamic path to its presently well-oxygenated atmosphere-ocean system, with unprecedented temporal resolution. We will present evidence for a precipitous rise and (previously unrecognized) fall in atmospheric oxygen early in the Proterozoic, which is in direct contrast to conventional models predicting a unidirectional oxygen rise. With this new paradigm in mind, future models will need to reexamine the links between the co-evolution of life and the chemical composition of the Precambrian oceans.

Does Fe electron transfer and atom exchange occur between Fe(II) minerals and aqueous Fe(III)?

TIMOTHY S. PASAKARNIS*, GENE F. PARKIN, AND MICHELLE M. SCHERER

Department of Civil and Environmental Engineering, The University of Iowa, Iowa City, USA, timothy-pasakarnis@uiowa.edu (* presenting author)

Fe oxides are transported as suspended sediment in rivers towards the oceans and act as a major source of iron for primary producers [1]. During this journey, the redox environment changes drastically, from dark, reducing environments in the subsurface, to light, oxidizing environments in fresh and marine surface waters and sediments. Here, we are interested in exploring whether our and others' recent findings of Fe(II)-Fe(III) electron transfer and atom exchange occur under more marine-like redox conditions, where Fe(II) can be structurally bound in a solid phase, and dissolved Fe(III) may be present as a sparingly soluble aqueous species complexed with ligands of various types [2].

In reducing environments, the reaction of Fe(II) and Fe(III) minerals is becoming widely recognized to be more complex than simply surface sorption of Fe(II). Rather, a complex process involving sorption, Fe(II)-Fe(III) electron transfer, and often extensive recrystallization both with and without secondary mineral transformation is beginning to emerge [3]. Whereas there is compelling evidence for oxidation of sorbed Fe(II) by structural Fe(III) in Fe minerals, such as goethite, magnetite, hematite, and ferrihydrite, it is unknown whether electron transfer will occur between sorbed Fe(III) and structural Fe(II) in Fe(II) minerals. It is also unclear whether significant Fe exchange will occur between aqueous Fe(III) and Fe(II) minerals.

We synthesized several Fe(II) containing minerals, such as magnetite, mackinawite, and siderite from ^{56}Fe and reacted it with aqueous ^{57}Fe(III) complexed with various Fe ligands. Mössbauer spectroscopy is specific to ^{57}Fe, and thus by synthesizing the underlying oxide from ^{56}Fe, we can turn off the signal from the solid, and isolate whether the aqueous ^{57}Fe(III) is reduced. In addition, we are using an enriched Fe isotope tracer approach, similar to our previous work [4] to determine whether significant Fe atom exchange occurs between the bulk solids and aqueous phase.

Graphite-bearing and graphite-depleted basement rocks in the Dufferin Lake Zone, south-central Athabasca Basin, Saskatchewan: Initial observations and future work.

MARJOLAINE PASCAL[1*], KEVIN ANSDELL[1], IRVINE R. ANNESLEY[1,2], DAN JIRICKA[3], GARY WITT[3] AND AARON BROWN[3]

[1]University of Saskatchewan, Saskatoon, Canada, mjp313@mail.usask.ca, (* presenting author) , kevin.ansdell@usask.ca
[2]JNR Resources, Saskatoon, Canada, jnrirvine@sasktel.net,
[3]Cameco Corporation, Saskatoon, Canada, dan_jiricka@cameco.com, gary_witt@cameco.com, aaron_brown@cameco.com

Unconformity-associated uranium deposits from the Paleo- to Mesoproterozoic Athabasca Basin in Saskatchewan, Canada, include the largest high-grade U ore deposits in the world. Most of the deposits are located at the unconformity between the sedimentary basin and the Archean to Paleoproterozoic basement. Graphite and/or carbonaceous matter (CM) are found in the basement, often concentrated along structures which can be identified as electromagnetic (EM) conductors, and potentially could act as a reductant that could trigger deposition of uranium.

The focus of this study is the Dufferin Lake Zone, an extensive "conductive" block along the trend of the Virgin River Shear Zone in the south-central Athabasca Basin. The Centennial uranium deposit occurs along this trend, although it appears to be located away from the interpreted EM conductor at depth. The significance of this observation is that typical exploration strategies of trying to identify mineralized traps along EM conductors may not always be relevant. In order to address this issue, this study aims to examine, in detail, a drill hole fence of metamorphosed basement rocks that at depth contain variable proportions of graphite, either in structures or in pelitic gneisses, but appear to have lost some or all of their graphite as the unconformity is approached.

A combination of analytical techniques will be used to characterize the textural relationships, crystallinity, and type of CM/graphite in the pelitic gneisses and shear/fault zones at various depths below the unconformity. Lithogeochemistry, fluid inclusion and stable isotope analysis, and synchrotron techniques will be utilized to provide constraints on the chemical variability between graphite-bearing and graphite-depleted rocks, and the likely composition of fluids that may have removed graphite. For example, was the graphite removed by fluids moving along the unconformity or the underlying weathered rocks soon after the basin formed, or was it removed by fluids more directly involved in space and time with uranium mineralization, such as a highly corrosive basinal brine. Initial petrographic observations show much hetereogeneity and complexity in the textural relationships and type of CM/graphite in the pelitic gneisses and shear/fault zones at depth. Further work will first analyze these rocks, and then the rocks within the graphite-depleted zone, prior to establishing the link between the two zones. Did the graphite or its breakdown products act as the reductant for uranium deposition?

Carbonate clumped isotope closure temperatures

BENJAMIN H. PASSEY* AND GREGORY A. HENKES

Department of Earth and Planetary Sciences, Johns Hopkins University, Baltimore, MD 21218 (*bhpassey@jhu.edu)

Carbonate clumped isotope thermometry can potentially reveal information about the passage of inorganic carbon through the shallow- and mid-crust on its journey to and from the Earth's deep interior. The ordering of rare isotopes of C and O into the same carbonate groups creates 'multiply-substituted' isotopologues such as $Ca^{13}C^{18}O^{16}O_2$ (~67 ppm natural abundance). These isotopologues are surrounded in the mineral lattice by isotopically normal isotopologues such as $Ca^{12}C^{16}O_3$ (~982,000 ppm), and solid-state diffusion of C and O over unit cell distances will act to create and remove multiple substitutions. This short length scale of diffusion leads to the possibility of cooling rate-dependent carbonate clumped isotope closure temperatures in the ~100-300 °C range, much lower than traditional mineral oxygen isotope closure temperatures, and a range useful for studying shallow- and mid-crustal processes. We determined Arrhenius parameters for solid-state reordering of C-O bonds in calcite through a series of laboratory heating experiments. We present a closure temperature equation for carbonate clumped isotope thermometry analogous to Dodson's solution first order loss [1], where the closure temperature is a function of cooling rate and the Arrhenius parameters for solid-state C-O bond reordering. The sensitivity of closure temperature to cooling rate is sufficient for order of magnitude inference of cooling rate, provided the Arrhenius parameters of the studied minerals are well known. The inferred cooling rate of Carrara marble is ~ 3 °C per 10 ka, which is within error of independent estimates of the cooling history of the Alpi Apuane metamorphic core complex.

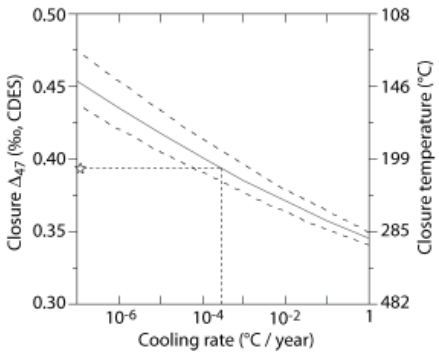

Figure 1: Carbonate clumped isotope closure Δ_{47} and closure temperatures as a function of cooling rate. Solid curved line is the best-estimate closure temperature relationship based on kinetics observed in the laboratory for an optical calcite. The curved dashed lines reflect uncertainty in Arrhenius parameters propagated through the closure temperature model. Star and horizontal dashed line show the mean Δ_{47} value of Carrara marble analyzed in four different laboratories [2]. CDES: 'Carbon dioxide equilibrium scale' [2].

Metamorphic 'cascade effects' due to nucleation-related overstepping

DAVID R.M. PATTISON

Department of Geoscience, University of Calgary, Calgary, Alberta, Canada, pattison@ucalgary.ca

Nucleation difficulty can lead to overstepping of metamorphic reactions. Overstepping can result in multiple reactions being energetically possible, both stable and metastable. The only criterion that has to be satisfied is that each possible reaction lowers the free energy of the system. Overstepping can therefore lead to a 'cascade effect', in which several reactions involving the same reactant phases proceed simultaneously in a small temperature interval. Two different types of cascade effect are recognized. The first, termed the 'Bushveld-type' in respect of its documentation in the Bushveld aureole (Waters & Lovegrove, J Met Geol, 2002), arises from delayed nucleation of a product phase and subsequent production of that product phase from several different reactants. In the Bushveld example, the low-entropy chloritoid to staurolite/andalusite reactions were overstepped to the point that they were overtaken in terms of reaction affinity by high-entropy muscovite+chlorite-consuming reactions. Nucleation of staurolite and andalusite by the latter reactions eliminated the principal kinetic barrier to the progress of the overstepped chloritoid-consuming reactions, such that several staurolite- and andalusite-producing reactions ran in parallel in a small temperature interval, creating a reaction cascade. Fluid release accompanying initial reaction may also have contributed to the cascade effect by facilitating dissolution of chloritoid. The second type of cascade effect, termed the 'Nelson-type' in respect of its documentation in the Nelson aureole (Pattison et al., J Met Geol, 2009; 2011) involves a catalytic trigger related to the sudden build-up or influx of fluid in rocks that have overstepped two or more stable reactions. The result is simultaneous production of different product phases from the same reactant minerals. In the Nelson aureole, the clustering of the garnet, staurolite and andalusite isograds, contrary to their predicted wider spacing according to equilibrium thermodynamics, and the textural evidence that each of these porphyroblasts formed from reaction of the matrix with no evidence of the predicted consumption of the earlier-formed porphyroblasts, suggests the simultaneous operation of several chlorite-consuming reactions. Once the nucleation-related barriers to initial garnet formation were overcome, fluid was released into the grain boundary network, enhancing rates of intergranular transport and possibly further nucleation. This created a positive feedback and a vigorous reaction interval involving production of several porphyroblast phases from the same matrix reactants.

Paleoceanographic interpretation of the light rare earth elements

GENNA M. PATTON[1], PAMELA A. MARTIN[2], EMILIA SALGUIERO[3], AND ANTJE H.L. VOELKER[3]

[1]University of British Columbia, Vancouver, Canada, gpatton@eos.ubc.ca (* presenting author)
[2]Earth and Environmental Sciences, IUPUI, Indianapolis, IN, United States (martinpa@iupui.edu)
[3] Unidade Geologia Marinha, Laboratorio Nacional de Energia e Geologia, Amadora, Portugal (emilia.salgueiro@lneg.pt, avoelker@softhome.net)

The rare earth elements (REE) in sea water have been used as indicators of the modern oceanic and paleoceanic environments. The Nd-isotopic composition (εNd) of ferromanganese crusts and nodules successfully record water mass changes integrated over 10^4 and 10^5 years; fossil fish teeth and debris pinpoint water mass changes through the Cenozoic, though also with low temporal resolution due to the scarcity of fish remains [*2; 3*]. Records of much higher temporal resolution have been produced from the εNd of bulk sediment leach, and over glacial-interglacial timescales [*4*]. Isolating the εNd of seawater from lithogenic contamination, however, is problematic. Detrital contaminants are much more easily removed from planktonic foraminifera and therefore may be more representative of a seawater signal [*1*]. The phase in which the εNd is associated with foraminiferal calcite is of critical importance for the paleoceanographic interpretation. In addition to Nd, the full sequence of rare earth elements can speak to diagenetic indicators and bottom-water conditions in which the authigenic signal is acquired. Studies of coupled planktonic benthic REE comparison allow for clear indications of diagenetic overprinting. Here, we present data from the Iberian Margin that demonstrate coherent, diagenetic signals indicative of environmental conditions associated with climate signals. Also, we present data generated using X-ray absorption near edge structure analysis that help to identify fine-scale spatial distribution of high concentrations of REE and also the oxidation state of redox sensitive cerium. With a combination of paleorecords and different analytical approaches, we can begin to identify the distinct phases of the REE and as a result, the paleoceanographic interpretation of these elements.

Petrology of syn-orogenic S-type leucogranites (Damara orogen; Namibia) – Constraints from Sr, Nd and Pb isotopes

ANDRE PAUL[1*], STEFAN JUNG[1], ROLF L. ROMER[2] AND ANDREAS STRACKE[3]

[1] Mineralogisch-Petrographisches Institut, Universität Hamburg, Germany, andre-paul@hotmail.de ([*]presenting author) stefan.jung@mineralogie.uni-hamburg.de
[2] GeoForschungsZentrum, Potsdam, Germany
[3] Institut für Mineralogie, Westfälische Wilhelms Universität, Münster, Germany

The northern central zone of the Damara Orogen (Namibia) consists of metasedimentary rocks, Pan-African syn- to late-tectonic granites, and rare basement gneisses. Leucogranites of S-Type character with ages of ca. 510-515 Ma appear to be little fractionated although the two suites have high K_2O (5.7-7.3 wt%), Th (30-74 ppm), and U (3-13 ppm) abundances and moderately high but relatively constant Rb/Sr ratios (2.7-4.4). High light rare earth elements but variable heavy rare earth elements concentrations result in high and variable La_n/Yb_n ratios ranging from 16 to 98, suggesting involvement of garnet during crustal melting. The granites have, relative to other syn-tectonic S-type suites from the Damara orogen, more unradiogenic $^{87}Sr/^{86}Sr_{init.}$ ratios (0.7095-0.7140 vs. 0.7150-0.7340). ε–Nd values range from -4.5 to -6.5; the majority of values being similar to those from syn-tectonic S-type granites (ε–Nd -3.0 to -5.5) and match those found in metasedimentary xenoliths (ε–Nd -5.0 to -7.0) from these syn-tectonic S-type granites. The Pb isotopic composition of acid-leached feldspar is broadly similar to the one of metapelitic xenoliths in Damaran syn-tectonic S-type granites suggesting that the leucogranites are derived from isotopically similar metapelitic rocks. Zircon saturation temperatures are high for crustally derived granites, but well within the range commonly accepted for S-type granites (800-840°C). U-Pb monazite ages and Rb-Sr whole rock ages indicate that the leucogranites intruded simultaneously with the main peak of metamorphism. The heating event that promoted melting of fertile rocks at depth might have been subsidized by high heat productivity, which is also reflected in the elevated K, Th, and U abundances of apparently unfractionated granites, and crustal thickening during the Pan African orogeny.

Lead isotopes in South Atlantic seawater: insights on anthropogenic inputs and ocean circulation

M. PAUL[1*], T. VAN DE FLIERDT[1], D. WEISS[1], M. REHKÄMPER[1]

[1]Imperial College, London, UK (*m.paul@imperial.ac.uk)

Trace elements and their isotopes play an essential role in biological processes in the marine environment. Like many micronutrient elements, lead (Pb) is mainly supplied to the remote parts of the ocean by atmospheric deposition. Unlike nutrients, however, its behaviour in seawater is dominated by passive scavenging onto particles. As Pb is one of the elements which is heavily influenced by anthropogenic contamination, its isotope composition in seawater can give us key information on (i) anthropogenic vs. natural sources affecting the modern oceans, and (ii) the movement of water masses within the global oceans [1,2]

To better exploit the potential of Pb isotopes for research in marine geochemistry, we have developed a new method for accurate high precision analyses of Pb isotopes in seawater. The methodology involves pre-concentration of Pb using $Mg(OH)_2$ co-precipitation [3] and further purification by ion exchange chromatography on two successive columns of AG1X8 100-200 resin. Samples are then loaded on single Re filaments with a mixture of silica gel and phosphoric acid. The isotopic analyses are carried out on a TRITON TIMS instrument at Imperial College London, using a $^{204}Pb/^{207}Pb$ double spike for the correction of instrumental mass fractionation [4].

Using our newly installed and tested technique, we analyzed several depth profiles of seawater from the South Atlantic Ocean collected in the framework of the UK-GEOTRACES program. More precisely, the samples are derived from a transect along 40°S between Cap Town (South Africa) and Montevideo (Uruguay). The key feature of this remote and little studied part of the Atlantic Ocean is a high productivity band in an otherwise nutrient-poor region, which may be due to a number of potential sources of nutrients. Our lead isotope data will help to constrain anthropogenic and natural dust inputs from both South Africa and South America and their migration within the vertical water column. In addition, intermediate and deep water analyses will reveal the presence of Southern Ocean and North Atlantic waters.

Characterization of Hg leaching from the riverbank sediments of the South River, VA

KRISTA PAULSON[1*], KRISTA DESROCHERS[1], CAROL PTACEK[1], DAVID BLOWES[1], BLAIR GIBSON[1], RICHARD LANDIS[2], JAMES DYER[2], NANCY GROSSO[2]

A large portion of Hg found in the natural environment originates from sediment and soils that are transported and dispersed by runoff and erosion. The associated particle-facilitated transport depends on the mineralogy and pore-water chemistry of the sediment and can impact the bioavailability and toxicity of Hg [1]. In this study, freshwater river sediments and bank soils that contained elevated concentrations of Hg were collected along two vertical transects perpendicular to the South River, Virginia, USA. The South River system accumulated Hg from industrial processes along the river during the early part of the 20th century. The sediment samples were analysed using a variety of techniques, including sequential chemical extractions and synchrotron-based X-ray absorption spectroscopy (XAS). Column transport experiments were conducted to evaluate Hg leaching from the sediment and bank soils. Specific issues addressed are the extent that Hg leaches from the sediment under varying geochemical conditions, which develop in the frequently inundated riverbanks, and the role of particle-facilitated and colloidal transport of Hg from the bank sediments.

Sediment samples from both transects contained both soluble (up to 32%) and less soluble forms of Hg (up to 94%), as determined by sequential chemical extractions [2]. Micro-XAS analysis produced spectra that were consistent with the mineral phase metacinnabar [HgS]. Column transport experiments conducted with the two sediment samples that contained the elevated concentrations of Hg indicated nearly identical leaching of Hg. These sediments contained similar concentrations of total Hg (280 μg g^{-1} total Hg for a sample collected from the unsaturated zone near the top of the river bank and 187 μg g^{-1} for a sample collected from an elevation just above the base flow level of the river), but contained markedly different fractions of extractable Hg. The effluent concentrations of Hg initially ranged from 1.5 to 3 μg L^{-1} for the 0.45 μm filter fraction for both columns and the unfiltered samples ranging from 2 to 5.3 μg L^{-1}. After 80 pore volumes, the concentrations decreased. Calculated cumulative masses of Hg leached from the sediments reached a plateau at < 2% of the water soluble fraction of Hg, suggesting a diminishing availability of Hg for leaching under saturated flow conditions. These results suggest that there is potential for leaching of elevated concentrations of Hg in both dissolved and particulate forms, that the mass available for leaching under saturated conditions appears to much less than predicted using standardized sequential extraction analyses, and that a portion of the Hg had remained in a relatively stable sulfide phase even after many decades of atmospheric exposure.

Sorption models for complex materials – modeling approaches and data requirements

TIMOTHY E. PAYNE

Australian Nuclear Science and Technology Organisation, Lucas Heights, Sydney, Australia, tep@ansto.gov.au

Surface complexation models (SCMs) can be applied to complex geologic materials such as sediments and soils using various approaches, which are generally variants on either the component additivity (CA) or generalised composite (GC) models [1]. The CA approach involves modeling the sorption of a trace metal (or radionuclide) by additively combining sorption models for the individual mineral components of a soil. The GC approach is more generic, but is often parameterised using bulk properties such as the specific surface area (SSA) or ion exchange capacity.

These approaches are demonstated using data for cobalt adsorption on complex materials from Australian field sites. The GC modeling estimated the number of sorbing sites from the measured BET surface area (assuming a site density of 2.31 sites/nm^2 [2,3]). A simplified CA model that conceptualised the surface sites as having equivalent sorption properties to amorphous Fe oxide was also moderately successful in explaining the pH dependence of the Co sorption data sets. This example demonstrates the basic utilility and predictive capability of these modeling approaches. However, as with literature examples of SCMs for complex materials, it does not fully test the underlying assumptions. These outcomes raise questions about the uniqueness and general applicability of these modeling approaches [3].

A principal requirement to further develop the CA modeling approach is adequate models for trace metal sorption on component mineral phases of complex environmental sorbents and conclusive demonstration of their role in each sample. Similarly, the GC approach requires experimental measurement of sorption data on a range of complex samples of differing mineralogy and SSA under various conditions. Given that it is relatively straightforward to experimentally study sorption and measure SSA, it might be expected that numerous sets of trace-metal sorption data for complex samples having a range of properties would be available. However, while individual studies typically report sorption data across a range of chemical conditions (pH, ionic strength, etc), the experiments often involve only a single solid sample (or limited number of samples). Consequently, a significant constraint on obtaining the required data for establishing relationships between sorption and SSA (or other soil properties) is that few literature data sets report sorption as a function of SSA (or mineralogy) for a number of different solid phases. Thus, there is an urgent need for more experimental sorption work with a range of sorbent samples.

Deciphering the Cenozoic Tl isotope record of marine ferromanganese crusts – new evidence from adsorption experiments

CAROLINE L. PEACOCK[1*], SUNE G. NIELSEN[2], LAURA E. WASYLENKI[3], ELLEN M. MOON[4] AND MARK REHKÄMPER[5]

Thallium stable isotopes, recorded in authigenic marine ferromanganese crusts, may provide new constraints on past changes in environmental conditions, the Earth's carbon cycle, and their impact on global climate.[1-3] Specifically, the Cenozoic Tl isotope curve shows a pronounced evolution of Tl isotope composition around the Palaeocene-Eocene boundary, from ~ 6 ε^{205}Tl at 55 Myr to ~ 12 ε^{205}Tl at 45 Myr (where ε^{205}Tl is the deviation of the ^{205}Tl/^{203}Tl ratio of a sample from the NIST SRM 997 Tl isotope standard in parts per 10000).[2] After this pronounced shift, the Tl isotope composition of crusts appears to have changed little over the last 40 Myr, with a globally uniform, modern signature of ~ 13 ε^{205}Tl. Despite the compelling appearance, the record provided by Tl isotopes (and other heavy-metal stable isotope systems) is not straightforward because the temporal shift in isotope composition may reflect either variability in the ε^{205}Tl value of seawater, or changes in the conditions that govern incorporation of the element into the structure of the ferromanganese minerals. Furthermore, modern crusts are ~ 19 ε^{205}Tl (or ~ 2 ‰) heavier than the contemporaneous seawater, and combined with their globally uniform signature this implies there is an equilibrium stable isotope fractionation between Tl in seawater and the Tl incorporated into crust minerals.

To improve our understanding of the Tl isotope record preserved in crusts it is important to develop a detailed characterisation of how Tl is sequestered by ferromanganese minerals, and a quantitative and mechanistic understanding of any stable isotope fractionation that occurs during this process. Here we present the results of novel experimental work that combines molecular-level, X-ray absorption spectroscopy with stable isotope analyses of Tl sorbed to ferromanganese minerals, as a function of time, temperature, pH and ferromanganese mineralogy. Based on the experiments, we have constrained the mechanistic basis for Tl enrichment and stable isotope fraction in ferromanganese crusts, and we will discuss the effect of the experimental parameters on the fractionation factor between simulated seawater and solid minerals.

Mechanisms of tetrahedral iron formation in ferrihydrite observed via soft x-ray spectroscopy

DEREK PEAK[1*], JAMES J. DYNES[2], ROBERT GREEN[1], AND TOM Z. REGIER[2]

[1]University of Saskatchewan, Saskatoon Canada, derek.peak@usask.ca (*presenting author) robert.green@usask.ca
[2] Canadian Light Source, Saskatoon, Canada, james.dynes@lightsource.ca tom.regier@lightsource.ca

Introduction

Ferrihydrite is a poorly crystalline ferric hydroxide nanomineral. It rapidly transforms to more stable crystalline minerals such as goethite (FeOOH) in the lab, but it is metastable in natural systems and found as persistant coatings as well as discrete particles. Its high reactivity and widespread occurrence make its structure important for geochemists, life scientists (as ferritin), and environmental engineers. However, disagreement among researchers remains as the structure of this enigmatic material. The central question in the structural debate is whether iron in ferrihydrite is purely octahedral, or if tetrahedral ferric iron is present. Recent studies proposing tetrahedral iron in this phase have proposed that it may form via condensation of keggin-type aqueous polymers similar to aluminum, but these have never been directly observed for iron.

Accordingly, the objective of our study was to monitor the precipitation of ferrihydrite from forced hydrolysis of ferric chloride *in situ* using high resolution Fe L-edge XANES spectroscopy of solutions in a flow through liquid cell. Spectra were collected using both Fe partial yield and the newly developed IPFY approach for self absorption-free bulk XAS measurements. The precipitation process was followed from pH 1 to 7.5, and results from these aqueous measurements were compared to air dried samples prepared at the same pH. STXM measurements of wet and dried ferrihydrite were also collected for comparison.

Our results demonstrate clearly that L-edge XANES are extremely sensitive to shifts in ligand field that accompany hydrolysis of metals and coordination changes. There is clear evidence that tetrahedral iron is present in air-dried samples, but that the *in situ* measurements are consistent with only octahedral iron. This suggests that the dominant mechanism for tetrahedral iron in ferrihydrite may be physical dehydration rather than a chemical reaction. This has enormous implications for natural systems, where wetting and drying cycles are expected to strongly influence mineralogy

Novel insights on a traditional proxy: Combining the stable and radiogenic Sr isotope systems to characterise continental weathering

CHRISTOPHER R. PEARCE[1*], IAN J. PARKINSON[1], KEVIN W. BURTON[2], EMILY I. STEVENSON[3], JÉRÔME GAILLARDET[4], ROBERTA L. RUDNICK[5], JOSH WEST[6] AND DOUG E. HAMMOND[6]

*Presenting and corresponding author: c.pearce@open.ac.uk

The radiogenic strontium isotope system ($^{87}Sr/^{86}Sr$) is one of the most established methods for tracing continental weathering, as subtle, but resolvable, differences in $^{87}Sr/^{86}Sr$ ratios enable the Sr content of water, vegetation and humans to be linked to specific locations and lithologies[1]. On a global scale, shifts in weathering processes control the composition of the oceans, with differences in the relative flux of silicate and carbonate material over geological timescales reflected in the $^{87}Sr/^{86}Sr$ ratio of marine carbonates[2]. Unlike the radiogenic system, variations in stable Sr isotopes ($\delta^{88/86}Sr$) are controlled by mass dependent processes, with the main driver of fractionation thought to be incorporation into carbonates[3]. The combined application of the $^{87}Sr/^{86}Sr$ and $\delta^{88/86}Sr$ systems therefore has the potential to differentiate source variations from other weathering processes, providing a valuable method for assessing strontium transport through the critical zone.

This study presents isotopic data from both Sr systems at various points in the hydrological cycle; $^{87}Sr/^{86}Sr$ and $\delta^{88/86}Sr$ values from glacial ice, precipitation, river water, dust and bedrock are used to constrain the sources and cycling of Sr on the continents. Samples dominated by atmospheric Sr transport typically display lower $\delta^{88/86}Sr$ compositions than equivalent surface waters, and are thought to be influenced by anthropogenic contamination effects. River water samples dominated by surface run-off have $^{87}Sr/^{86}Sr$ and $\delta^{88/86}Sr$ values that depend on the underlying lithology: Continental silicate terrains typically have $\delta^{88/86}Sr$ values within 0.10 ‰ of the global riverine mean (0.34 ‰), whereas rivers draining carbonate and basaltic terrains (i.e. those with $^{87}Sr/^{86}Sr$ ratios <0.7100) show considerably greater $\delta^{88/86}Sr$ variation, ranging from 0.10 ‰ to 0.86 ‰. Differences are also observed within individual drainage basins and between wet and dry flow regimes, confirming the sensitivity of the stable Sr system to fractionation processes during weathering and transport. The findings of this study are compared to other isotopic weathering proxies, and the implications for the future application of the Sr weathering proxy are discussed.

Mineral, fluid and gas interactions under CO_2 storage conditions – the role of SO_2, NO_X, and O_2

J. PEARCE[1,2*], D. BIDDLE[2], S. GOLDING[1,2], V. RUDOLPH[2] AND D. KIRSTE[1,3]

[1]Cooperative Research Center for Greenhouse Gas Technologies
[2]University of Queensland, Brisbane, Australia, j.pearce2@uq.edu.au (* presenting author), s.golding1@uq.edu.au, deanb@cheque.uq.edu.au, v.rudolph@uq.edu.au
[3]Simon Fraser University, Vancouver, Canada, d.kirste@sfu.ca

Co-contaminant gases such as SO_2, NO_X, and O_2 are present in gas streams from power stations and oxy fuel power plants. Storage of CO_2 streams containing co-contaminants significantly reduces capture costs however they may have significant physical and chemical impacts on well materials, reservoir and cap rocks when in contact with formation water. Geochemical modelling of SO_2 co-injection indicates formation of sulphuric acid and lowered formation water pH compared to pure CO_2 injection resulting in increased mineral dissolution in the near well bore, and possible precipitation of minerals such as ankerite and dawsonite downstream with a decrease in porosity and injectivity.[1] However modelling is hampered by a lack of experimental data at carbon storage conditions for reactions involving co-contaminants SO_2, O_2 or NO_X.

In this context a new experimental apparatus has been constructed to reproduce in situ carbon storage temperature and pressure conditions for mineral – fluid –scCO_2 – co-contaminant gas reactions, with periodic sampling of fluids and gases for analysis.

Experimental results and geochemical modelling of the dissolution of pure mineral phases siderite, labradorite and illite in CO_2 saturated brines of high (150 g/l NaCl) and low salinity at representative reservoir conditions (80 °C, 200 bar) will be presented. Recent work on far from equilibrium siderite dissolution at up to 100°C and ~50 bar CO_2 shows increased dissolved iron at pH below 5 owing to proton promoted dissolution (PPD).[2] Labradorite dissolution is expected to be incongruent with enhanced release of sodium, calcium and aluminium over silica at our temperature conditions.[3] Labradorite dissolution may be expected to decrease under saline conditions by comparison to feldspar dissolution experiments in the absence of CO_2.[4] The effect on siderite at our conditions is less clear cut, however recently Testemale *et al*. observed an order of magnitude decrease in the rate constant for siderite dissolution at 100°C and 300 bar with the addition of 1 mol kg^{-1} NaCl resulting from competition of Na^+ with H^+ affecting PPD.[4] Further experiments will include the co-contaminants O_2 (5%) and SO_2 (1%). Renard *et al*. observed increased reactivity of carbonate and clay by up to a factor of 10 on addition of SO_2 and O_2.[6] With SO_2 co-injection the lowered pH conditions are expected to increase mineral dissolution rates.

Tetraether lipids of Archaea in paleoceanography: Unresolved questions and new directions

ANN PEARSON[1*]

[1]Harvard University, Department of Earth and Planetary Scienes, Cambridge, MA, USA, pearson@eps.harvard.edu (* presenting author)

Abstract

Thaumarchaeota [1, 2], formerly known as Marine Group I Crenarchaeota, are believed to be the primary source of the ubiquitous glycerol dialkyl glycerol tetraether lipids (GDGTs) found in the environment. GDGTs, including the unique compound crenarchaeol, are abundant in marine and terrestrial aquatic environments, in sediments and soils, and over at least an 85°C temperature range from the polar ocean to hydrothermal springs. Experiments on pure cultures, enrichment mesocosms, and empirical correlations for marine sediments (TEX_{86}; [3]) all show a positive relationship between environmental temperature and the number of cyclopentyl or cyclohexyl rings contained within the GDGT structure. The TEX_{86} paleotemperature proxy has been applied across a large temporal range of geologic events and to sediments of widely varying depositional and diagenetic history. Evaluating whether such broad applicability is widely robust requires answers to a number of lingering questions about: (*1*) the physiological mechanism governing the number and distribution of these types of rings; (*2*) the degree to which microbial community structure influences the TEX_{86} relationship, including the extent to which environmental Euryarchaeota also produce GDGTs; (*3*) the mechanism that transfers the TEX_{86} signal to marine sediments; (*4*) the extent to which this signal is modified via diagenesis, *in-situ* production, or sediment redistribution; (*5*) the taxonomic, ecophysiological, and evolutionary significance of the cyclohexyl ring-containing compounds, crenarchaeol and its regioisomer; and (*6*) the fidelity of empirical temperature correlations based on core-top sediments. I will review these questions with a focus on the promise and prospects offered by isotopic approaches, which to date have remained underutilized.

Development and application of LA-ICP-MS in the geosciences: past, present and future

N.J. Pearson[1] *, W.L. Griffin[1] and Suzanne Y. O'Reilly[1]

[1]ARC Centre of Excellence for Core to Crust Fluid Systems, Department of Earth and Planetary Sciences, Macquarie University, Sydney, NSW 2109, Australia norman.pearson@mq.edu.au (*presenting author); william.griffin@mq.edu.au; sue.oreilly@mq.edu.au

The rapid advances in *in situ* laser ablation (LA) inductively coupled plasma-mass spectrometry (ICP-MS) and multicollector (MC)-ICPMS have provided datasets in geochronology and geochemistry that have revolutionised our understanding of the geodynamic Earth at all scales. The development and application of LA-ICP-MS continues to grow at a dramatic rate and *in situ* analyses for elements and isotopic ratios are now performed routinely in numerous laboratories worldwide. Like other microbeam techniques LA-ICP-MS provides the benefit of high spatial resolution and produces data that can be interpreted in a microstructural context.

The development of new LA-ICP-MS methodologies has been enabled by advances in instrumentation in conjunction with studies of the fundamental processes involved in ablation and in the ICP (e.g. laser-induced elemental and isotopic fractionation, plasma loading, mass bias). The emergence of the multi-collector ICP-MS for high-precision *in situ* measurement of radiogenic (e.g. Hf in zircon [1]) and 'non-traditional' stable isotopes (e.g. Cu and Fe in sulfides) has revolutionised analytical geochemistry. On the laser front, Nd:YAG (266, 213 or 193 nm) or ArF excimer (193 nm) remain the most commonly used laser sources. In comparison with these nanosecond pulse-width systems, ablation using femtosecond lasers has been shown to approach stoichiometric sampling and reduce laser-induced fractionation effects. However the high cost of the commercial femtosecond systems has restricted their uptake.

Despite the significant advances of the last decade, the continued rapid spread and acceptance of the technology may be jeopardized while any significant analytical issues remain unsolved. The accuracy and precision of *in situ* isotope ratio measurements are inherently lower than solution measurements because of the complexity of matrix effects and corrections for mass bias and isobaric interferences. Optimising precision of elemental and isotope ratio measurements while maintaining spatial resolution brings challenges, and emphasises the need for improved understanding of measurement uncertainties and error budgets. Well characterized and readily available reference materials combined with more inter-laboratory comparison exercises are essential.

Future goals for LA-ICP-MS include a quantum increase in sensitivity, fine-scale compositional mapping of geological samples, and overcoming effects of elemental and isotopic fractionation. Elimination of elemental fractionation will accelerate development of procedures to measure major, minor and trace-element abundances without depending on matrix-matched calibration materials and independently determined internal standard concentrations.

[3]University of Manitoba, Winnipeg, Canada, bekker@cc.umanitoba.ca

[4]Universidad de la República, Montevideo, Uruguay, gerardo@fcien.edu.uy

It is widely believed that the Earth's oceans became increasingly oxygenated during the late Neoproterozoic, most notably after the end of the Marinoan glaciation approximately ~635 million years ago. However, recent geochemical data for Ediacaran sediments suggest that some deep ocean basins were instead anoxic and ferruginous [Fe(II)-enriched] throughout the Ediacaran and possibly into the Cambrian, suggesting a more complex global redox structure than previously envisioned. An apparent absence of Ediacaran iron formations (IF) presented a challenge to this emerging paradygm; these chemical sediments were common under Fe-rich conditions in the Archean and Paleoproterozoic oceans.

Here, we report detailed sedimentological, stratigraphic, petrographic and geochemical data from an Ediacaran IF and associated rocks, including 'iron-rich' black shales, siltstones and cherts of the Arroyo del Soldado Group in Uruguay [1]. The IF and cherts occur at the top of two siliciclastic units characterized by retrogradational stacking patterns with fining-upward cycles deposited during transgressive system tracts and represent two major episodes of basin flooding and sediment starvation. Geochemically, the IF and cherts have coherent rare earth element and yttrium (REY) patterns and display the essential shale-normalized characteristics of marine precipitates. REY signatures and mixing calculations show that they differ from Archean and Paleoproterozoic IF as far as high-temperature hydrothermal input did not influence their chemistry. Instead, we suggest that low-temperature hydrothermal input may account for the geochemical signatures displayed. By analyzing the REY signature of chemical precipitates (cherts and IF) and evaluating the redox chemistry of the marine water column within a sedimentological and sequence stratigraphic framework, our results confirm that ferruginous conditions dominated the pre-Gaskiers but also the post-glaciation deep-water chemistry. Therefore, global ocean oxygenation may not have occurred unitl well into the upper Ediacaran or even during the Cambrian as was recently proposed [2].

Revisited multicomponent chemical geothermometry: application to the Dixie Valley geothermal area

L. PEIFFER*, C. WANNER, N. SPYCHER, E. SONNENTHAL, B.M. KENNEDY

Lawrence Berkeley National Laboratory, Berkeley, USA, lpeiffer@lbl.gov (* presenting author)

The multicomponent chemical geothermometry method [1,2] involves computing the saturation indices of potential reservoir minerals over a range of temperatures, given a known geothermal fluid composition, then inferring reservoir temperature from the clustering of mineral saturation indices near zero. This method was automated as a stand-alone computer program (geoT), easing its application and allowing optimization of model input parameters using parameter-estimation software [3]. The code can process simultaneously multiple water compositions, and correct for dilution and mixing effects as well as gas loss. The temperature of the reservoir is estimated from statistical analysis of computed mineral saturation indices. One difficulty of the method is that it is sensitive to potentially erroneous Al chemical analyses, an issue which can be partly resolved by resorting to computed Al concentrations assuming equilibration with selected Al-bearing minerals [2].

The geothermometry method and new code are being tested on geothermal fluids from Dixie Valley (Nevada, USA) using an extensive set of water and gas analyses [4]. These data include total and dissolved ("ionized") Al analyses in filtered (0.45 and 0.2 μm) and unfiltered water samples, allowing testing the effect of these various reported Al concentrations on predicted temperatures. A set of minerals prevailing in the geothermal reservoir was assumed based on XRD data from well cuttings [5]. Gas analyses were added back to the well waters, and increased salinity effects caused by the reinjection of flashed brines into the reservoir were also considered. Using "ionized" Al concentrations in unfiltered samples, reservoir temperatures of ~250°C were obtained. These temperatures were similar to values obtained by computing Al concentrations assuming equilibrium with Al minerals (albite, microcline, muscovite). These temperatures seem reliable because they are consistent with measured downhole water temperatures. In contrast, the 0.2-μ filtered Al analyses led to lower computed temperatures close to sampling temperatures (160°–180°C) and corresponding to different equilibrated minerals. In this case, the 0.2-μ filtered Al concentrations appear too low, apparently reflecting the filtering-out of colloidal Al formed by cooling. Hot spring waters from the wider Dixie Valley area were also investigated. The lack of consistency between their reconstructed equilibrium temperatures, as well as significant differences in their chemical composition may indicate that Dixie Valley hosts several distinct reservoirs. Batch geochemical modelling and reactive transport simulations are being conducted to understand processes affecting the deep geothermal fluids on their way to the surface and to characterize the hydrologic relations between the deep reservoir and the superficial hot springs.

Microbial sulfur isotope fractionation is controlled by the energy metabolism of sulfate reducing microorganisms. It represents a well-defined and precisely measurable characteristic of the phenotype of the microorganism. As such, it is dependent both on the underlying genotype and on the response of that genotype to variability in the local environment. Since genotype and environment have both changed throughout Earth's history, the geological record of biogenic S isotopes must reflect the influence of both environmental change and molecular evolution. However, the basic interplay between microbial evolution and S isotope fractionation has not been examined.

We investigated the evolutionary response of S isotope fractionation in the sulfate-reducing bacterium *Desulfovibrio vulgaris* Hildenborough (DvH). Two bacteria – the wild type DvH as well as a mutant derived from that strain in which one copy of a gene putatively encoding lactate dehydrogenase was deleted and replaced with an antibiotic resistance cassette were used as model organisms. In defined media (sulfate and lactate limited) at 33°C, ancestral wild type and mutant DvH exhibit fractionation factors that reproducibly differ by 0.5‰. We serially transferred six replicate lines of the wild type and six replicate lines of the mutant for 600 generations in batch cultures. Over the course of the experiments, we assayed fitness through direct competition experiments between the ancestral mutant and descendant wild-type strains (or vice versa). In these competition experiments, we used qPCR to monitor the relative abundance of the mutant through a unique genetic barcode associated with the antibiotic resistant cassette. After 300 generations, the descendant strains were markedly more fit than their ancestors, with relative growth rate increases of nearly 30%. This means that the descendant strains have a clear selective advantage in the defined media, illustrating that DvH can undergo evolutionary adaptation on laboratory timescales.

Despite the clear evidence for evolutionary changes over the course of our experiment, isotopic assays of the descendant wild-type and mutant strains reveal that the 0.5‰ difference in their fractionation factors is conserved. Preservation of such a small isotope effect implies that the sulfate reducing energy metabolism is remarkably robust to the selective pressures of our experimental setup.

Discovery of metals-rich hydrothermal manganese deposits in the South-West Pacific

E. PELLETER[1]*, Y. FOUQUET[1], J. ETOUBLEAU[1], S. CHERON[1], S. LABANIEH[1] AND THE SCIENTIFIC PARTIES

[1]Ifremer c/Brest, Laboratoire de Géochimie et Métallogénie, BP70, 29280, Plouzané, France (*correspondance: ewan.pelleter@ifremer.fr)

Manganese oxides in the deep marine environment can be separated in three genetic groups: (i) hydrothermal, (ii) hydrogenetic, and (iii) diagenetic. The hydrothermal Mn deposits are characterized by low to very low contents of Cu, Ni, Co, Zn whereas the hydrogenetic Mn deposits can be enriched in a characteristic suite of trace elements (e.g. Co, Ni, Zn, REE, HFSE, Pt). As a consequence, only hydrogenetic manganese crusts and polymetallic nodules have been considered as a potential resource for some commercially important metals. Here we report on occurrence of metals-rich hydrothermal manganese deposits discovered in the south-west Pacific during a French cruise (fall 2010). These deposits occur at depth between 800m and 1800m and are controlled by volcanic structures. Volcanism is dominated by pyroclastic rocks (e.g. hyaloclastite, tuffite, pumice) at depth shallower than 1000 m and by pillow-lavas at greater depth. Mineralization occurs as crusts, meter-scale mounds and impregnations composed of well-crystallized birnessite and todorokite with variable amount of iron oxy-hydroxide and nontronite. The manganese oxides exhibit bluish-black to grey-black color with a submetallic luster typical of many hydrothermal Mn mineralizations [1]. Mn oxides are abnormally enriched in Ni (up to 4.6%), Co (up to 2.2%) and Cu (1.5%) but exhibit low REE and HFSE concentrations. Post-Archean Australian Shale-normalized REE patterns exhibit typical seawater signature with prominent negative Ce anomalies. Therefore, trace elements data point to a contribution of hydrothermal fluids for Ni, Co and Cu and a seawater contribution for REE and HFSE. Further, different genetic models to explain the mechanism for metal enrichment will be discussed.

Organic geochemisty of the Late Paleozoic black mudstone in Hailaer basin, NE China: Implications for hydrocarbon-forming potential

X.L. PENG*, N. LIU, L. LIU

College of Earth Sciences, Jilin University, Changchun, 130061,China (*correspondence: Pengxl@jlu.edu.cn)

It is being dissussed hotly that whether the Late Paleozoic strata in NE China have hydrocarbon forming potential or not. However, organic geochemical data of the black mudstones from the Late Paleozoic in Hailaer basin provides insights for that. It has been known that the Mesozoic strata in Hailaer Basin NE China, was a famous hydrocarbon accumulation zone. In addition, the outcrop rocks of the Carboniferous and Permian around the basin was in the late stage of diagenetic and low-lever metamorphic belt [1].

Amount to 39 wells of Beier and Wuerxun depression from Hailaer basin were drilled into the Paleozoic black mudstone, and the thickness of the mudstone is about 393m. In this research, organic geochemical analysis has been taken on 40 black mudstone samples from 11 selected wells. It is indicated that the TOC values ranged between 0.09% and 4.407%, with the mean value of 0.73%, and 40% samples are over threshold of the organic matter abundance (0.5).

Organic geochemical analytical data for the Late Paleozoic black mudstones in the well of Wu 9 and Bei 2 of Hailaer basin was collected from Daqing oil field. TOC values from Wu 9 (7 samples) show a mean value of 0.9%, and the maximum value is 1.66%, thus about 43% samples are moderate source rocks. The potential of pyrolysis hydrocarbon generation values are 4.4mg/g ~ 0.01mg/g (average 1.5mg/g), suggesting that 33.3% samples can be regarded as moderate source rocks. For the black mudstones from Bei 2 (29 samples), the average values for TOC and S1+S2 are 0.733% and 0.35 mg/g. The average value for IH is 26mg/g (maximum 123mg/g), showing a typical kerogen type of III. The mean values for Tmax and Ro are 433°C and 0.81, respectivety, suggested that the source rock are high maturity. Combined with the Paleozoic strata in Hailaer Basin is well-protected, we consider that this strata could have a good hydrocarbon-forming potential, and the source rocks from the Late Palezoic strata in Hailaer basin could be an ideal target for a new round of hydrocarbon exploration in NE China.

Geogas Nano Material Elements Analysis For Detecting Concealed Structures in Dashui Gold Deposit in Gansu Province, China

XIUHONG PENG[1,2], HUI DENG[3*], BO XU[1],CHENGSHI QING[1],JIANGSU ZHANG[1,4]

[1]Geochemistry Dep., Chengdu University of Technology , China

[3] State Key Laboratory of Geohazard Prevention and Geoenvironment Protection, Chengdu University of Technology (*correspondence:dh@cdut.edu.cn)
[4] Third Geology and Mineral Resources Exploration Academy of Gansu Province, Lanzhou, China

The nanoparticles in ore bodies can adsorb on gas and migrate in the updraft. It has strong penetrability which can rise vertically from the deep Earth to the surface, and creates a distribution anomaly (geogas anomaly) of nano material above the projection of ore bodies. Many scholars[1]-[2] have confirmed the prospecting effect of geogas method. From 1988 to 1999, Chunhan Tong et al. [3]-[4] had experimented on the geogas measure method in Laojie Gold Deposit in Yunnan Province and so on successively. They had successfully indicated the locations of ore bodies hundreds of meters deep underground, and observed the nanoparticles in geogas.

The dynamic geogas analysis adopted in this research is to use the pump to exact the geogas in the cover; then the nano materials will be captured by the liquid capture agent; and finally the various kinds of elements in geogas can be analyzed by ICP-MS to obtain the geogas information. Combining the geochemical exploration and the actual situation of the mine, five exploration lines and 40 elements of 139 samples were set in the survey area, including two experiment measuring lines on the known ore bodies.

Results and Conclusion

On the basis of the analysis of the trace elements and rare earth elements characteristics in ores and wall rocks, and the comparison of the geogas experimental profile, the geogas indicating elements were selected. The geogas indicating elements characteristics of the three exploration lines demonstrate that there are two concealed faults: one concealed structure and one ore-controlling structure in the survey area. The first concealed structure goes through No.7-13 measure point of Line a, No.15-19 measure point of Line b and No.7-14 measure point of Line c. The width of the structure (or the combination width of multiple microcracks) is 90-200m. The second ore-controlling structure goes through No.25 measure point of Line a, No.23-27 measure point of Line b and No.23-28 measure point of Line c. The width of the structure is about 80-100m. Because the results of radon survey is as the same as the geogas's, the prospecting exploration efforts should be greatly strengthened in the western periphery of Dashui Gold Deposit.

The study on the solubility of the vanadium system focused on Panzhihua, China

Y. PENG[1,2], Y. ZENG*[1,2]

[1]College of Materials and Chemistry & Chemical Engineering, Chengdu University of Technology, Chengdu, Sichuan, 610059, P. R. China
[2]Mineral Resources Chemistry Key Laboratory of Sichuan Higher Education Institutions, 610059, P. R. China
(* correspondence: zengyster@gmail.com)

In recent years, the interest of the relationship between microelement and human health increased. Vanadium absence may have negative effects, and it also can be toxic if exposure occurs at high enough levels. It has strong transfer ability in environment. This ability related to the solubility of vanadium in soil solution.

Panzhihua, Sichuan is an important production base of vanadium and titanium magnetite. The vanadium storage is 64% of the total vanadium in China. The vanadium mining and smelting accelerated the vanadium diffusion in soil and water. It causes special environmental problems of vanadium in Panzhihua. Different surface soil in the region, the average mass fraction of vanadium is over 100 $\times$ 10^{-6},[1] far exceeding the background values of Chinese soil vanadium 86 $\times$ 10^{-6}.[2] The amount of vanadium in the soil surrounding smelter is 16.5 times of contrast values. The amount of vanadium in the plant samples is 6.6 times of contrast values.[3]

The solubility of vanadium in soil solution is effected by coexisting ions in soil，such as potassium, sodium, phosphorus and so on. In order to investigate the relationship of solubility between vanadium and the other co-existing ion in soil, the phase equilibria of the quinary system $NaVO_3$ + KVO_3 + NaH_2PO_4 + KH_2PO_4 + $(NH_2)_2CO$ + H_2O and its five quaternary sub-systems were studied at 298 K with isothermal dissoluble method. According to the experimental results, the crystallization form of metavanadate is polyoxovanadate in the weakly acid system. The dissolution and migration of vanadium in aqueous solution has negative correlation with $H_2PO_4^-$ and $(NH_2)_2CO$. The exisiting of K^+ has little effect on the solubility of vanadium. This suggest that in similar soil environment, the solubility of vanadium was restrained by the increase of $H_2PO_4^-$ and $(NH_2)_2CO$, which can affect the transfer ability of vanadium.

Do Critical Zone carbon and water fluxes control chemical denudation?

What controls the magnitude of weathering fluxes in the Critical Zone (CZ) and how vulnerable are those fluxes towards changes in climatic forcing? We believe that these fundamental questions can be uniquely addressed through an integrative approach that includes multiyear CZ water, carbon and lithogenic element flux records using a scaling approach that bridges multiple CZ sub disciplines. Based on the theoretical framework of the Santa Catalina Mountains - Jemez River Basin (SCM-JRB) CZO, we postulate that effective energy and mass transfer (EEMT, MJ m^{-2} y^{-1},[1]) is a predictive variable for chemical denudation. This parameter can be estimated from meteorological variables, as we have done previously for our CZO [2], or it can be measured directly, as we report in this presentation. Within the CZO framework, we are now testing the hypothesis that direct hydrologic and organic geochemical quantifications of EEMT in CZ fluids are correlated with fluxes of major and trace lithogenic elements for several montane forest catchments. Rare earth elements (REE) are investigated as tracers for chemical denudation mechanisms and preliminary data on REE-organic carbon interaction indicate the importance of labile organic carbon (the biomass energy flux component of EEMT) as a key controller of chemical denudation patterns. Climatic impacts on inter-annual variations in EEMT seem to exert an overarching constraint on chemical denudation.

Modeling the hydrothermal circulation and the hydrogen production at the Rainbow site with Cast3M

FLORIAN PEREZ[1*], CLAUDE MÜGLER[1], PHLIPPE JEAN-BAPTISTE[1] AND JEAN LUC CHARLOU[2].

[1]LSCE, CEA-CNRS-UVSQ, Gif-Sur-Yvette, France florian.perez@lsce.ipsl.fr (* presenting author)

[2] Géosciences Marines, IFREMER, Brest, France Jean.Luc.Charlou@ifremer.fr

Background and Aims

On the Mid-Atlantic Ridge, the Rainbow venting site is described as an ultramafic-hosted active hydrothermal site and releases high fluxes of methane and hydrogen [1, 2]. This behavior has first been interpreted as the result of serpentinization processes. But geochemical reactions involving olivine and plagioclase assemblages, and leading to chlorite, tremolite, talc and magnetite assemblages, could contribute to the observed characteristics of the exiting fluid [2].

Objectives and methods

The predominance of one of these geochemical reactions or their coexistence strongly depend on the hydrothermal fluid circulation. We developed and validated a 2D/3D numerical model using a Finite Volume method to simulate heat driven fluid flows in the framework of the Cast3M code [3, 4]. We also developed a numerical model for hydrogen production and transport that is based on experimental studies of the serpentinization processes [5]. This geochemical model takes into account the exothermic and water-consuming behavior of the serpentinization reaction and it can be coupled to our thermo-hydrogeological model.

Results and conclusion

Our simulations provide temperatures, mass fluxes and venting surface areas very close to those estimated in-situ [6]. We showed that a single-path model [7] was necessary to simulate high values such as the in-situ measured temperatures and estimated water mass fluxes of the Rainbow site [6].

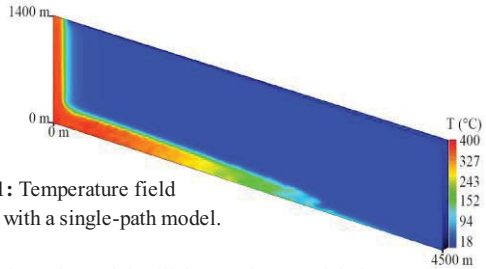

Figure 1: Temperature field obtained with a single-path model.

This single-path model will be used to model the production and transport of hydrogen at the Rainbow hydrothermal site.

El Niño impact on mollusk shell biomineralization

ALBERTO PÉREZ-HUERTA[1*], MIGUEL F. ETAYO-CADAVID[1,2], C. FRED T. ANDRUS[1], AND TERESA E. JEFFRIES[3]

[1] Department of Geological Sciences, The University of Alabama, Tuscaloosa, AL 35487, USA, aphuerta@as.ua.edu (* presenting author)
[2] BP America Inc., Houston, TX 77079, USA, metacad@gmail.com
[3] Mineralogy Department, Natural History Museum, London SW7 5BD, UK, t.jeffries@nhm.ac.uk

Marine macroinvertebrates are ideal sentinel organisms to monitor rapid environmental changes associated with climate change. Chemical proxies from mollusk shells are widely used for detecting variations in seawater parameters (e.g., temperature and productivity) related to such changes. However, the influence of known, and recurrent, climatic events on biological processes during active mineralization, and thus on shell chemistry, is still insufficiently understood.

Analysis of Peruvian cockles from the 1982-83 large magnitude El Niño event show significant alterations in shell biomineralization, linked to microstructural changes and the loss of organic matrix components. These alterations are associated to modifications in magnesium and barium content of aragonite cross lamellar shell layers, while strontium content is nearly constant throughout the event. An increase in magnesium is a possible response of the mollusk specimens to the loss of proteins and the need for the stabilization of amorphous calcium carbonate. Additionally, the increase of barium after the El Niño onset is related to upwelling. Overall, these findings contribute to a better understanding the effects of abrupt climate change on mollusk shell structures, while also offering a new view for proxy application to the reconstruction of El Niño events.

Mobility of trace elements from the Sunbury Shale, eastern Kentucky

ROBERT PERKINS[1*], CHARLES MASON[2], AND DAVID PIPER[3]

[1]Portland State University, Department of Geology, Portland, OR, USA, rperkins@pdx.edu (*presenting author)
[2]Morehead State Univeristy, Earth and Space Sciences, Morehead, KY, 40351, USA
[3]U.S. Geological Survey, Mineral Resources Group, Menlo Park, CA, USA

Black shales contain high concentrations of trace elements and may serve as important sources of strategic metals, U and REEs as conventional ore deposits become scarcer. However, the increased use of hydrofracturing for shale gas development as well as possible future mining and processing of black shales for extraction of shale oil could potentially facilitate release of toxic trace elements to hydraulic fracturing or retort process waters, surface water and ground water. Quantifying the concentrations and relative mobility of trace elements from black shales is thus important from both economic and environmental perspectives. A better understanding of trace element mobility from natural weathering of these deposits may also be of use for researchers using outrcop samples to determine paleodepositional conditions.

The Sunbury Shale (lower Mississippian) is one of the youngest units making up the thick Devonian and Mississippian black shale sequence in the Appalachian Basin. This study compares the trace element geochemistry of samples collected from two exposures of Sunbury Shale located < 8 km apart along the eastern margin of the Cincinnati Arch (western flank of the Appalachian Basin). At one site, fresh to minimally weathered samples were collected from a roadcut excavated only a month prior; the second site was a roadcut exposed for ~40 years, wherein the shale was visibly weathered. The Sunbury Shale has, on average, higher levels of trace elements than the much thicker Devonian Ohio Shale that outcrops in the study area (Perkins et al., 2008) and its 5-m thickness readily allowed for comparative sampling of the entire unit from each of the sites. The results indicate that the 40 year period of surface weathering resulted in significant ($\alpha = 0.05$) loss of some trace elements, particularly those associated with sulfides (e.g., Cd, Cu, Ni, Zn). No significant differences were found with respect to the concentrations of Cr, Mo, V that are associated with refractory phases. No significant differences were found with regards to As or Se concentrations, although these elements are also associated with sulfides. This may be due to preferential sorption of these oxyanions under the locally acidic conditions resulting from sulfide oxidation.

Atmospheric iron from crustal sources: prognostic aerosol composition in GISS/ModelE

JAN P. PERLWITZ[1], CARLOS PÉREZ[1*], RON L. MILLER[1] AND SERGIO RODRIGUEZ[2]

[1]NASA Goddard Institute For Space Studies and Dept of Applied Physics and Applied Math, Columbia University, New York, USA, jan.p.perlwitz@nasa.gov, carlos.perezga@nasa.gov, ronald.l.miller-1@nasa.gov (* presenting author)

[2]Izaña Atmospheric Research Centre, Agencia Estatal de Meteorología, Tenerife, Spain, srodriguezg@aemet.es

Introduction

The emission of aerosol iron from crustal sources is subject to significant uncertainty. Many atmospheric model studies assume spatially homogeneous total iron content at dust sources, typically 3.5% by mass. Moreover, as iron oxides and hydroxides are comprised of more than 50% iron by mass, models usually consider them as the main suppliers of dissolved iron resulting from dust deposition. A recent experiment [1] has shown a large contribution by clays - their low iron content offset by their large solubility - to the total dissolved iron from dust samples. This and other studies suggest the need for explicit representation of individual minerals in dust-climate models in order to improve our understanding of the atmospheric iron cycle and iron deposition as an input to ocean biological productivity.

Methodology

We have implemented prognostic budgets of separate mineral types into an Earth System Model: GISS/ModelE. Each mineral type (composed of iron and/or other elements) is separately transported and modified within the atmosphere. Spatially-dependent concentrations of illite, kaolinite, smectite, calcite, quartz, feldspar, iron (hydr)oxide, and gypsum are predicted by the model based on an updating of the source mineralogy proposed in the seminal work of [2]. We use downwind observations to constrain the mineral content of aerosols leaving the source.

Discussion

We evaluate model results against global observations of mineral aerosols with emphasis on multiyear measurements of size-segregated dust elemental composition at the Izaña Observatory (Tenerife, Canary Islands), situated downwind of important North African dust sources. We highlight the strengths and limitations of the source prescription of [2] and propose new strategies to represent mineral tracers in dust models.

Monomethylmercury (MMHg) is the main chemical form of mercury that threatens human populations via food consumption after its bioaccumulation and biomagnification in food webs [1]. Nowadays, Hg stable isotopes mass dependent and mass independent fractionation (MDF and MIF) is a powerful tool to identify Hg sources and transformations within the environment [2]. In aquatic ecosystems, several Hg transformations may affect Hg molecular speciation and thus Hg isotopes fractionation, inferring toughness to unravel accurately Hg isotopic signature observed in samples. The aim of this study was to investigate Hg bioaccumulation, trophic transfer and its metabolization in top predator organs, through the measurement of total Hg isotopic composition and Hg compounds (i.e. MMHg and inorganic Hg(II)) specific isotopic composition (CSIC) in the pelagic food web of the oligotrophic and remote freshwater Lake Baikal (Russia).

Carnivorous pelagic sculpins fish (Comephoridae and Cottocomephoridae families) and their predator seals (*Phoca sibirica*) were especially investigated. Significant MIF was observed in both samples with no significant differences (Δ^{199}Hg of 4.59±0.55‰ (n=27) and 4.62±0.60‰ (n=7), respectively. This high MIF was related to efficient MMHg demethylation before bioaccumulation in organism's muscles. On the other hand, Hg trophic transfer (from sculpins to seals) does not produce Hg MIF whereas MDF is likely during this process since seals muscles have δ^{202}Hg about 1‰ higher than sculpins muscles. Seals organs (liver, kidney, muscle, hair, intestine …) displayed significantly different Hg speciation, with liver and kidney mostly composed of Hg(II) whereas hair and muscle have more than 80% MMHg (figure 1).

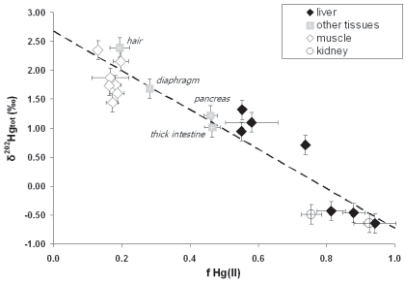

Figure 1. $\delta^{202}Hg_{tot}$ as a function of the fraction of inorganic Hg in seals tissues

Hg CSIC in seals tissues showed MMHg and Hg(II) enriched in heavier and lighter isotopes, respectively, with a δ^{202}Hg difference of about 3.2‰. MMHg demethylation in these top predator mammals was thus identified as a major process leading to MDF, but no MIF, of Hg isotopes before storage and/or elimination within the different organs, such as residual MMHg in muscle and Hg(II) in liver.

New insights on crystal growth and dissolution by investigating micro-scale entities.

MASSIMO PERUFFO[*1], MICHAEL M. MBOGORO[1] AND PATRICK R. UNWIN[1]

[1]Electrochemistry and Interfaces Group, Department of Chemistry, The University of Warwick, Coventry, CV4 7AL, UK.

M.peruffo@warwick.ac.uk (* presenting author)

Abstract

A new approach to the study of crystal growth/dissolution kinetics is reported, that involves measuring the time-evolution of entire isolated micro-crystals or micro-etch pits in macro crystals via a variety of microscopic techniques (2D and 3D). [1,2] By coupling such measurements to finite element diffusion models, the importance of mass transport to the overall rates can be elucidated readily. Furthermore the approach reveals directly plane-specific intrinsic kinetics free from diffusional effects. Investigations on gypsum ($CaSO_4.2H_2O$) highlight notable sensitivity to solution stoichiometry (Ca^{2+} and SO_4^{2-} ratio) which results in different crystal and pit morphology[3]. In summary, the method is powerful in linking microscopic observations to macroscopic rates and is expected to be of general applicability.

[6]University of Houston, TX, USA, tjlapen@uh.edu

Fourier transform infrared spectrometry (FTIR) and laser ablation inductively coupled plasma mass spectrometry (LA-ICPMS) were used to determine water, rare earth (REE), lithophile (LILE), and high field strength (HFSE) element contents in garnet and pyroxene from mantle xenoliths, Kaapvaal craton, southern Africa. Water enters these nominally anhydrous minerals as protons bonded to structural oxygen in lattice defects [1,2]. Pyroxene water contents (150-400 ppm in clinopyroxene; 40-250 ppm in orthopyroxene) correlate with their Al, Fe, Ca and Na and are homogeneous within a mineral grains and a xenolith. Garnets from Jagersfontein are chemically zoned for Cr, Ca, Ti and water contents. Garnets contain 0 to 20 ppm H_2O.

Despite the fast diffusion rate of H in mantle minerals [3], the observations above indicate that the water contents of mantle xenolith minerals were not disturbed during kimberlite entrainment and that the measured water data represent mantle values. Trace elements in all minerals show various degrees of light REE and LILE enrichments indicative of minimal to strong metasomatism. Water contents of peridotite minerals from the Kaapvaal lithosphere are not related to the degree of depletion of the peridotites. Instead, metasomatism exerts a clear control on the amount of water of mantle minerals. Xenoliths from each location record specific types of metasomatism with different outcomes for the water contents of mantle minerals. At pressures $\leq$ 5.5 GPa, highly alkaline melts metasomatized Liqhobong and Kimberley peridotites, and increased the water contents of their olivine, pyroxenes and garnet. At higher pressures, the circulation of ultramafic melts reacting with peridotite resulted in co-variation of Ca, Ti and water at the edge of garnets at Jagersfontein, overall decreasing their water content, and lowered the water content of olivines at Finsch Mine. The calculated water content of these melts varies depending on whether the water content of the peridotite (2 wt% H_2O) or individual minerals (<0.5-13 wt% H_2O) are used, and also depend on the mineral-melt water partition coefficients. These metasomatic events are thought to have occurred during the Archean and Proterozoic, meaning that the water contents measured here have been preserved since that time and can be used to investigate viscocity and longevity of cratonic mantle roots [4].

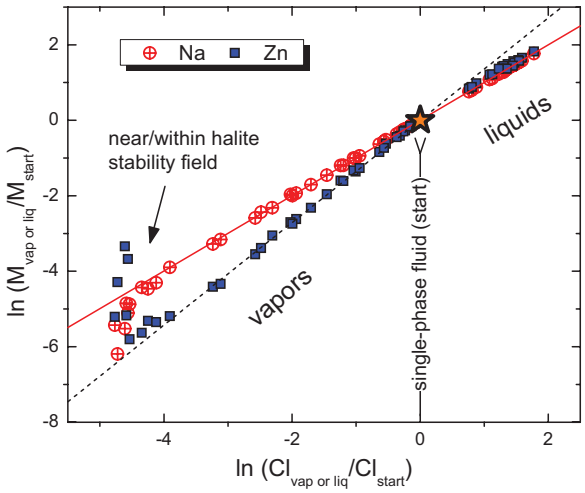
Experimental vapor-liquid partitioning of transition metals in NaCl dominated fluids

NICHOLAS J. PESTER[1*], KANG DING[1], AND WILLIAM E. SEYFRIED, JR.[1]

[1]Dept. of Earth Sciences, University of Minnesota, Minneapolis, MN, U.S.A. (* presenting author: peste005@umn.edu)

Multi-phase fluid flow is a common occurrence in magmatic hydrothermal systems, and extensive modeling efforts using empirically derived PVTx properties of the NaCl-H_2O system are frequently conducted. We have performed hydrothermal flow experiments in the near-critical and two-phase region (410-465 °C, 250-400 bars) to derive sufficiently resolute partition coefficients for some important accessory metals. NaCl solutions (3-6 wt%) containing variable amounts (1-20 mmolal) of alkaline earth and transition metal chlorides were pumped through a Ti alloy reactor with an outlet control valve capable of maintaining set pressure within ± 0.5 bars. Flow rates were optimized to obtain the equilibrium vapor phase and the coexisting liquid was then simultaneously sampled. The included figure shows Zn data as a representative example of the metals studied (shown normalized to starting composition of the single phase fluid). Na dominates phase behavior in the system, where all metal cations must be charge balanced



by Cl. The Zn/Na ratio decreases with chlorinity in the vapor phase until conditions approach halite saturation where the trend abruptly reverses with a concommitant decrease in pH (possibly due to hydrolysis). Such volatility may play an important role in concentrating transition metals in magmatic hydrothermal systems. Uniform slopes for each metal in the vapor phase equate to relative partition coefficients (Na = 1) of the order: Cu(I) ≤ Na < Fe(II) < Zn < Mg ≤ Ni(II) ≤ Mn(II) ≤ Co(II) < Ca < Sr < Ba. While the absolute concentration of such elements in natural fluids is controlled to a first order by temperature dependant mineral solubility, phase separation can be decoupled from fluid-mineral equilibria depending on flow rate/residence time. Thus, such partition coefficients can be used to aid in both geochemical modeling and reconstruction of P-T history for multiple hydrothermal fluid samples or inclusions.

Nucleation: concentration fluctuations and polymorph selection

BARON PETERS[1]

[1]University of California at Santa Barbara, Chemical Engineering, baronp@engineering.ucsb.edu

Nucleation is the stochastic process that creates the first stable embryo of a new phase to initiate a phase transition. The mechanism is poorly understood because rare events processes like nucleation present special challenges to both experiments and simulations. The difficulties are particularly acute for multi-component condensed phase nucleation processes where most applications lie. I outline recent advances toward understanding nucleation mechanisms. First, I show how the free energy landscape and dynamics for development of competing polymorphs can be understood using simulations.[1,2] Then I present a new droplet theory of nucleation that couples local concentration fluctuations to nucleus size evolution.[3] The new theory may explain why recent simulations with very different solutes show similar two-step nucleation mechanisms.

Lavern.Stasiuk@shell.com

Introduction

The subsurface geochemical distribution of non-hydrocarbon "sour" gases (H2S, CO2) in oil/gas reservoirs is controlled mainly by thermochemical sulphate reduction (TSR) and organic matter cracking of organic sulfur compounds (OSC) in high temperature reservoirs versus bacterial sulfate reduction (BSR) in low-temperature reservoirs [1]. Their subsequent interactions with the hydrocarbon phase yield organic sulfur compounds in reservoirs and can result in sulfur rich bitumen formation via natural vulcanization processes [2]-[4].

To elucidate such mechanisms as sulfur incorporation and bitumen formation, we developed an integrated experimental approach of organic/inorganic geochemical and spectroscopy methods combined with in-house modeling capabilities. With presenting the main elements of the analytical workflow involving bulk geochemical data, X-ray absorption and photoelexctron spectroscopy techniques, isotope geochemistry, fluid inclusion studies and modeling approaches, we aim for a profound understanding of gas/fluid-rock interactions involving sulfur geochemistry in the suburface realm.

The workflow was developed on stacked Upper Devonian to Mississippian sour gas reservoirs situated in the Rocky Mountains Foothills of Alberta, Western Canadian Sedimentary Basin (WCSB), Canada. Production from these reservoir units is mainly dry gas and condensates with different forms of sulfur. H_2S contents range from 5% to almost 90%.

Results and Conclusions

Preliminary data on studied bitumens from WCSB assets revealed a sequence of solid bitumens with increasing amounts of sulfur incorporated. The distribution of sulfur compounds in the bitumen matrix comprises various oxidation states from -2 to +6. Major sulfur compound classes quantified are sulfide bridged compound classes, thiols, thiophenes and sulfates.

Uniform distribution of p-process ^{174}Hf in extraterrestrial materials

STEFAN T.M. PETERS[1,2,*], CARSTEN MÜNKER[1,2]

[1]Institut für Geologie und Mineralogie, Universität zu Köln, Germany; stefan.peters@uni-koeln.de (* presenting author)
[2]Steinmann-Institut für Geologie, Mineralogie und Paläontologie, Rheinische Friedrich-Wilhelms-Universität Bonn, Germany

Nucleosynthetic heterogeneity in extraterrestrial materials is found for several (but not all) p-process isotopes, and reflects the injection of material synthesized by at least one supernova event shortly before the first solar system objects formed. Further information on the distribution of p-process isotopes is relevant to characterise the source of this "late injection" and to unravel the different nucleosynthetic processes producing p-process isotopes. Here we present high precision MC-ICPMS measurements of p-process isotope ^{174}Hf in silicate materials that have originated at different ages and from different regions within the inner solar system. ^{174}Hf is of particular interest because of its similar mass range to p-process ^{180}W, which displays large excesses in iron meteorites [1].

For Hf purification, we optimised the existing protocol by [2]. This was necessary to (1) successfully correct for the interference by isobaric ^{174}Yb; and (2) avoid matrix effects. Furthermore, we extensively tested sample cones with a large aperture ("Jet cones") in combination with an OnTool™ Booster interface pump. This setup enhances instrument sensitivity by a factor of more than 5 (ca. 3000 V/ppm Hf), but we also observed anomalous mass bias behavior in the presence of only minute amounts of matrix. All samples were therefore measured in setup with standard sample and X-skimmer cone, typically consuming ~60 ng Hf at precisions of ±70 ppm (2σ).

^{174}Hf/^{177}Hf ratios in analysed EL, H, L and CV chondrites, eucrites, and one lodranite sample are indistinguishable from the terrestrial value. In contrast, a silicate inclusion of the El Taco IAB iron meteorite and one EL6 chondrite (Pillistfer) exhibit higher ^{174}Hf/^{177}Hf ratios than the terrestrial standard, namely 190 ±72 ppm and 210 ±75 ppm respectively. These are correlated with higher ^{178}Hf/^{177}Hf ratios (18±5 and 21±5 ppm, respectively). The latter most likely result from secondary neutron capture reactions at epithermal energies due to the high Fe content of the samples [3]. The high ^{174}Hf/^{177}Hf ratios therefore most likely reflect a deficit in ^{177}Hf. ^{174}Hf itself has a low neutron capture cross-section (RI ~345 barn [4]) and is expected to be unaffected by cosmic ray interactions.

The absence of nucleosynthetic heterogeneity in ^{174}Hf indicates that either the protosolar nebula was homogenous in ^{174}Hf, or, alternatively, that existing ^{174}Hf heterogeneities had been efficiently homogenized by the time of parent body formation. The second scenario would be consistent with a single source for p-process ^{180}W and ^{174}Hf, and is therefore more plausible.

[3] LRAE (ENIS), Sfax Univerty, Sfax,Tunisia

Assessment of groundwater recharge and ages is critical to study the sustainability of groundwater resources. However, determining "active" recharge areas within large aquifer systems, such as the North-Western Sahara Aquifer System (NWSAS) remains challenging. Here, we combine three geochemical tracers (^{14}C, ^{36}Cl and U isotopes) to infer past or recent recharge and evaluate groundwater ages in the Tunisian Continental Intercalaire (CI) Aquifer, the confined aquifer unit of the NWSAS.

Thirty-two boreholes were sampled, covering the whole Tunisian part of the CI aquifer. We paid a special attention on the Dahar Mountains where CI formations outcrop (11 samples). Only two samples located in the Northern Dahar are significantly above background in ^{14}C activity (1 pmc and 1.1 pmc). Uranium content varies from 2.8 to 5×□□$^{-4}$ ppb and ^{234}U/^{238}U activity ratio from 1 to 14. The stepwise decrease in U concentration goes with a high increase of the ^{234}U/^{238}U ratio followed by a decrease, clearly indicating the occurrence of a redox front. ^{36}Cl/Cl ratio varies from 5 to □□□×□□$^{-15}$. Four samples in the upper range (35-40 ×□□$^{-15}$) are again located in the northern oxidizing region of the Dahar as revealed by U concentration. Therefore, these data all converge to indicate that mixing with recent recharge waters occur to some extent in the northern Dahar region, while the southern part of this region shows no evidence of recent recharge.

This constitutes valuable information for hydrodynamic model and comparison with direct simulation of groundwater age (e.g. age-mass approach). We will assess at the meeting the consistency of these data with flow lines of water circulation inferred from piezometric data and hydrological modelling. Crude time constraints and mixing ratios will be also estimated from the comparison between these samples and those collected from the shallower Continental Terminal (CT) aquifer closer to present-day recharge waters.

A structure refinement for monoclinic hydrohematite

KRISTINA M. PETERSON[1]*, PETER J. HEANEY[2] AND JEFFREY E. POST[3]

[1]Pennsylvania State University, Department of Geosciences, University Park, USA, kmp286@psu.edu (* presenting author)

[2]Pennsylvania State University, Department of Geosciences, University Park, USA, pjh14@psu.edu

[3]Department of Mineral Sciences, Smithsonian Institution, USA, postj@si.edu

Introduction

In ferruginous soils, nano- to micro-scale hematite (α-Fe_2O_3) plays a central role in redox processes and contaminant cycling. Hematite is known to incorporate structural OH^- and water, and the requisite charge balance is achieved by iron vacancies. Prior researchers have suggested that the defective hematite structures form unique phases called "protohematite" (PH) and "hydrohematite" (HH) [1-3]. These phases are distinguished from stoichiometric hematite (SH) by their degree of hydration and iron deficiency. Furthermore, past infrared and Raman spectroscopic studies have assigned a lower-symmetry space group to PH/HH (*R*3*c*) relative to that of SH (*R*-3*c*) [4]. However, the existence and structure of these phases has been contentious, largely due to the lack of *in situ* X-ray diffraction data [5].

Here we present a new structure refinement for HH in a monoclinic space group (*I*2/*a*) using time-resolved X-ray diffraction (TR-XRD) data collected at the Advanced Photon Source (APS). Starting with ferric chloride solutions, we collected TR-XRD data during the *in situ* hydrothermal precipitation of akaganéite and its transformation to HH. Sealed quartz capillaries (1.0 mm diameter) were heated at 200 °C while XRD data were collected every 25 – 30 seconds. Rietveld refinements suggested a new monoclinic HH structure.

Results and Conclusions

In our experiments, distinct peak splitting was observed in the hematite diffraction patterns, indicating a violation of the 3-fold rotational symmetry. The observed peak splitting in our data was outside the range calculated for sample displacement, and furthermore video footage obtained during the reaction showed particles uniformly convecting throughout the volume of the capillary. We therefore refined the structure in the various subgroups of *R*-3*c*. As the fit using *I*2/*a* was statistically no worse than that in lower symmetry groups, we selected this space group for our refinement. A monoclinic unit cell with parameters of a = 13.7493(15) Å, b = 5.0121(4) Å, c = 5.4418(6) Å, β = 147.6250(17)° provided a good fit and significant reduction in χ^2 and R_{wp} relative to S.G. *R*-3*c*. Our results demonstrate that the *in situ* formation of the defective hematite phase, HH, was successfully captured. Moreover, HH is structurally distinct from SH and may form as a lower-symmetry monoclinic phase in soils.

The microbial role in diagenetic dolomite formation

DANIEL A. PETRASH[1*] AND KURT O. KONHAUSER[1]

[1]University of Alberta, Edmonton, Canada, petrash@ualberta.ca (* presenting author)

In the Neogene, the presence of extensive dolomite intervals exhibiting multigenetic crystal morphologies, distinctive $\delta^{13}C$ signatures and variable concentrations of Fe and Mn, strongly suggest the involvement of various microbial heterotrophic pathways in both dolomite nucleation and ageing [1,2]. However, the relevance of enhanced organic burial, and the catalytic role of microbes in post-depositional dolomite formation, and as an overall control of the Cenozoic abundance of dolomite, remains to be demonstrated.

Most recently, the anaerobic oxidation of methane (AOM), typically by a consortium involving archaea and sulfate reducer bacteria, has been found to be a significant geochemical process in marine sediments [3,4,5]. The activity of microbial communities capable of AOM is usually recorded by a distinctively depleted ^{13}C signal in their carbonate by-products [3]. However, in diffusion-dominated sediments more positive $\delta^{13}C$ could be the result of an admixture of methanogenic $^{13}CO_2$, or alternatively from extensive AOM, which may also increase the residual carbon pool in ^{13}C [5]. In Neogene sequences, the occurrence of multigenic dolomite-rich intervals with $\delta^{13}C$ varying from markedly negative to positive values points to AOM as a likely mechanism of ageing, and potentially extends the microbial dolomite induction zone a few hundred meters below the sediment water interface [e.g., ref. 4].

To fully understand the burial diagenetic history of such intervals, and by extrapolation, their ancient analogues, a comprehensive analytical approach is required. For instance, in addition to the possible presence of ^{13}C-depleted lipid biomarkers [3], when compared with their near-surface precursors dolomite cements formed under the influence of syntrophic AOM should exhibit relatively higher Fe, Mn, and probably bioactive Ni, Zn and Cu concentrations [6]. Unravelling the role of AOM in dolomite formation during burial into the methanogenic zone may provide new insights into the long-standing dolomite problem.

[3]NGRI, Uppal Road, 500 007 Hyderabad, India

Overexploitation of crystalline aquifers in a semi-arid climate leads to a degradation of water quality. The Maheshwaram watershed is a typical Southern India rural watershed, with intensive groundwater abstraction (more than 700 productive irrigation wells), and a predominant paddy field cropping pattern [1-2]. We outline the process of F accumulation in this small endorheic watershed [3] where the groundwater has a high fluoride concentration of up to 4 mg l^{-1} (WHO guideline value <1.5 mg l^{-1}). The main processes responsible for the observed salt loads are probably being due mainly to irrigation return flow (IRF) and a high evaporation rate [4].

A solute recycling model that includes water/rock interactions and climatic parameters was used to assess the processes controlling fluoride contamination in a crystalline aquifer intensively exploited for paddy field irrigation. we used a 1D PHREEQC reactive-transport column [5] to conceptualize the infiltration of paddy field IRF under watershed-scale evaporation conditions.

Increase of F^- in IRF caused by evaporation and mineral dissolution (no fertilizer input) leads to the accumulation of F- in the aquifer. Crystalline aquifer overexploitation in semi-arid areas enhances geogenic pollution derived from the dissolution of fluoride-bearing minerals (fluorapatite, allanite, biotite) through a combination of complex hydrochemical processes [6]. The present model aims to provide a robust method for the development of prediction tools dedicated to aquifer management in this specific context.

Metals and microbes: imaging organic matter-mineral relationships at high resolution with STXM/NanoSIMS

JENNIFER PETT-RIDGE[1*], MARCO KEILUWEIT[1,2], JEREMY BOUGOURE[1], PETER S. NICO[3], PETER K. WEBER[1], LYDIA ZEGLIN[2], DAVID D. MYROLD[2], MARKUS KLEBER[2]

[1]Lawrence Livermore National Laboratory, Physical and Life Sciences Directorate, Livermore, CA (*pettridge2@llnl.gov)
[2] Department of Crop and Soil Science, Soils Division, Oregon State University, Corvallis, OR
[3] Lawrence Berkeley National Laboratory, Earth Sciences Division, Berkeley, CA

Advancing understanding of soil organic-mineral interactions requires disentangling the complex interactions between soil mineral surfaces, decomposed organic compounds, and soil microbes in structurally intact soil. To avoid method-related artifacts that are associated with the common physical soil fractionation techniques, non-invasive high-resolution imaging techniques have been recently developed to simultaneously determine the molecular composition, source and fate of added OM, and location of OM within soil micro-aggregates. Simultaneous high-resolution chemical characterization and isotope tracing can be achieved by combining nano-scale imaging mass spectrometry (NanoSIMS) and spatially resolved spectroscopy (STXM/NEXAFS). These techniques allow precise, high-resolution, quantitative measurement of molecular and isotopic patterns in an undisturbed sample.

In a series of recent experiments, we combined these techniques to map organic carbon distribution, and image associations of organics with specific metal-oxide minerals in soil. In these experiments, we used ^{15}N- and ^{13}C-organic matter incubations and NanoSIMS imaging to track the fate of specific microbial and plant polymers. This has allowed us to measure preferential OM associations with Fe and Mn oxides and clay particles. Using synchrotron-based scanning transmission X-ray microscopy (STXM) analysis of the same microstructures, we can then measure the molecular class of these particles, for example, thin amine N coatings covering Fe (hydr)oxides, and microbial lipids coating montmorillonite particles.

These high-resolution imaging approaches are complementary to more traditional bulk analyses (^{14}C dating, NMR, density fractionation) and can yield mechanistic explanations for proceses which influence organic matter decomposition in soil.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Investigating controls on chemical weathering in the Cascade Mountains, Oregon

JULIE C. PETT-RIDGE[1*] WILL KRETT[1], NICK CURCIO[1], AND MARKUS KLEBER[1]

[1]Oregon State University Faculty of Soil Science, Corvallis OR, USA, julie.pett-ridge@oregonstate.edu

The steep volcanic terrain of the wet western side of the Cascade Range is likely to support relatively fast weathering rates. In this study we present data from a weathering study at H.J. Andrews Experimental Forest in the western Oregon Cascades. Our goal is to better understand controls on weathering processes, namely the controls on secondary mineral formation and on the magnitude of streamwater dissolved silica fluxes.

Controls on both temporal and spatial variability of streamwater silcia fluxes are investigated using 40+ year streamwater chemistry records from 7 small gauged watersheds within the site, and using synoptic sampling data from 40 locations across the site sampled in 1 day under baseflow conditions. Three sets of paired watersheds with contrasting land-use treatments (control, clear-cut, partial timber harvest, road building) but similar topography, aspect, bedrock and vegetation do not reveal significant land-use effects on streamwater silica fluxes. Over two orders of magnitude variation in instantaneous streamwater silica fluxes across the site is observed in the synoptic sampling. Stream temperature and landscape position correlate with silica flux, suggesting that deeper hydrologic flowpaths are the source of high silica fluxes.

10 soil pits were excavated, sampled, and characterized for physical and chemical properties including clay mineral XRD analyses and selective chemical dissolutions. Paired pits were sited to compare effects of slope aspect, bedrock type, and elevation. We found that higher elevation soils that experience more permanent winter snowpack contained smaller fractions of crystalline Fe-(hydr)oxides and larger fractions of organo-metal complexes relative to lower elavation soils. Among lower elevation soils, neither slope aspect (which corresponds to 30% difference in soil water flux), nor bedrock type (basalt versus andesitic breccia and tuff) varied consistently with soil properties. In this steep mountainous terrain (average slope 60-70%), geomorphic factors such as creep and treethrow appear to play a dominant role in controlling the degree of soil profile development.

Using this and previous data from the well-characterized H.J. Andrews study site, we evaluate weathering processes observed at both soil pit and small watershed scale in the larger context of controls on weathering. Specifically, we evaluate the role of climate variables (runoff, temperature, and snowpack persistence), topography, erosion rate, and hydrologic variables (soil water flux and distributions of fluid residence time) in controlling weathering fluxes as proposed in recent studies.

The osmium isotope record of seawater: 20 years of research

BERNHARD PEUCKER-EHRENBRINK[1*] AND GREG RAVIZZA[2]

[1]Department of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, MA, USA behrenbrink@whoi.edu (*presenting author)

[2]Department of Geology and Geophysics, SOEST, University of Hawaii at Manoa, Hawaii, HI, USA ravizza@hawaii.edu

Secular variations in the $^{187}Os/^{188}Os$ of seawater were discovered twenty years ago [1]. Since then, significant progress has been made towards reconstructing $^{187}Os/^{188}Os$ variations throughout the Cenozoic, and select time intervals in the Mesozoic and Palaeozoic.

Osmium is an ultra-trace element in seawater with a residence time of less than 50,000 years, and possibly as short as a few thousand years. While initially thought to be well mixed throughout the oceans, high-precision data – including in the modern ocean - have indicated spatial variations of the order of a few percent. The residence time of osmium makes the isotope system not only ideally suited for tracing processes on time scales of glacial-interglacial variations, but also for investigating longer, tectonically driven changes on the Earth's surface.

Osmium is enriched in marine sediments that have been deposited under reducing, and - to a lesser extent – oxic, conditions. In such sediments, variations in its isotope composition - recorded as $^{187}Os/^{188}Os$ - have left a rich archive that reflects changes on the Earth's surface. The affiliation of osmium with sedimentary organic matter makes the marine $^{187}Os/^{188}Os$ record a sensitive indicator of cycling of old sedimentary organic matter. The lack of a buffering mechanism similar to the formation and weathering of marine carbonates in the $^{87}Sr/^{86}Sr$ record of seawater leads to variations that span most of the range in isotope variations between geochemical endmembers.

Here we focus on the most highly resolved events in the Cenozoic and Mesozoic that are reviewed in detail in the soon to be published chapter 8 in the *Geologic Time Scale 2012* [2]. These events fall into two categories: transient excursions to more radiogenic values that are thought to be caused primarily by hyperthermal events (e.g. PETM), and transient excursions to less radiogenic values that are caused by extraterrestrial impacts (e.g. KTB, late Eocene impacts), large volcanic eruptions (e.g., CAMP, Deccan, and Yemeni-Ethiopian flood basalts), or erosion of osmium-rich, unradiogenic lithologies at convergent plate margins (e.g. erosion of the Papuan ophiolite in the late Eocene).

Widespread anoxia may lead to rapid removal of osmium from the water column, thereby generating conditions for the predominance of local fluxes to seawater in an isotopically non-homogenous water column (e.g. Ocean Anoxic Events in the Mesozoic). In addition, the isolation and reconnection of ocean basins to the global circulation may leave an isotope fingerprint if inputs to such basins deviate from the globally averaged input of osmium to seawater (e.g. Arctic Ocean).

[2] Peucker-Ehrenbrink and Ravizza (2012) *Geologic Time Scale 2012, Chapter 8: Osmium isotope stratigraphy* (Gradstein et al., Eds.), doi: 10.1016/B978-0-444-59425-9.00008-1.

Does the naturally elevated sulfur content of *Ulva lactuca* play a role in the uptake and speciation of arsenic?

CATHERINE PHAM[1,2*], LAURENT CHARLET[2], AND GARRISON SPOSITO[1]

[1]University of California, Department of Environmental Science, Policy & Management, Berkeley, United States, pham@cal.berkeley.edu (* presenting author), gsposito@berkeley.edu

[2]Université de Grenoble, Institut des Sciences de la Terre, Grenoble, France, charlet38@gmail.com

Algae are ubiquitous in surface waters and are known to influence the chemodynamics of the priority toxic metalloid, arsenic (As), in polluted marine environments. Marine algae initially transform As(V) to As(III), after which As(III) is methylated and then converted to a diverse set of organoarsenic compounds by mechanisms that remain unclear.[1] Recently it has become evident that the common marine green alga *Ulva lactuca* contains elevated levels of sulfur (S) and has the capacity to generate toxic concentrations of H_2S in the presence of excess nitrates. In light of the fact that As is chalcophilic, it is important to understand the interaction between As, S, and nitrates in *Ulva lactuca* because the algae may serve as an As reservoir and pose an emerging threat to coastal environments where nitrate inputs are increasing.

In the present study, using synchrotron-based X-ray absorption spectroscopy and X-ray microfluorescence mapping, we investigated the bioavailability and chemical speciation of As in *Ulva lactuca* sampled from contaminated coastal waters in order to understand As cycling in the marine environment. We also conducted batch culture experiments with *Ulva lactuca* to explore the role of thiolation in As biotransformation and toxicity.

Using X-ray microfluorescence mapping, we observed trends in the distribution of S along the thallus of *Ulva lactuca*. We are investigating whether the As distribution and concentration may be correlated with areas of elevated S content along the thallus. Using synchrotron-based X-ray absorption spectroscopy, we characterized the complexation of As with S moities in environmental samples collected from industrially-polluted sites.

Our research aims to determine the potential risks As may pose to both aquatic ecosystem and human health as it is transformed into various chemical forms and moves from algae up trophic levels, potentially to fish and humans.

Natural gas leaks in Boston

NATHAN G. PHILLIPS[1*], ROBERT ACKLEY[2], ERIC CROSSON[3], ADRIAN DOWN[4], JON KARR[4], AND ROBERT B. JACKSON[4]

[1]Boston University, Boston, USA, nathan@bu.edu (* presenting author)

[3]Picarro, Inc, Santa Clara, USA, eric@picarro.com
[4]Duke University, Durham, USA, adrian.down@duke.edu, jkarr@duke.edu, jackson@duke.edu

Introduction and Methods

There are large uncertainties in the fate of lost and unaccounted gas from the natural gas process chain, including in distribution pipeline systems [1,2]. To assess the spatial pattern and typical leak rate of natural gas leaks in an urban distribution system, we drove and mapped leaks on the 785 centerline road miles in the City of Boston. We used a GPS-equipped cavity ringdown methane analyzer, sampling the air above road surfaces. Additionally, to assess leak rates, we deployed gas accumulation chamber on 25 representative gas leaks. Finally, we identified sources of methane leaks using carbon isotope analysis and human olfactory detection of the odorant mercaptan, which is added to pipeline gas.

Figure 1: Methane leaks from natural gas pipelines in the Beacon Hill neighborhood of Boston. Yellow bars represent methane concentrations in parts per million; the highest values recorded exceed 15 times background levels.

Results and Conclusions

We detected ca. 3,900 distinct elevated methane sources within the City of Boston. Isotopic and olfactory methods indicate that a majority of these methane sources are associated with the natural gas pipeline distrib ution system. Individual leak rates ranged from 28 cubic feet per day (CFD) to 315 CFD, averaging 110 CFD, more than half daily US household natural gas use. We conclude that the magnitude of gas lost by typical leaks and their frequency in urban areas like Boston have potential to amount to substantial total lost natural gas. The magnitude of lost and unaccounted gas [1] can represent several percent and more of typical total state greenhouse gas inventories, and total more than $1B nationally. Our discovery of widespread urban gas leaks provides impetus for concerted efforts to determine the total leak rate and corresponding greenhouse warming potential from natural gas distribution systems.

Isotopic constraints on the genesis of basanitic lavas beneath Haleakala

ERIN H. PHILLIPS WRITER[1*], KENNETH W.W. SIMS[1], VINCENT J.M. SALTERS[2]

[1]University of Wyoming, Department of Geology and Geophysics, Laramie, WY, USA, ephilli8@uwyo.edu (* presenting author), ksims7@uwyo.edu
[2]Florida State University, Department of Geological Sciences, Tallahassee, FL, USA, salters@magnet.fsu.edu

Although tholeiitic volcanism is predominant in Hawaii, the study of smaller volume, late-stage alkaline volcanism is imperative to understanding the magmatic history of the Hawaiian Islands and the dynamics of mantle plumes. Recent basanitic lavas from Haleakala represent an end-member in the compositional range of Hawaiian lavas and are hypothesized to tap magma from the fringe of the Hawaiian plume [1]. Indeed solid mantle upwelling rates inferred from U-series data from a limited number of samples from Haleakala [1] are consistent with both iso-viscous and thermo-viscous fluid mechanical models of plume upwelling [2,3].

However, these conclusions were based on a very small data set (5 samples) and additional isotopic data on alkaline lavas are essential for a more complete understanding of the genesis of late stage and rejuvenated stage volcanism. We present Hf, Nd, Sr, and Pb isotopic data, ^{238}U-^{230}Th and ^{235}U-^{231}Pa-^{227}Ac and major and trace-element data for a suite of 13 samples from Haleakala crater. These samples are relatively young, with ^{14}C ages ranging from 870 ± 40 to 4070 ± 50 years [4]. They are nepheline normative and LREE enriched, indicating that they represent small degree melts. Relative to main-stage tholeiites (Kilauea and Mauna Loa) and late-stage alkali basalts (Mauna Kea and Hualalai), the Haleakala crater samples come from a relatively depleted source (ε_{Nd} = 7.37-8.60; ^{87}Sr/^{86}Sr = 0.70314-0.70333; ε_{Hf} = 12.66-14.68). All samples have ^{230}Th/^{238}U >1 indicating that they originate from a source containing residual garnet. Consistent with earlier studies, the ^{230}Th/^{238}U (1.19-1.32) and ^{231}Pa/^{235}U (1.65-1.79) of these samples are much higher than other young Hawaiian lavas suggesting that basanitic lavas from Haleakala are the manifestation of a small degree of partial melting and relatively slow mantle upwelling rates.

Opening the black box: Imaging nanoparticle transport through rock with MRI

VERNON PHOENIX[1*], SUSITHRA LAKSHMANAN[1], WILLIAM SLOAN[2], WILLIAM HOLMES[3].

[1]University of Glasgow, Geographical and Earth Sciences, Glasgow, UK, vernon.phoenix@glasgow.ac.uk (* presenting author)
[2]University of Glasgow, Infrastructure and Environment, Glasgow, UK, william.sloan@glasgow.ac.uk
[3]University of Glasgow, Wellcome Surgical Institute, Glasgow, UK, william.holmes@glasgow.ac.uk

Introduction

Magnetic Resonance Imaging (MRI) is perhaps best known for its use in medicine. However, its ability to non-invasivly image inside materials that are opaque to other imaging methods is of benefit to the geological and environmental sciences. Here we report on the application of MRI to image transport of nanoparticles through sandstone. This approach is beneficial as it enables 2D and 3D 'videos' of nanoparticle transport inside rock to be collected, providing spatially resolved data from which we can enhance our understanding of nanoparticle transport in groundwater systems.

Methods

Commercially available nano-magnetite nanoparticles with an organic polymer cap were used. The superparamagnetic nature of these nanoparticles ensured they were visible to MRI. These were pumped through bentheimer sandstone rock core and MR images were collected every 5 minutes. Images were calibrated to maps of actual nanoparticle concentration using the MRI parameter T_2 (the spin-spin relaxation of ^{1}H nuclei), as $1/T_2$ is proportional to nanoparticle concentration.

Results and conclusion

Transport of positive and negativly charged nanoparticles were succesfully imaged, with transport of positivly charged nanoparticles retarded significantly due to electrostatic attraction to quartz surfaces. Images collected after flushing with nanoparticle free water showed negative nanoparticles were sucesfully removed from the sandstone, while significant quantities of positive nanoparticles remained. Concentration profiles were evaluated with CXTFIT and colloid filtration theory at regular distances along the length of the sandstone core to test for variations in dispersivity, dispersion coefficient, recovery, deposition rate constant, collision efficiency and transport –attachment efficiency. MRI's ability to collect spatially resolved data ensures it can act as a useful tool to unpick nanoparticle transport heterogeneity and test and develop transport models.

Direct Mass Spectrometric Analysis of Position Specific $\delta^{13}C$ in Organics

ALISON PIASECKI [1*], JOHN EILER[1]

[1] California Institute of Technology, Pasadena CA, USA, apiaseck@caltech.edu (*presenting author)

It is recognized that natural organic molecules can exhibit position-specific isotopic fractionations (i.e., differences in isotopic composition for a single element between non-equivalent molecular sites). For example, lipids can exhibit up to ~30 ‰ difference in $^{13}C/^{12}C$ between adjacent carbons as a result of fractionations arising during decarboxylation of pyruvate in lipid biosynthesis [1]. Little in detail is known about such isotope effects in natural products, but it seems possible that observations of isotopic ordering of carbon could distinguishing among the mechanisms and conditions of biosynthetic reactions. And, such position specific isotope effects may be inherited by alkanes produced from thermal degredation fatty acid chains, perhaps modified as functions of the conditions and mechanisms of thermal maturation.

Here we examine the potential of the MAT 253 Ultra, a new kind of high resolution gas source isotope ratio mass spectrometer [2], to make measurements that will permit reconstruction of position specific carbon isotope compositions in organic molecules, as preserved in alkanes. We focus on propane, the smallest alkane that could exhibit position specific carbon isotope differences. Electron impact ionization of propane yields three families of product ions: C1Hn, C2Hn and C3Hn; fragments made by H loss are abundant, including bare carbon ions and clusters. H adducts are present but rare. An analysis of the $^{13}C/^{12}C$ ratio of any two of these familes of product ions constrains the position specific C isotope fractionation in propane, provided such fragment species can be analyzed stably and reproducibly and one has accounted for exchange through recombination. We have demonstrated that $13CH3/^{12}CH_3$, $^{13}C^{12}CH_4/^{12}C_2H_4$, and $^{13}C^{12}C_2H_8/^{12}C_3H_8$ ratios can be analyzed with sub-per mil precision (as good as 0.1 ‰ for the most abundant species), and zero-enrichments yeild accurate results. It remains to be seen whether this approach accurately reproduces independently known position-specific isotopic differences, though the low abundance of adducts suggests recombination will not be a significant artifact; i.e., accuracies similar to the precisions reported here are expected.

Petrogenesis of alkaline mafic rocks from Sivas, Central Anatolia: New insight into ancient continental assembly and break-up

MEGAN PICKARD[1*], TANYA FURMAN[1], BILTAN KÜRKCÜOGLU[2], BARRY HANAN[3], KAAN SAYIT[3]

[1]Department of Geosciences, Pennsylvania State University, University Park, PA, USA, mup163@psu.edu (* presenting author), tfl3@psu.edu

[2]Department of Geological Engineering, Hacettepe University, Ankara, Turkey, biltan@hacettepe.edu.tr

[3]Department of Geological Sciences, San Diego State University, San Diego, CA, USA, bhanan@mail.sdsu.edu, kaansayit@hotmail.com

Alkaline mafic lavas are a common feature of intraplate extensional volcanic settings. We examine mafic lavas from Sivas, Central Anatolia, in order to understand controls on their genesis in a setting with a complex tectonic history extending over the past 1.3 billion years. Continental assembly and break-up, both associated with geochemical modifications to the associated lithosphere, has long played a significant role in Anatolia. The present tectonic regime consists of a complex juxtaposition of rift, strike-slip, and transtensional faulting and an overall WSW movement of the continental microplate.

We identify two groups of alkaline lavas that record different petrogenetic histories. Select incompatible trace element variations (e.g., Ti, Zr) indicate that abundant basalts and basaltic andesites (BBA) evolved by fractional crystallization of a frequently-erupted parental magma with ~9 wt.% MgO. The BBA lavas have overall smooth primitive mantle normalized incompatible trace element patterns that suggest derivation from a source region geochemically similar to that of ocean island basalts. In contrast, basanites erupted over a small geographic area show little fractionation but rather represent individual magma batches with different degrees of partial melting. These lavas exhibit enrichments in Ba, Th, and U and depletions in Rb, Hf and Ti that are characteristic of melts derived from metasomatized lithosphere. Pb abundances in both groups are anomalously high, though this feature is more pronounced in the basanites, suggesting interaction with a Pb-rich continental component.

In general, Sr-Nd-Hf radiogenic isotopic signatures of the BBA lavas are less radiogenic than those measured in the basanites. The BBA and basanite groups overlap in eNd-eHf isotope space, plotting on and above the mantle array between data fields for oceanic basalt-like and continental lithosphere-like compositions. The least radiogenic BBA lavas ($^{87}Sr/^{86}Sr$ 0.7040-0.7044; $^{143}Nd/^{144}Nd$ 0.51278-0.51280) approach compositions of asthenospheric melts. Radiogenic Pb isotope compositions of both groups plot within the range of Indian MORB. Nd model ages of Sivas lavas are consistent with a DUPAL-like source region with Rodinia (~1.2 Ga) continental lithosphere affinity. The observation that basanitic lavas are found only to the southeast of a major strike-slip fault suggests that post-Miocene faulting either controls or reflects significant subsurface chemical heterogeneity related to topography across the lithosphere-asthenosphere boundary.

Reduction of biogenic and abiogenic Fe(III) minerals by humic substances

ANNETTE PIEPENBROCK[1*], IRIS BAUER[2], AND ANDREAS KAPPLER[2]

[1]University of Tuebingen, Center for Applied Geosciences, Tuebingen, Germany, annette.piepenbrock@student.uni-tuebingen.de (* presenting author)

[2]University of Tuebingen, Center for Applied Geosciences, Tuebingen, Germany, andreas.kappler@uni-tuebingen.de

Humic substances (HS) have been shown to shuttle electrons between microorganisms and poorly soluble electron acceptors such as Fe(III) minerals. HS can be reduced by a wide variety of microorganisms including Fe(III)-reducing, sulfate-reducing and dechlorinating bacteria, but also chemically for example by sulfide. In contrast to the reduction of the HS, the second electron transfer step from reduced HS to the Fe(III) minerals proceeds abiotically and is controlled mainly by the properties of the Fe(III) minerals, such as their redox potential. The electron transfer from HS to the Fe(III) minerals is rate limiting for the whole electron shuttling process, but only little is known about the dynamics and limitations of this second electron transfer step itself. This is in particular the case since most laboratry studies were carried out under geochemical conditions differing significantly from those typically encountered in the environment. Thus, the importance of humic substances as electron shuttles under environmental conditions is currently unknown.

To elucidate some of the remaining questions, we aimed to quantify the rate and extent of electron transfer between reduced and non-reduced HS and various Fe(III) minerals. We focused, in particular, on the difference between reduction of biogenic vs. abiogenic Fe(III) minerals by HS. Our studies showed that more electrons were transferred from chemically reduced HS to biogenic than compared to abiogenic Fe(III) minerals. Since biogenic and abiogenic Fe(III) mineral suspensions were normalized to the same BET surface area, it could be ruled out that this outcome resulted from a difference in specific surface area between the mineral suspensions. Furthermore, our results indicate that laboratory experiments with abiogenic Fe(III) minerals might significantly underestimate the amount of electrons transferred between HS and Fe(III) minerals and, as a result, they might also underestimate the importance of HS electron shuttling in environmental systems wherein minerals might be of mainly biogenic origin. This is of great importance, since electron transfer via humic substances has the potential to contribute significantly to the electron fluxes in the environment and thus might affect the fate of organic and inorganic pollutants.

Evolution of the East Antarctic ice sheet across the mid-Miocene climate transition based on ice-rafted detritus provenance studies

E.L. PIERCE[1*], T. VAN DE FLIERDT[2], S.R. HEMMING[1,3], T. WILLIAMS[3] AND C. COOK[2]

[1]Columbia University, New York, USA, epierce@ldeo.columbia.edu (* presenting author)
[2]Imperial College, London, UK
[3]Lamont-Doherty Earth Observatory, Palisades, USA

The Mid-Miocene Climate Transition (MMCT, ~14 Ma) is an interval of major climate reorganization, accompanied by significant decreases in global temperatures and sea-level. During this interval the East Antarctic Ice Sheet (EAIS) expanded to at least 85% of its present volume, and may have transitioned from a wet- to frozen-bed regime. The geology of East Antarctica exhibits a distinct variation from the Ross Sea to Prydz Bay that allows for the application of geochemical tracers to determine the provenance of ice rafted detritus (IRD) and identify EAIS sectors that supply IRD [1,2]. Prior work from ODP Site 1165 (Prydz Bay) indicates major ice-rafting events sourced from the Adélie and Wilkes margins from late Miocene through early Pliocene, but not during the early Miocene (19-14 Ma) [3], indicating a change in EAIS dynamics and IRD production from these margins through the MMCT.

IODP Site U1356A, located off the coast of Adélie Land, is well positioned to capture the signal of iceberg discharges from this sector. Six peaks in the number of clasts >2mm between ~14.1-13.2 Ma were identified from U1356A; samples were selected across each of these to represent peak, intermediate and low clast counts. Samples were sieved at 150μm, the weight% >150μm was determined, and every hornblende grain >150μm was dated by $^{40}Ar/^{39}Ar$. $^{40}Ar/^{39}Ar$ hornblende ages from each sample show a dominant population of 1400-1600 Ma, consistent with the Mertz shear zone, but slightly younger than the coastal geology of Adélie Land (>1700 Ma), and indicating no significant sourcing of IRD from George V Land or the Ross Sea sector. Ongoing provenance work with 6 additional IRD peaks surrounding the original peaks is underway to further evaluate EAIS evolution over the MMCT.

Solid-Solution Interfacial Reactions: Effect of Solution Saturation State

ERIC M PIERCE[1*] AND SEBASTIEN N KERISIT[2]

[1]Oak Ridge National Laboratory, Oak Ridge, TN, USA, pierceem@ornl.gov (* presenting author)
[2]Pacific Northwest National Laboratory, Richland, WA, USA, sebastien.kerisit@pnnl.gov

Solid-solution interfacial reactions—specifically silica-rich inorganic surface coatings—play a critical role in the evolution of natural and engineered systems and the transport of radionuclides in the environment. For example, Nugent et al.[1] has shown that development of silica-rich inorganic surface coatings form quickly on albite samples in the field and suggests the formation of these coatings are the reason for the discrepancy between laboratory and field measured weathering rates. Similar surface-layers have been observed in weathering studies conducted with mineral-based glasses, French and Roman glass samples, and surrogate nuclear waste glasses[2,3,4]. Knowledge gaps in the fundamental understanding of alteration layer formation impede the ability to link macroscopic reaction kinetics to nanometer scale interfacial processes that occur at the surface of mineral and glasses, especially under near-saturated conditions.

Therefore to address the scientific challenge of deciphering the complex reactions controlling the formation and evolution of silica-rich surface layers; a series of flow-through experiments were conducted as a function of $a[SiO_2(aq)]$, from dilute to near-saturated conditions with respect $SiO_2(am)$, at pH(23°C) = 9.0 and T = 90°C. Results illustrate that as the saturation state of the solution increases the dissolution rate decreases by approximately two to three orders of magnitude. Furthermore, analysis of reacted grains illustrate significant changes in the elemental composition and structure of the hydrated-surface.

In addition to the afore-mentioned experimental measurements, Monte Carlo simulations are being used to gain additional insight into the evolution of the elemental profiles. Recent advances to the code developed by Kerisit and Pierce [5] enable visualization of the history of the Si sites in a reacted glass sample to determine the origin of elements that comprise the hydrated-surface layer.

Although the data collected to-date provide key information on the processes occuring at the glass-water interface, additional experimentation and modeling will be required to develop a more robust understanding of these reactions.

Voluminous magmas in intra-continental setting: Hf and O isotopes in zircons from Late Paleozoic volcanic rocks in NE Germany

PIETRANIK ANNA[1*], CRAIG STOREY[2], BREITKREUZ CHRISTOPH[3], ELŻBIETA DEJA[1]

[1]University of Wrocław, Geological Sciences, Poland; anna.pietranik@ing.uni.wroc.pl (* presenting author)
[2]University of Portsmouth, Earth and Environmental Sciences, UK craig.storey@port.ac.uk
[3]TU Bergakademie Freiberg, Geology and Paleontology, Germany, Christoph.Breitkreuz@geo.tu-freiberg.de

Voluminous rhyolitic rocks (ca. 34 000 km^3) were formed in the NE German Basin in an intra-continental setting ca. 300 Ma ago. εHf and $\delta^{18}O$ have been measured in dated magmatic and inherited rhyolitic zircons from three drill cores across the NE German Basin. Inherited zircons have crystallisation ages from ca. 1.7 to 0.5 Ga, εHf values of -20 to 7 ε units and $\delta^{18}O$ values of 5.8 to 9.3 ‰. The inherited zircons have Hf model ages of 1.9 - 2.2 Ga, indicating that much of the basement was initially derived from the mantle at that time. High $\delta^{18}O$ magmatic zircons have similar model ages highlighting that the 300 Ma magmatic event involved the melting of sediments derived from basement generated at ca. 2.1 Ga. The εHf values in magmatic zircons vary from -7 to +1 ε units and $\delta^{18}O$ = 6.0 to 9.4 ‰. The range of εHf and $\delta^{18}O$ values in magmatic zircons in the three sites investigated have been modelled by simple assimilation - fractional crystallization processes of mantle derived magma contaminated by sediments with model ages of ca. 2.1 Ga. Zircons record crystallization from magmas with 10-80 % mantle contribution, with an average of 45%. This implies that these silicic magmas contain on average 15000 km^3 of mantle derived material and that they represent a significant contribution to the net growth of the continents. Zircons from the NE German Basin have more inter-grain variability, but they record less complex magma evolution processes than zircon and whole rock data from other large silicic volcanic provinces, e.g. in North America. This is consistent with zircon crystallizing in small magma batches, which are amalgamated in larger, but short - lived upper crustal magma chambers.

The origin of chemical heterogeneity in the Hawaiian mantle plume

Inter-shield differences in the composition of lavas from Hawaiian volcanoes are generally thought to result from the melting of a heterogeneous mantle source containing variable amounts or types of oceanic crust (sediment, basalt, and/or gabbro) that was recycled into the mantle at ancient subduction zones (e.g., [1-3]). Here we investigate the origin of chemical heterogeneity in the Hawaiian mantle plume by comparing the incompatible trace element abundances of tholeiitic basalts from (1) Kilauea, Mauna Loa, and Loihi Seamount (the three active Hawaiian volcanoes) and (2) the extinct Koolau shield (a compositional end member for Hawaiian volcanoes). Model calculations suggest that the mantle sources of Hawaiian volcanoes contain variable amounts of recycled oceanic crust (ROC) from ~8-16% at Kilauea and Loihi to ~15-21% at Mauna Loa and Koolau. We propose that the Hawaiian plume contains a package of ROC (basalt and gabbro, but little or no marine sediment) that was altered by interaction with seawater or hydrothermal fluids prior to being variably dehydrated in an ancient subduction zone. The ROC in the mantle source of Kilauea and Loihi lavas is dominated by the uppermost portion of the residual slab (gabbro-free and strongly dehydrated), whereas the ROC in the mantle source of Mauna Loa and Koolau lavas is dominated by the lowermost portion of the residual slab (gabbro-rich and weakly dehydrated). The model results suggest that the large-scale distribution of compositional heterogeneities in the Hawaiian plume (at the present time) cannot be described by either a radial zonation [1] or a bilateral asymmetry [4,5]. Instead, the Hawaiian plume is heterogeneous on a small scale with a NW-SE oriented spatial gradient in the amount, type (i.e., basalt vs. gabbro) and extent of dehydration of the ancient ROC.

Introduction

The reduction of the limit for As concentration in drinking water from 50 to 10 µg/l led many resource manager to deal with expensive treatments. In the case of arsenic levels around the limit, knowing its origin and temporal evolution is of great importance. Here, a study case from an alpine basin is presented.

Results

Arsenic speciation, isotopic compositions of pyrites, sulfate and water, and major and trace element concentrations indicate a geogenic source of arsenic due to the dissolution of pyrite. New tools are provided to study As in water: $\delta^{34}S_{SO4}$ and [As] are negatively correlated, $\delta^{18}O_{SO4}$ and $[As^V]/[As^{III}]$ are correlated. A monthly monitoring of [As] in some springs started in 2005 and shows an increase of [As] compared with scattered data from 1998-2002. A 3-year monitoring at high resolution demonstrated that drought conditions enhance pyrite dissolution. The 2003 summer heat wawe had a major effect. The increase in [As] between years 1998-2002 and 2005-2011 may result from the effects of droughts.

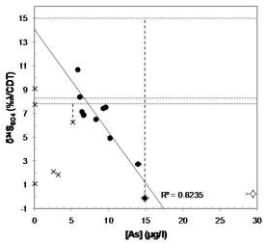

Figure 1 : Arsenic concentrations correlate negatively with $\delta^{34}S$ of dissolved sulfates. Larger As mobilization is linked with larger S-isotope fractionation resulting from larger pyrite dissolution.

Conclusions

As^V is the major arsenic species in the form $HAsO_4^{2-}$ but As originates in a more reducing environment than measured. The increase of fractionation factors leads to a negative correlation between $\delta^{34}S_{SO4}$ versus [As] and oxygen isotopes show that pyrite dissolution appears in anaerobic conditions.Temporal evolution shows that pyrite dissolution is enhanced by droughts.

The Itaju do Colônia Sodalite Litchfieldite Stock, NE Brazil

ADJANINE CARVALHO S. PIMENTA[1*], HERBET CONCEIÇÃO[1], MARIA LOURDES SILVA ROSA[1], ROBERT F. MARTIN [2], DÉBORA CORREIA RIOS[3]

[2]MacGill University, Eath and Planetary Sciences, Montreal, Canada, robert.martin@mcgill.ca
[3]Bahia Federal University, Instituto de Geociências, Salvador, Brazil, dcrios@ufba.br

General Aspects

The Itaju do Colônia sodalite litchfieldite stock is located in the South Bahia Alkaline Province (SBAP) in the São Francisco Craton, NE Brazil. It is an approximatelly 3 km^2 ellipsoidal intrusive body that cuts the Archean–Paleoproterozoic granulitic basement of the Itabuna Belt. SBAP is the unique Brazilian source of the blue sodalitites, and Itaju do Colônia is the most important of them.

Lithogeochemical and Isotopic Data

The crystallization age for these rocks is 732 ± 8 Ma (U–Pb titanite). Diverse types of syenites with variable amounts of blue sodalite constitute this massif. The contacts between syenites and granulitic rocks are sharp, and dykes and pegmatites of syenitic composition are common in those areas. In the Eastern area, a layer of massive blue sodalite (sodalitite) 6-8 m wide occurs. Nearby, the transition between sodalite–nepheline syenites and granulites show interrelated metric apophises of calcite, phlogopitite and carbonatite, in which xenoliths of blue sodalite are common. Flux structures and contact relationship suggest the coexistence of three (3) distinct magmas, that seem to be coeval in this stock: (i) Cl-rich phonolitic, (ii) thomsonite-bearing carbonatitic, and (iii) ultrafemic-ultrapotassic (calcite phlogopititic). The blue syenites show a wide range of textures and sodalite contents. They consist of sodalite, perthitic alkali feldspar, aegirine, nepheline, albite, cancrinite, annite and paragonite; the accessory minerals include calcite, zircon, titanite, apatite, and magnetite. Late fractures are filled with white minerals identified by X-ray diffractometry as natrolite, ferrihydrite, manganosite, halite, gonnardite, halloysite and "chloromagnesite". Lithogeochemical data show that these syenites are strongly fractionated ($53 < SiO_2 < 61$), have high contents of alkalis ($14 < Na_2O+K_2O < 20$); $1.5 < Na_2O/K_2O < 4.2$; and $19 < Al_2O_3 < 25$. These are peralkaline rocks with elevated amounts of chloride (Cl up to 3%), Zr (up to 20,000 ppm), Nb (up to 160 ppm), Y (up to 70 ppm), Th (up to 50 ppm) and Pb (up to 18 ppm). The REE patterns are flat, 10 to 100 times richer than chondrites, and show a strong negative anomaly in Eu.

Concluding Remarks

The new data show that the crystallization of the Itaju do Colônia syenites resulted from a magmatic system in which Cl-rich phonolitic, carbonatitic and ultrafemic-ultrapotassic magmas have developed late and bear complex relationships. *Acknowledgments: This work was supported by CNPq, CBPM and FAPITEC.*

Epitaxy of calcite on dolomite and kutnahorite (104) surfaces

CARLOS M. PINA[1*], CARLOS PIMENTEL[1], AND ENRICO GNECCO[2],

[1] Departamento de Cristalografía y Mineralogía, Universidad Complutense de Madrid, Spain, cmpina@geo.ucm.es; cpimentelguerra@gmail.com. (* presenting author)
[2] IMDEA Nanociencia, Madrid, Spain, enrico.gnecco@imdea.org.

Carbonate minerals with dolomite-type structure show an anomalous reactivity in aqueous environments. Two examples of this are the complex dissolution paths of kutnahorite, $Mn,Ca(CO_3)_2$, in pure water [1] and the growth inhibition of dolomite, $Mg,Ca(CO_3)_2$, from supersaturated aqueous solutions at ambient conditions, i.e."the dolomite problem" [2]. Key to resolving the problems linked to the reactivity of these minerals is the systematic investigation of the interaction between their surfaces and aqueous solutions with various compositions and saturation states [3,4].

Here we present Atomic Force Microscopy (AFM) observations of the epitaxial growth of calcite on dolomite and kutnahorite (104) faces at room temperature. Growth was promoted by immersing freshly cleaved dolomite and kutnahorite crystals into highly supersaturated aqueous with respect to calcite ($20 < \beta_{calcite} = [a(Ca^{2+})\cdot a(CO_3^{2-})/K_{sp,calcite}] < 100$). Epitaxial growth of calcite occurs by both the spreading of thin layers and the nucleation and growth of oriented three-dimensional islands on (104) substrates. While the growth of calcite thin films is highly anisotropic, the nucleation of 3D-islands occurs preferentially on step edges. This indicates relatively large substrate-overgrowth interfacial energies. Moreover, sequences of AFM images of 3D-islands show that spiral growth on simple or multiple screw dislocations is frequent. The presence of such dislocations can be related to the accommodation of lattice-misfit strains as epitaxial growth proceeds. Additional information provided by recording lateral (friction) forces during the scan with increasing loading forces indicates low adhesion forces between 3D-islands and (104) substrates.

Our AFM observations show that the epitaxial growth of calcite on dolomite and kutnahorite (104) surfaces is a complex phenomenon that leads to the formation of surface patterns at the nanometric scale. The development of such patterns is discussed considering the factors that control the epitaxial growth modes, i.e. Frank-Van der Merwe, Volmer-Weber and Stranski-Krastanov [5].

Next generation of *in situ* chemical analysis of Titan aerosols via laser desorption mass spectrometry

VERONICA PINNICK[1,2*], JOSHUA SEBREE[1], XIANG LI[1,2], MELISSA TRAINER[1], WILLIAM BRINCKERHOFF[1], PAUL MAHAFFY[1]

[2]University of Maryland, Baltimore County, Baltimore, MD, USA

Laser desorption mass spectrometry is an attractive analytical tool for the search for organics in space flight missions. Laser desorption provides complementary information to that obtained via the more ubiquitous methods like pyrolysis GC-MS and EGA because it provides molecular information without the need for sample heating. It is also well suited to space flight missions due to the relative ease (or complete lack) of sample preparation. Many mass analyzers have been used in previous missions, such as time-of-flight and quadrupole mass spectrometers, but ion traps in particular have the potential to operate at higher pressures with lower power requirements. One such space flight mission in the development phase is the Mars Organic Molecule Analyzer (MOMA), aboard the joint NASA/ESA rover ExoMars set to launch in 2018. There, Martian soil core samples from a depth of ~2 meters will be interrogated by either pyrolysis gas chromatography or laser desorption mass spectrometry in ambient atmospheric conditions. The mass analyzer is a linear ion trap, capable of providing chemical structural analysis via tandem mass spectrometry (MS/MS). A similar mass spectrometer can also be used for analysis of atmospheric particulates, if collected or concentrated properly. Potential applications could include the analysis of Titan's atmospheric components or deposited organic material on the surface.

To better understand the instrumental response to Titan-like aerosols, a series of aerosol analogs have been generated via far-UV irradiation of relevant Titan precursors. Aerosols are collected and deposited onto a sample plate interfaced to a commercial version of the MOMA instrument (Thermo MALDI LTQXL). By exploring different aerosol precursors, we are able to test sensitivity of the instrument to different chemical characteristics of the aerosol, including pure hydrocarbons, nitrogen-containing compounds, and large aromatic structures. We will present mass spectrometric results for the range of synthesized analog aerosols; for example, we will compare the spectra of benzene-sourced aerosol to those sourced from the nitrogen-heteroatom equivalent pyridine. These results will highlight the compatibilty of the laser desorption method to give abundant molecular and fragment ions for these classes of compounds. Further, the results from the commercial instrument will be compared to analyses utilizing the prototype MOMA instrument, currently in development.

[5] The University of Tokyo, AORI, Kashiwa, Japan
ntaka@aori.u-tokyo.ac.jp

N, He, Ar and Pb isotopic compositions were measured in pyroxenes and amphiboles from Monteregian Hills (Québec, Canada) rocks in order to constrain the mantle sources that originated this alkaline igneous province, a controversial issue lasted for more than 30 years. Most common hypothesis is that Monteregian Hills formed by the passage of the North-American craton over the Great Meteor hotspot [1]. However, melting of subcontinental mantle and magma rising through faulting related to the Cretaceous North-Atlantic opening has been also advocated [2].

Noble gases and N were extracted by crushing. Measured He, Ar and N isotopic and elemental compositions are partially fractioned by magma degassing and fluid-rock interactions during magma ascent. In contrast, $^{40}Ar/^{36}Ar$ ratios are not fractionated, but diluted by an atmospheric/crustal source. An observed correlation between the $^{40}Ar/^{36}Ar$ and $^{208}Pb/^{206}Pb$ ratios suggests two-component mixing. The first component may be related to a plume source with high $^{208}Pb/^{206}Pb$ ratios (≤ 2.06) and moderate $^{40}Ar/^{36}Ar$ ratios (~ 1,200) that are less than the values of depleted mantle ($^{40}Ar/^{36}Ar$ =35,000). The second component shows lower $^{208}Pb/^{206}Pb$ ratios (≤ 1.95) and near-atmospheric $^{40}Ar/^{36}Ar$ ratios (~ 300) and could be related to a recycled source such as HIMU.

Although measured $N_2/^{36}Ar$ ratios are diluted by an atmospheric-like source, they show an inverse correlation with $^{206}Pb/^{204}Pb$. This correlation is interpreted as the mixing between a recycled component (HIMU) and an ambiguous mantle source that could be either a plume source or the depleted mantle. Indeed, the non-fractionated $\delta^{15}N$ values for this mantle source are close to -8‰, which favors a depleted mantle source similar to that feeding N-MORBs ($\delta^{15}N$ = -5±2‰). Consequently, a part of the volatile budget might have a depleted mantle isotopic signature. This study shows the great potential of coupling radiogenic isotopes together with Ar and N isotopes. Nitrogen and argon are efficiently recycled in the mantle and thus can be helpful in discriminating the crustal and mantle sources in oceanic and continental volcanism.

The nearly-primary magmas at the Phlegraean Volcanic District (Italy): new insights by the isotope and trace element whole-rock and in-situ melt inclusion geochemistry

PIOCHI MONICA[1]*, DE ASTIS GIANFILIPPO[2], MORMONE ANGELA[1], MORETTI ROBERTO[3], ZANETTI ALBERTO[4]

[4]Isituto di Geoscienze e Georisorse, Consiglio Nazionale delle Ricerche, Pavia, Italy, zanetti@crystal.unipv.it

The Phlegraean Volcanic District in Italy, including Procida and Ischia islands and the Campi Flegrei caldera, homes to recent volcanism, impressive geothermal system and high volcanic risk. Here, as well along the eastern Tyrrhenian Sea edge, the role of genesis and evolution on magma compositions is continuously debated because of the lack of mantle-derived xenoliths, the paucity of primary rock compositions and the large variability of isotope rock geochemistry. The debate also extends to the significance of high-temperature fumaroles, the origin of which is directly attributed to a deep source, as to the mystery of its geochemical features beneath the Campania. We focus on the least evolved shoshonite that belongs to the sole Procida and defines a roughly common whole-rock chemical trend with the Campi Flegrei products. The new data concerns with: 1) O isotopes for whole-rocks and mineral phases; 2) mineral and glass in-situ major oxide geochemistry by Electron Microprobe; 3) in-situ trace element geochemistry on olivine-hosted melt inclusions and glassy matrix by Laser Ablation Inductively Coupled Plasma Mass Spectrometry and 4) in-situ halogen and B isotope in the olivine-hosted melt inclusions by Secondary Ion Mass Spectometry. These new data on glass and mineral have incremented the diagnostic power of the available information on the geochemistry and isotope Sr, Nd, Pb, B, O and He-systematics of the Phlegraean whole-rocks, supporting the idea that the Procida magmas are the primitive end-member for the Campi Flegrei caldera volcanism. The $\delta^{18}O$ values are <5.88‰ for the Procida samples, wherea the highest values (>7.79‰) characterize the Campi Flegrei samples. The lowest $\delta^{18}O$ is associated with low $^{87}Sr/^{86}Sr$ ($\geq$0.70561), high Mg#, Cr, Ni and $^{3}He/^{4}He$ ($\leq$4.76-5.47Ra) values and Fo-richer olivines; instead, the heavy Sr and He isotopes always increase in the Campi Flegrei rocks. Procida also shows $^{143}Nd/^{144}Nd \leq 0.512553$ and $\delta^{11}B$=-3÷-8‰, higher with respect to the Campi Flegrei. REE produce fractionated patterns with Eu negative anomalies that are absent in the Procida melt inclusions and variously developed in the most evolved Phlegrean glassy matrix and whole-rock. Trace elements are typically enriched with respect to the Enriched MORB composition, with positive spikes for Pb. Interestedly, analyzed Procida melt inclusions mime the OIB composition, although showing very high Cs and Pb and moderate Rb, Ba, Th and U enrichments, as well as Nb and Ti depletions. The detected variation appears correlated to crystallization depth of mineral phases suggesting the main role of evolutionary processes within the crust at the Campi Flegrei caldera.

From many thousand tons to the laboratory balance pan

Francis F. Pitard [1]

1. Francis Pitard Sampling Consultants, LLC, Broomfield, Colorado, USA. fpsc@aol.com

ABSTRACT

We could define an unshakable optimist as someone who sincerely believes that the analysis of a few milligrams by micro-XRF, ICP-MS, or other sophisticated techniques may be representative of a several-thousand-ton ore block in a mountain or of a full shipment of any commodity traveling around the world. The many steps involved between the many orders of magnitude in weight changes are often dismissed as the steps that will totally ruin the analyst efforts. The assumption that the final analytical subsample is representative of the bulk from which it originated is an audacious one and extreme precautions involving theory and practice must be taken. Unfortunately, many important steps are too often casually addressed at best and the ultimate fault is too often attributed to the incompetence of the analyst, disregarding causes arising out of improper sampling and subsampling. Furthermore, at the laboratory, the most probable assay result is not independent of the weight of the selected subsample analyzed. Case histories are summarized. Solutions borrowed from the well-established Theory of Sampling are suggested. Appropriate sampling and subsampling diagrams providing good visual indicators are recommended. Precautions for the development of Standard Reference Materials are also listed.

The Upper Pennsylvanian Hushpuckney Black Shale Member from the Swope Formation in Kansas: Rhenium – Osmium Isotope Systematics, and the Highly Siderophile Elements.

LYNNETTE L. PITCHER[1*], E. TROY RASBURY[1], RICHARD J. WALKER[2], W. LYNN WATNEY[3]

[1]Stony Brook University, Stony Brook, USA (*presenting author: llpitcher@live.com, erasbury@notes.cc.sunysb.edu)
[2]University of Maryland, College Park, USA rjwalker@umd.edu
[3]Kansas Geological Survey, Lawrence, USA lwatney@kgs.ku.edu

The Pennsylvanian Hushpuckney "core" black shale of the Midcontinent USA has been well studied geochemically and stratigraphically, but lacks Re, Os, and other HSE (Ir, Ru, Pt, and Pd) data. We studied eleven samples from interpreted anoxic and euxinic intervals of four cores and found highly uniform chondrite-normalized HSE patterns. The concentrations are as follows: Os (0.27-9.8), Ir (0.02-0.07), Ru (0.04-0.31), Pt (3.0-11.3), Pd (0.32-13.3), and Re (34.6–1,827), in parts per billion. The Re-Os data show significant scatter on a $^{187}Re/^{188}Os$ versus $^{187}Os/^{188}Os$ isochron plot but give the expected early Kasimovian (Missourian) age of 306 Ma. The HSEs and Mo were used to consider geological processes that might have influenced the Re-Os systematics, and caused the extraordinary spread in $^{187}Re/^{188}Os$ (713-9122). Chondrite-normalized HSE patterns are similar to that of seawater, but with slightly higher relative Re and slightly lower relative Os, consistent with the interpretation that the Midcontinent Seaway had a fairly unrestricted opening to the global ocean. Rhenium and Mo show a positive correlation that suggests sulfidic conditions were, in part, responsible for Re enrichment.

It has been suggested that high Re concentrations from late Permian black shales reflect the unusual conditions during that interval, including warming deep water temperatures and increasing ocean acidity, which were linked to the deterioration of environmental conditions at the end of the Permian[1]. The Re concentrations and $^{187}Re/^{188}Os$ from the Hushpuckney black shale are higher than any reported from the late Permian, suggesting environmental deterioration is not the only reason for late Permian Re enrichment (Fig.1). More data from across the interval that represents the time of unification of Pangea (Early Carboniferous to Late Permian) may offer further insight into processes that control availability of HSE in black shales.

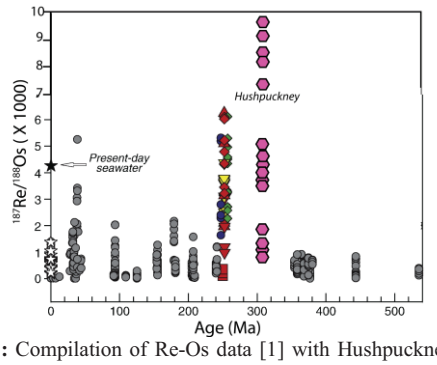

Figure 1: Compilation of Re-Os data [1] with Hushpuckney data shown for comparison.

Natural organic matter roles in floc/sediment Pb dynamics

JANINA PLACH[1*] AND LESLEY WARREN[1]

[1]McMaster University, School of Geography and Earth Sciences, plachj@mcmaster.ca (* presenting author) warenl@mcmaster.ca

Introduction

Natural organic matter (NOM) is a fundamental component of freshwater ecosystems and a geochemically significant substrate for lead (Pb) transport, retention and fate in watersheds. Although Pb release into the environment by atmospheric deposition has declined in recent decades, concern remains whether Pb remobilization from sediments (e.g. pH driven Pb solid-solution partitioning) and subsequent transport by soluble organic-Pb complexes and floc-aggregates may continue to pose risk to freshwater ecosystems. As such, the objectives of this study were to: (1) investigate Pb and NOM distributions among suspended floc, surficial bed sediment and water-column compartments; (2) identify the important solid phases for Pb sequestration in floc and surfical bed sediments; and (3) establish the role of pH (pH 5-8) impacting dissolved organic carbon (DOC) and Pb solid-solution partitioning from natural limnetic floc, as well as lake, stream and wetland sediments both *in situ* and under controlled laboratory settings.

Results and Conclusions

Water, floc and sediments were collected for aqueous Pb and NOM analysis across nine highly variable freshwater (wetland, stream, lake) ecosystems of Ontario, Canada. Results indicate soluble organic-Pb complexes dominated Pb aqueous species in NOM-rich environments. Surficial sediments and floc showed distinct Pb sequestration and solid-solution partitioning patterns across sites driven by differential roles of living versus refractory NOM within each compartment. Stable organo-Pb complexes dominated sediment Pb solid-solution partitioning, as mobilization of DOC and Pb occurred with increasing pH from NOM-rich sediments, while Pb release was inhibited from NOM-poor sediment. In contrast, amorphous Fe oxyhydroxides, collected by microbes and extracellular polymeric substances, were the best predictor of floc Pb solid-solution partitioning and the key floc Pb sequestration phase across sites. These results and their implications for Pb mobility in freshwater catchments from upstream NOM-rich wetlands through to downstream NOM-poor littoral lake environments will be presented.

Significance of sulfidic organic-rich Archean shales

NOAH J. PLANAVSKY[1], CLINTON T. SCOTT[2], CHRIS REINHARD[1], BOSWELL WING[2], TIMOTHY W. LYONS[1]

In the past few years multi-proxy studies of black shales have transformed our view of the evolution of Precambrian Earth system processes[1-4]. Part of the utility of black shale studies lies with our ability to tie them to well-understood modern and Phanerozoic analogs. Geochemical signatures in black shales have the potential to hold information about concentrations of key trace nutrients, the emergence of an oxidative biosphere, and the onset of significant oxidative weathering. However, there have been relatively few truly comprehensive, multi-proxy studies of Precambrian units, which has made it difficult to delineate temporal trends from the black shale record and to evaluate the significance of emerging geochemical results. This problem is particularly acute for the Archean. To fill this gap, we have conducted a multielement (C-S-Fe-trace metal) biogeochemical study in black shales from several (ca. 2.7 Ga) drill cores within the Abitibi Greenstone belt in Ontario. We are particularly interested in the Abitibi since it was a strongly hydrothermally influenced basin.

The shales are marked by variable but in some cases extremely high organic carbon concentrations (up to 32% TOC). C-S-Fe systematics and simple sediment dilution calculations suggest that oxygenic photosynthesis was the primary source of organic carbon in the basin. Further, our data reveal a sustained and spatially widespread episode of Fe-limited pyrite formation under an anoxic water column. The Abitibi work, therefore, supports the emerging view that euxinic conditions where a common feature in productive Archean settings. Trace metal systematics allow us to tease apart the influence of hydrothermal systems on abundances of bio-essential metals in Archean anoxic oceans. We will foucus on Mo, Zn, Cu, and U systematics and co-variation.

Water loss from melt inclusions in pyroclasts of differing sizes

TERRY PLANK[1*], ALEX LLOYD[1], PHILIPP RUPRECHT[1], ERIK HAURI[2], WILLIAM ROSE[3]

[1]Lamont Doherty Earth Observatory, Columbia Univ., Palisades, NY, USA, tplank@ldeo.columbia.edu (* presenting author)

[3]Michigan Tech Univ, Houghton, MI, USA, raman@mtu.edu

Our understanding of the pre-eruptive H_2O contents of parental magmas has come to rely on the measurement of olivine-hosted melt inclusions, and yet there is increasing recognition of the potential short-comings of olivine as a perfect container of undegassed melt. Several laboratory experiments have now demonstrated how melt inclusions can lose or gain H_2O through host olivine on short timescales (hours to days), relevant to eruptive processes. Here we have designed an experiment using natural tephra samples that cooled at different rates: ash (≤ 1 mm diam.), lapilli (2 cm), and bomb (6-7 cm) samples that were deposited on the same day (10/17/74) of the sub-plinian eruption of Volcán de Fuego in Guatemala. Ionprobe, laser ablation-ICPMS and electron probe analyses of olivine-hosted melt inclusions yield a similar range in major element (50-59% SiO_2), trace element (Ba/Zr = 4-6) and olivine compositions (Fo#72-79) in the different clast populations, that also match the range in the host bulk tephra and groundmass. Melt inclusions from the ash and lapilli samples record the highest H_2O contents, up to 4.4 wt%. On the other hand, melt inclusions in the bomb samples indicate up to 30% lower H_2O contents (loss of ~ 1 wt% H_2O), despite similar S, CO_2 and K_2O concentrations, consistent with the longer time available for re-equilibration with degassing magma through the olivine. Inclusions from bombs also record up to 10% post-entrapment crystallization of olivine, while those from the ash samples record none. Thus, taken at face value, melt inclusions from small bombs may lose H_2O and crystallize olivine within the 10 minutes maximum that it takes for a 3-4 cm radius bomb core to cool conductively. This could only occur if the fast redox exchange mechanism for H diffusion in olivine were operating (D ~ 10^{-9} to 10^{-10} m^2/s). On the other hand, several lines of evidence point to some of this water loss also occurring pre-eruptively, during magma ascent and degassing in the conduit. Some of the smallest melt inclusions (< 50 micron diameter) within ash and lapilli appear to have lost up to 10% water, and yet sufficient time is not available during post-eruptive cooling to allow this even given the fastest known H diffusivities. Moreover, inclusions selectively sampled from the outer cm of bomb clasts record greater water loss than those in 1 cm radius lapilli, consistent with a longer timescale for H_2O loss for all the bomb magma, and not just the slowly cooled bomb interiors. Thus, our results point to both slower post-eruptive cooling and slower magma ascent affecting bomb melt inclusions, leading to H_2O loss over the timescale of 10 minutes to hours. The important implication of this study is that a significant portion of the published data on H_2O concentrations in olivine-hosted melt inclusions may record some H_2O loss and not primary water, particularly for samples taken from lavas or bombs, or small inclusions (< 40 microns diameter) in general. Future sampling and analysis should bear these considerations in mind.

Characterisation of the Cr isotopic signature of marine sediments deposited in the S1 Mediterranean sapropel

The record of past changes in the dissolved oxygen concentration of seawater is crucial for understanding past climate changes, and for predicting future climate scenarios. Initial measurements of chromium (Cr) stable-isotope fractionation showed the potential of Cr as a tracer of dissolved oxygen concentrations in groundwaters (Ellis et al., 2002). More recently, analyses of ancient marine carbonates and banded iron formations have revealed large variations in $\delta^{53}Cr$ values, from -0.28 to 5.00‰, (Bonnand et al., 2011; Frei et al., 2009, 2011), which are distinct from the continental crust and terrestrial mantle (~-0.12 ‰; Schoenberg et al., 2008) and are interpreted to reflect past variations in seawater oxygenation.

In order to fully assess the validity of this new proxy, the effects of post-depositional diagenesis on Cr and Cr isotopes need to be quantified. To this end, we will present the results of analyses of Cr isotopes in sediment cores that record the deposition of the most recent eastern Mediterranean sapropel (S1) between 7 and 10 ^{14}C kyrs BP. The sapropel has experienced heavy diagenetic alteration which is revealed by the presence of maxima in the concentration of many redox-sensitive elements outside of the sapropel layer (Thomson et al., 1995). The Cr data will be compared with these other redox-sensitive elements, and measurements of the Cr isotopic composition of seawater samples that have different levels of dissolved oxygen. These new data will allow us to assess the mobility of Cr during diagenesis and the robustness of Cr isotopes as a redox-proxy.

New approaches for the prediction of contaminated neutral drainage

BENOÎT PLANTE[1*], BRUNO BUSSIÈRE[2], AND MOSTAFA BENZAAZOUA[3]

[1]Université du Québec en Abitibi-Témiscamingue (UQAT), Institut de Recherche en Mines et Environnement (IRME), benoit.plante@uqat.ca (* presenting author)
[2]UQAT, IRME, bruno.bussiere@uqat.ca
[3]INSA-Lyon, mostafa.benzaazoua@insa-lyon.fr

Context and objectives

Contaminated neutral drainage (CND) is the presence of metal concentrations above regulatory requirements at circumneutral pH in mine drainage [1]. The generation of CND by tailings and waste rocks is a growing concern for the mining industry due to increasingly restrictive regulatory requirements. Difficulties in CND prediction arise from the low oxidation rates of sulfide minerals and from the metal retention potential within the wastes. The latter induces an important delay in the formation of CND conditions [2]. For now, it is not possible to account for this delay using prediction techniques developed for acid-mine drainage (AMD) prediction, such as humidity cells, columns and lysimeters. This presentation aims to present (1) the main differences in AMD and CND predictions, and (2) new approaches currently under study for CND prediction.

Overcoming the metal retention prediction challenge

The main challenge of CND prediction is to quantify the metal retention potential of mine wastes, especially when sorption phenomena are involved in metal retention [1]. Three approaches are currently used to overcome this difficulty. Firstly, the sorption potential is estimated using batch sorption studies [2, 3]. The second approah consists of artificially saturating the sorption potential of the mine waste [4]. This can be done by contact with a contaminated leachate in sorption-enabling conditions until saturation of the retention potential. These approaches both require that the possible metals involved in CND are known prior to the tests, which require an exhaustive material characterization. Although they enable the qualitative estimation of the retention potentials of mine wastes, their results are virtually impossible to scale up from the lab to the field. A third approah currently under study is to inhibit metal sorption at the source using complexing agents. The ideal complexing agent for this matter would inhibit sorption phenomena by chelating the metals generated by sulfide oxidation, therefore disabling it from any other geochemical reaction, while it would not interfere with any other geochemical processes involved.

Conclusion

New approaches are currently developped to define the sorption potential and its impact in the mobilization of metals for CND prediction. These approaches will help in the development of a CND-specific protocol for the prediction of mine drainage quality.

Impact of biological Mn(II) oxidation on the fate of subsurface U(IV)

K.L. PLATHE[1*], S-W. LEE[2], Z. WANG[3], D.E. GIAMMAR[3], B.M. TEBO[2], J.R. BARGAR[4]; R. BERNIER-LATMANI[1]

[3]Washington University in St. Louis, St. Louis, MO, USA
[4]Stanford Synchrotron Radiation Lightsource, Menlo Park, CA, USA

Uranium contamination of the subsurface, resulting from mining and processing of the radionuclide, is a concern in numerous locales. The oxidized form of U, hexavalent uranium (U(VI)), is soluble and mobile. Therefore, understanding its fate and transport is critical for the management of contaminated environments. U(VI) can be biologically reduced to U(IV) species that are less soluble, such as the mineral uraninite (UO_2) or monomeric U(IV). Stimulating biological activity in the subsurface has emerged as a possible remediation strategy for uranium contamination and would result in the formation of an *in situ* waste form consisting of U(IV). However, the long-term stability of U(IV) in the subsurface is still poorly understood. In particular, the formation of biogenic manganese oxides, known to rapidly oxidize UO_2 [1], may significantly impact the persistence of U(IV). This study focuses on probing the occurrence of Mn oxidation in the subsurface at a U contaminated site (Rifle, CO USA) and the ultimate fate of U in the system. Agarose gel pucks, containing Mn oxidizing spores and reduced U, were prepared as initial probes of the U/Mn redox system to determine if U(VI) was released from the gel after oxidation of U(IV) by Mn oxides. Initial results indicate extensive Mn oxidation within gels and almost no release of U from the gels after a month. U was present as U(VI) in the gels and X-ray absorption results indicate it may be a sorbed species. To investigate such reactions at the field scale, columns containing sediment previously enriched with reduced U *in situ* were prepared for deployment in the same aquifer's sub-oxic zone under Mn oxidizing conditions. Initial results from these experiments indicate U oxidation and release over a two month period. In order to more accurately pinpoint cause and effect in this system, laboratory columns were prepared with the same sediment and artificial groundwater. These experiments will determine the relative contribution of O_2 and Mn(IV) to U(IV) oxidation. Furthermore, TEM and XAS analysis of both field and lab sediments will determine spatial location of U in relation to Mn. These combined methods will give a more detailed view of the interactions between Mn and U in the subsurface. Because bioremedation technology is contingent on the product being stable, this is valuable information which can help evaluate the viability of future remediation approaches.

Caveats for assessing crystallinity in biogenic minerals

BEN XU, MICHAEL GRUDICH, AND KRISTIN M. PODUSKA*

Memorial University, Department of Physics and Physical Oceanography, St. John's (NL), Canada, kris@mun.ca (presenting author)

Assessing local and long-range order in biogenic minerals

The degree of structural order within biogenic minerals is key for understanding the temporal evolution of mineralization in biological systems.[1] Standard material characterization techniques, including Fourier transform infrared spectroscopy (FTIR) and X-ray diffraction (XRD), are widely used to assess structural differences in biogenic magnesium calcites and carbonated hydroxyapatites.[2,3] However, no single measurement tool can adequately assess both local order (as can be done with FTIR) as well as long-range periodicity (as can be done with XRD). In this work, we identify serious pitfalls that can occur when trying to extract details about the structural order in a mineral from broadened spectroscopic or diffraction peaks. We also show that these challenges can be addressed by using relatively simple analyses to track FTIR spectral changes in amorphous and poorly crystalline materials with biogenic, geogenic, or anthropogenic origins.

Results of diffraction-limited infrared spectroscopic studies

Comparisons between FTIR transmission spectra from conventional bench-top instruments and data collected under spatially resolved, diffraction-limited conditions at the Canadian Light Source (Mid-IR beamline) highlight that there are both structural (material-specific) and measurement geometry contributions to spectral line widths. These conclusions are based on auto-correlation analyses[4] applied to spectra from a series of calcite samples with different particle size distributions. Using similar auto-correlation analyses with carbonated hydroxyapatites and other biominerals is straightforward, but the interpretation and implications of the results present new and interesting questions related to structural order at intermediate length scales. In this context, we compare our approach with other common metrics for tracking crystallinity, including the infrared splitting factor that is routinely reported for apatitic phosphate biominerals.

Conclusions

We demonstrate that the co-existence of material-specific and measurement-specific contributions to infrared peak broadening can be beneficial for extracting information about the differences in structural order that can occur in biogenic, geogenic, and anthropogenic minerals. These effects can be decoupled in FTIR transmission measurements, obtained with standard bench-top instruments, by using a robust auto-correlation analysis of peak widths. An important implication of this result is that infrared spectroscopy has enormous potential as a quantitative tool for tracking changes in the structural order during biomineralization and biomimetic mineralization processes.

eedinger@mun.ca

Baffin Bay seawater espilon Nd signature was measured more than 25 years ago (Stordal and Wasserburg, 1986) at a very low value when compared to the average North Atlantic Ocean. This unradiogenic value is introduced into the North Atlantic Ocean through the Labrador current that flows on the East coast of Canada.

Seawater from all water masses from Baffin Bay and the Labrador Sea (near Orphan Knoll) were sampled during cruises of CCGS Hudson in 2008 and 2010. Using McLane™ pumping systems equipped with Mn-oxide coated cartridges, dissolved neodymium (Nd) was recovered from ~200 liters of seawater for many casts. The geographical area covered allows us to monitor the present day εNd signatures of Baffin Bay overflow water, as well as that of all other water masses involved in the Atlantic Meridional Overturning Circulation (AMOC).

During the 2010 cruise, the Canadian remotely operated vehicule (ROPOS) was used to sample specimens of deep-water cup corals (alive and fossils) from Orphan Knoll, at a depth of approximately 1700-1800 m below surface, i.e., near the depth-limit of the Present Labrador Sea Water mass. U-Th data in modern (live-collected) specimens of *Desmophyllum dianthus* yield critical information on the efficiency of the cleaning procedure used, with respect to the removal of oxide coatings ("clean" samples must yield zero ^{230}Th-ages), and thus on the representativity of the Nd isotope data obtained. The same approach combined with ^{14}C-ages is used in fossil coral studies, as a means to document, back in time, water mass changes at Orphan Knoll, in relation with the AMOC/climate variability.

The geochemical features of the garnets from peridotites of Udachnaya pipe (Yakutia)

LYUDMILA N. POKHILENKO[1]*, VLADIMIR G. MALKOVETS[1], ALEXEY M. AGASHEV[1], AND WILLIAM L. GRIFFIN[2]

[1] V.S.Sobolev Institute of geology and mineralogy SB RAS, Novosibirsk, Russia, lu@igm.nsc.ru (*presenting author)

[2] GEMOC National Key Centre, Macquarie University, Sydney, Australia

Iintroduction

Study of mantle xenoliths from the kimberlite pipes allows to get an important information about the origin and transformations of the lithosphere substance. The most deep-seated rocks of the lithospheric mantle are deformed peridotites, having the features of recrystallization and structures of the flow. These rocks undergo significant transformations and enrichment with different components under the effect of asthenospheric melts penetrating by the cracks and faults [1]. The most depleted rocks which are not affected by the enrichment processes are supposed to be the megacrystalline dunites [2].

Methods and samples

The garnets from 5 deformed lherzolites (mineral composition: olivine, orthopyroxene, clinopyroxene, garnet), and 20 megacrystalline harzburgite-dunites (mineral composition: olivine, garnet, sometimes chromite, orthopyroxene) from the kimberlite pipe Udachnaya (Yakutia) were analyzed by the LAM-ICPMS.

Results and Conclusion

The chondrite normalized [3] REE patterns of garnets from deformed lherzolites are mostly characterized by smooth increasing of LREE values with gradation in the field of HREE. The distribution curves of REE in garnets of megacrystalline dunites have highly sinusoidal character. The very big difference in REE values is seen in the width of dunite field. It shows the different degree and time of their enrichment.

The most of distribution curves for garnets of megacrystalline dunites have the peaks at the LREE and MREE showing increased Ce (7 samples), Pr (4 samples), Nd (7 samples), Sm (2 samples) concentrations proving early enrichment. The sharp sinusoidality of REE distribution curves, early enrichment with the LREE prove that some garnets of studied dunites were not in the equilibrium with the melt. In general these garnets could be formed as a result of transformation of earlier chromites [4], which is confirmed by the increased Cr-concentration in them (for example, garnet UV167/09 contains 11.84 wt.% Cr_2O_3), either as a result of exsolution of primary Al, Cr-containing orthopyroxene, presenting in garzburgites.

Composition evolution of peridotites of Siberian craton lithosphere roots: harzdurgite→lherzolite→wehrlite

NIKOLAY P. POKHILENKO*, ALEXEY M. AGASHEV, AND LYUDMILA N. POKHILENKO

VS Sobolev Institute of Geology and Mineralogy SB RAS, blingoreluiy@ya.ru (*presenting author)

Peculiarities of chemical composition and geochemical features of extremely fresh xenolith of unique mantle peridotites from Udacnaya kimberlite pipe were studied. The studied xenoliths were formed at the P-T conditions corresponding to the diamond stability field. A studied collection includes some varieties of megacrystalline Cr-pyrope harzburgites [1,2], metasomatized depleted peridotites [3]; c) fresh sheared Cr-pyrope lherzolites [4].

Obtained results show that ultra depleted peridotites: Cr-pyrope dunites and harzburgites including their diamondiferous varieties were secondary enriched in different scale by two different types of metasomatic agents. The first of them had a geochemical features close to those of carbonatitic melts. Increase of Ca in system caused a transformation of initial paragenesis ol+en+low-Ca knorringite-rich Cr-pyrope to ol+Cr-cpx+high-Ca uvarivite-rich pyrope (up to 76% Ca-comp.). This process caused enrichment of initially depleted peridotites in LREE and Ca.

The second type of metasomatic agent had definitely basanitic composition, and it caused secondary enrichment of initial ultra depleted peridotites by Si, Ti, Al, Fe, Ca, Na, K, incjmpatible and HREE, and obviously this process was synchronous to the kimberlite melt generation. CPX and magnesian ilmenite were a prohibited phases in initial ultra depleted peridotites, and in some the most enriched peridotites their amounts are up to 20 and 5 vol.%, correspondingly.

Sheared pyrope peridotites have a multistage character of a composition evolution including: a) initial depletion as a result of extraction from them melts of high degree of partial melting; b) enrichment by agent with high content of incompatible elements that caused significant increase of La/Yb ratio; c) enrichment by basanitic components synchronous to process of kimberlite formation [5].

Mesoarchean hydrous upper mantle: Evidence from the Fiskenæsset Complex, SW Greenland

ALI POLAT

Department of Earth and Environmental Sciences, University of Windsor, Windsor, ON, CANADA, polat@uwindsor.ca

The Fiskenæsset Complex, SW Greenland, contains the world's best preserved Archean (~2970 Ma) layered anorthosite, leucogabbro, gabbro, and ultramafic rock association. The ultramafic rocks consist mainly of olivine-pyroxene hornblendites, peridotites, dunites, and pyroxenites. The complex appears to have been emplaced into Archean oceanic crust (now amphibolite) and later intruded by tonalites, trondhjemites and granodiorites (TTGs). The complex and bordering TTG intrusions and mafic volcanic rocks were variably affected by granulite facies metamorphism and retrogressed under amphibolite facies conditions. Despite poly-phase deformation and amphibolite to granulite facies metamorphism, primary igneous structures and intrusive relationships are well preserved in many outcrops in the complex [1-3]. The Fiskenæsset ultramafic rocks share many petrographic characteristics of unmetamorphosed mafic to ultramafic layered intrusions and Alaskan-type ultramafic complexes. In ultramafic rocks, many orthopyroxene grains occur between amphibole and olivine grains and contain an intergrowth of symplectitic (vermicular) magnetite. These orthopyroxene-magnetite intergrowths appear to have grown at the expense of olivine. The origin of the orthopyroxene-magnetite symplectitic intergrowths is attributed to chemical reactions between residual, hydrous, hornblende-forming melts and olivine. In several locations, the Fiskenæsset ultramafic sills were intruded by a network of 5 to 40-cm-thick hornblendite veins. Given that horblendites and hornblende-bearing gabbros and peridotites are mainly restricted to Phanerozoic supra-subduction zone ophiolites and magmatic arcs, it is suggested that the Fiskenæsset Complex represents a relic fragment of a Mesoarchean oceanic island arc. The trace element systematics of the Fiskenæsset layered rocks and spatially and temporarily associated basaltic amphibolites and TTGs also indicate that these rock suites originated in an oceanic island arc setting. Petrographic observations and geochemical data provide strong evidence for a hydrous sub-arc mantle source for the igneous Fiskenæsset layered intrusion. Amphibole (mostly hornblende) occurs as an interstitial mineral to olivine, pyroxene, plagioclase, chromite and chrome-spinel and as inclusions in these minerals in the cumulates, consistent with an igneous origin. It is suggested that water was recycled to the source of the Fiskenæsset rocks through subduction of altered oceanic crust. Recycling of water to the upper mantle not only resulted in the generation of igneous amphibole in the complex, but it may also have contributed to the generation of neighbouring TTG-dominant continental crust by Archean subduction processes.

Sorption and incorporation of radio-nuclides at mineral surfaces studied with quantum chemical methods

R. POLLY*, B. SCHIMMELPFENNIG, M. FLÖRSHEIMER, F. HEBERLING, T. STUMPF, R. KLENZE, H. GECKEIS

Karlsruher Institut für Technologie (KIT), Campus Nord, Institut für nukleare Entsorgung (INE), Postfach 3640, 76021 Karlsruhe, Germany (email: polly@kit.edu)

The reliable long-term prediction of actinide migration in geological formations requires understanding of the adsorption/desorption and incorporation mechanism at the molecular level. The sorption and incorporation of metal ions at mineral surfaces is a very important process which leads to the retention/retardation of radionuclides such as actinide ions and fission products.

We present three different investigations in this talk: (1) the interaction of trivalent lanthanides and actinides with the solvated corundum (110) surface, (2) interaction of selenite with the hydrated calcite surface and (3) the incorporation of trivalent lanthanides and actinides in calcite. Study (1) is carried out with orbital based ab inito and DFT methods using TURBOMOLE, whereas (2) and (3) with plane-wave DFT, as implemented in the Vienna Ab initio Simulation Package (VASP).

The corundum (110) surface is a challenging task for a theoretical investigation because singly, doubly and triply coordinated aluminol groups are present simultanously. We used the $Al_{27}O_{75}H_{67}$ cluster in this study as a model system for the corundum (110) surface. In a first step, we determined the structure and deprotonation properties of this cluster and calculated the vibrational frequencies of the surface aluminol groups. These results are compared with experimental data to validate our cluster model. In a second step we determined the structure of the inner-sphere complexes of the trivalent lanthanides and actinides at the surface. Various multidentate surface bound inner-sphere complexes are found to predominate. They are characterized and compared with experimental results.

Se-79 is a fission product of U-235 with a long radioactive half life of $1.1x10^6$ years. Selenite (SeO_3^{2-}) and selenate (SeO_4^{2-}) interact only weakly with common mineral surfaces. Therefore they have been identified as crucial radio nuclides for long term safety assessments of nuclear waste disposal. We determined the structure of the water/calcit interface and identified surface sorbed and incorporated selenite species at the calcite/solution interface.

The last point tackles the incorporation of trivalent lanthanides and actinides into calcite. Earlier spectroscopic investigations suggest incorporation of lanthanide/actinide ions occupying Ca-sites in the calcite lattice. Charge compensation is achieved by the substiution of two Ca atoms by one trivalent lanthanide/actinide and one Na ion. Here, we studied modifications of the calcite structure induced by the substitution.

The Eddy Covariance: a new technique to assess sediment-water O_2 exchanges over various environments

The Eddy Covariance (EC) is a novel technique used to quantify the sedimentary O_2 consumption of marine ecosystems [1]. It measures O_2 exchanges at the sediment-water interface over large spatial scales (> 100 m^2) without being intrusive or disturbance of the flow field. This new technique has recently been used in various natural environments as tropical lagoon [2], tidal flat [3], river [4] and deep ocean [5] systems.

In autumn 2011, EC deployments were carried out in a 18 m long flume tank (NIOZ Yerseke, The Netherlands) filled with muddy sediment (Figure 1). Based on simultaneous measurements of near-sediment velocities (ADV Vector, *Nortek*) and O_2 concentrations (*Unisense* Clark-type microelectrode) at high frequency (64 Hz), O_2 exchanges at the sediment-water interface were calculated by EC. These EC fluxes were then compared with values based on microsensor profiling and chamber incubation.

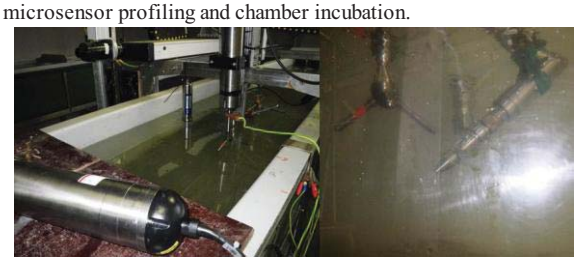

Figure 1: The flume Eddy Covariance deployment (Sept. 2011) showing sensor set-up (velocimeter, left and microelectrode, right).

First results and conclusions

EC O_2 fluxes were similar or greater than those obtained by incubation and microsensor profiling, i.e -23.8˜-62.9, -42.2˜-56.0 and -15.8˜-19.5 mmol m^{-2} d^{-1} respectively. EC fluxes varied with flow velocity, sensor depth and upstream location. The deployment of the EC technique in the flume facility allows to investigate various aspects of boundary layer hydrodynamics under controlled conditions.

Introduction

In addition to the major component of mantle carbon, which has $\delta^{13}C$ values of about -5±3‰, some reduced (carbide, hydrocarbons) and neutral (diamond, graphite, dissolved C) carbon compounds from mantle xenoliths and other sources have $\delta^{13}C$ values in the range of -20 to -35‰. Contamination of organic carbons near the Earth surface and the recycling of sedimentary organic matter via subduction zones have often been invoked to explain the depleted ^{13}C signatures of these mantle rocks. However an increasing number of studies do not support this scenario. Two other possibilities exist. First, mantle carbon could have been isotopically heterogeneous since the accretion from the solar nebula and the core–mantle segregation in the first 100 My of Earth history. Chondrites, carbonaceous chondrites particularly, which are widely considered to represent primitive undifferentiated materials from which the Earth accreted, have $\delta^{13}C$ values ranging widely from -28 to 0‰. Another possibility is that there exist some mechanisms and processes for large carbon isotope fractionation at high temperatures and pressures. For example, Craig [1] and Deines and Wickman [2] reported *ca*. 12 ‰ differences between graphite and cohenite, $(Fe, Ni, Co)_3C$, from iron meteorites. A recent experimental study by Satish-Kumar *et al*. [3] reported 2.7 - 4.5 ‰ differences between graphite/diamond and FeC melt at 1350 - 2100°C and 5 - 10 GPa.

Theoretical study

Here, we report our updated reuslts of theoreitcal calcualtions on $^{13}C/^{12}C$ fractionation among major C-bearing materials (CO_2, calcite, diamond, graphite, and SiC). Our results show that SiC is depleted in ^{13}C realtive to diamond/graphite and calcite even at very high temperautes: 2.5 - 9 ‰ at 1000 - 2000°C. Our results for SiC is consistent with the experimental results for FeC melt [3]. High preussures (>10's of GPa) under deep-Earth conditions may also affect measurably equilibrium isotope fractionation of C-bearing species [4]. Thus, the recent experimental study and our theoretical calculaitions clealry demonstate that carbides (Fe_3C and SiC) are significatnly depleted in ^{13}C at high tmeperatues and pressures. We need to revise and improve our understanding of carbon cycles and associatted isotope fractionation in the deep-Earth.

Association with poorly crystalline metal oxides: Effect on soil organic matter storage and stability in four eastern deciduous forest soils

R. Porras[1*], M.Torn[2], K. McFarlane[3]

Redox-active metals and the global carbon cycle

Strong association with mineral surfaces has been suggested as one mechanism underlying the long-term stabilization of organic matter in soils. Several recent studies have demonstrated a positive correlation between the content of poorly ordered crystalline metal oxide and hydroxide mineral phases and soil organic matter (SOM) or ^{14}C-based residence time. This positive correlation suggests that mineral-associated SOM persists over long time scales.

We utilized selective chemical dissolution (acid ammonium oxalate in the dark and sodium pyrophosphate) coupled with radiocarbon measurements to investigate the relationship between poorly crystalline Fe, Al, and Mn oxyhydroxide phases on organic matter storage and turnover time across four deciduous forest sites in the eastern U.S.comprising three different soil orders (inceptisol, spodosol alfisol).

Our results demonstrate that association with poorly-crystalline Fe and Al oxides (via adsorption to mineral surfaces and/or formation of soluble metal-OM complexes) do slow the turnover of SOM, with a significant positive linear relationship between radiocarbon turnover time and the content of oxalate extractable Al and Fe overall (R^2= 0.60,P=0.0001,CL=95%). Piecewise regression analysis on turnover time vs. oxalate extractable metal oxide content for all four sites shows an apparent metal oxide threshold value at 5g kg^{-1}. Sites with oxalate extractable Fe and Al content below this value showed no statistically significant influence on SOM stability, presumably because the metal oxides are present in insufficient quantity to exert a measureable influence on the decomposability of SOM.

Soluble Fe and Al oxyhydroxide-OM complexes extracted via treatment with Na-pyrophosphate had a statistically significant influence on carbon storage at only one site (Bartlett Experimental Forest, spodosol) (R^2=0.92, P<0.0001, 95%CL). However a significant linear relationship between ^{14}C-based turnover time and Na-pyrophosphate extractable Fe and Al could not be demonstrated for any individual site. Thus, complexation of organic matter via reaction with Fe and Al oxide phases does not appear to be the dominant control on turnover time in the 0-15cm depth at the sites under study.

Harvard Forest (inceptisol) had the highest poorly crystalline Fe concentrations estimated as (oxalate extractable Fe) – (Na-pyrophosphate extractable Fe) and exhibited the strongest influence on ^{14}C based turnover times (R^2=0.82, P=0.0003,CL=95%); in this soil, poorly-crystalline Fe oxides and hydroxides are quantitatively important in stabilizing organic inputs against decomposition. Poorly crystalline Mn was found to exert a significant influence on SOM stability at a single site: Missouri Ozark Forest (alfisol) (R^2=0.65,P=0.0051,CL=95%). No significant effect for Mn on SOM storage could be demonstrated for any of the four sites under study.

Analysis of oil inclusions by fs-laser ablation and ToF-SIMS

Femtosecond (fs) Laser Ablation

Recent advances in laser technology have led to ultrashort laser pulses capable of selectively opening and liberating oil within single inclusions. Coupling of an on-line femtosecond laser to a gas chromatograph-mass spectrometer successfully analysed hydrocarbon compounds from individual inclusions [1], but C_{19+} compounds were undetected and potentially remained in the ablation chamber. To test this hypothesis, well characterized oils were ablated with an infrared (1030 nm) high repetition rate femtosecond laser and directly collected on filters placed at the exit of the ablation chamber. Analyses of filter extracts by GCxGC-ToF-MS showed the presence of unaltered C_{12+} compounds including biomarkers. The success of the femtosecond laser as a sampling tool for biomarker analysis of oils was extended to the analysis of individual inclusions.

Time of Flight Secondary Ion Mass Spectrometry (ToF-SIMS)

ToF-SIMS technology has been used to detect hopanes and steranes in single oil-bearing fluid inclusions [2]. Standard oil suites were used to calibrate the ToF-SIMS instrument for various hydrocarbon source rock facies allowing the determination of the origin of oils trapped in inclusions within the Elk Basin Field, Big Horn Basin, WY. The oils appear to be derived from a distal carbonate source (Phosphoria Formation) supporting long distance, lateral migration into the Big Horn Basin Fields from a mature Phosphoria source rock ~65-120Ma.

Contrasted response of U-Th bearing minerals to albitization:

A case study from 3 albitite occurences in the Pyrenees

MARC POUJOL[1*], PHILIPPE BOULVAIS[1]

1Université de Rennes 1, UMR CNRS 6118 Géosciences Rennes, 35042 Rennes cedex, France. Marc.poujol@univ-rennes1.fr (* presenting author))

Albitization is a common metasomatic process active in various geodynamic environments. In the northern Pyrenees, several occurrences of albitites are described.

Like many other orogenic belts, the Pyrenees recorded numerous fluid-rock interaction events. Fluids led to talc mineralization in dolostones,ophicalcite development at the expense of peridotite massifs and albitization of granitoids and metamorphic rocks.. Because the Pyrenees have undergone the effects of both the Hercynian and Alpine orogenies, precise dating of the different fluid flow events is not straightforward.

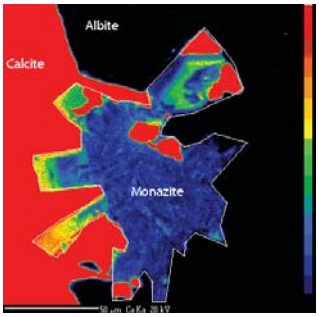

Fig 1: Ca chemical mapping of monazite

In this study, we focused on zircon, monazite and titanite, found either in metasedimenatry or meta-igneous protoliths that undergone pervasive albitization. Zircon grains were present in all the studied samples. Monazites were found only in an albitite occurrence developped from an igneous protolith while titanites were found in a albitized metasedimentary sample. These three types of mineral where selected in well characterized hydrothermal assemblages: zircons in metasomatically Zr-enriched rocks or in hydrothermal structures (millimetric veins cross-cutting granitoids); monazites when associated with calcite and/or albite in centimetric veins (Fig 1) and titanite with albite.

In-situ LA-ICP-MS ages obtained directly in thin sections from euhedral titanite and monazite grains from distinct albitites are 110 ± 8 and 98 ± 2 Ma, respectively [1]. The zircon U-Th-Pb isotopic system did not record this Cretaceous metasomatic event in any of the selected sample. This demonstrates that none of the zircons were affected (or grew anew) during fluid circulations. This confirms the robustness of zircon with respect to interaction with fluids.

We argue that the total time span of 20 Ma recorded by albitites corresponds to a long-lived hydrothermal system that was active during the rotation of Iberia around Europe. Because albitization and talc mineralization share a common spatial and temporal distribution in the Pyrenees, we argue that these two metasomatic phenomena are two independent records of this single, regional-scale, long-lived hydrothermal system.

The bulk composition of Rare Earth Elements (REE), Sc and Y in 36 chondrites: insight into elemental fractionation in the solar nebula

ALI POURMAND[1,2*], NICOLAS DAUPHAS[1], THOMAS J. IRELAND[1]

[1] Origins Lab, Department of Geophysical Sciences, University of Chicago, Chicago, IL 60637, USA

[2*] Neptune Isotope Lab, University of Miami - RSMAS, Miami, FL 33149, USA, apourmand@rsmas.miami.edu (presenting author)

Enrichment or depletion of the REE, Sc and Y in chondritic meteorites, relative to solar abundances preserved in the least equilibrated chondrites, has provided valuable insight into the condensation/evaporation history of refractory lithophile elements in the solar nebula during the early formation of the solar system [1-3]. A large portion of the existing data from bulk meteorite samples and their refractory inclusions, however, suffer from low precisions, or do not include mono-isotopic elements (Pr, Tb, Ho and Tm). Recently, we presented novel analytical techniques, utilizing low-blank fusion with $LiBO_2$ flux, TODGA extraction chromatography, and MC-ICP-MS for measuring the isotopic composition of actinides, REE, Sc and Y in extra-terrestrial materials [4], and revised the accretion age of Mars [5] and the mean of CI-chondrites for these elements [6]. Here, we present bulk concentrations of REE, Sc and Y in 36 (28 falls and 8 finds) carbonaceous (5), ordinary (15) and enstatite (16) chondrites using this new analytical methodology. All meteorite groups show varying degrees of enrichment or depletion in REE, Sc and Y relative to the mean of CI-chondrites. In general, three types of fractionation are dominant among other irregular patterns: 1) more refractory heavy REE (Gd, Tb, Dy, Ho, Er and Lu) are enriched relative to light REE (La, Ce, Pr, Nd, Sm and Tm), 2) more volatile elements (Eu and Yb) show positive or negative anomalies accompanied by minimal fractionation in other REE, 3) all elements show relatively similar enrichment or depletion without significant anomalies. More dispersion is also observed in the anomalies of more volatile elements (*e.g.,* Eu/Eu*) with increasing degrees of equilibration. While some fractionation patterns can be attributed to the presence of (ultra) refractory inclusions [3] or minerals (*e.g.,* phosphate) that concentrate REE in chondrites, other mechanisms may be needed for patterns that cannot be explained by dominance of a particular group of inclusions.

Reassesment of the rare earth elements external cycle in french watersheds - a high potential resource for the future

O. POURRET[1*], J. TUDURI[2], R. ARMAND[1], G. BAYON[3] AND M. STEINMANN[4]

[1] HydrISE, LaSalle-Beauvais, Beauvais, France olivier.pourret@lasalle-beauvais.fr (* presenting author)

[3] Département Géosciences Marines, IFREMER, Plouzané, France
[4] UMR 6249 Chrono-Environnement, Univ. Franche-Comté, Besançon, France

The distribution of rare earth elements (REE) was studied in streams of the Armorican Massif and the Massif Central (France). The water chemistry of both watersheds was dominated by silicate weathering. The REE distribution patterns of stream water showed, from the source to the catchment outlet, a fractionation of the upper continental crust normalized REE distribution patterns from heavy REE (HREE) enriched to more flat and middle REE (MREE) enriched patterns, together with a progressive disappearance of a negative Ce anomaly. Ultrafiltration data (at 3 or 5 kDa) showed that the ultrafiltrates had HREE-enriched patterns with negative Ce anomalies, whereas the organic colloids showed relatively flat patterns. These data thus suggest that the observed general evolution from HREE-enriched to MREE-enriched patterns with distance is related to a growing importance of organic colloids as REE carriers from upstream to downstream.

The REE patterns of the ultrafiltrates are very similar to seawater patterns. The REE pattern of seawater could thus be inherited from river water. Commonly, the REE patterns of ocean water are usually considered to reflect (i) the respective REE inputs from rivers, aeolian transport, hydrothermal vents and dissolution of marine carbonates and (ii) interactions with the biogeochemical cycle, involving REE-removal from surface waters by adsorption onto settling Fe-Mn particles. The strong Ce depletion and the HREE-enrichment of ocean waters are commonly attributed to the redox chemistry of Ce and to the high stability constants of HREE carbonate complexes. Nevertheless, different processes may lead to REE and/or Ce removal from solution. The most often discussed hypothesis is fractionation during estuarine mixing, enhanced by extremely high particle reactivity of the REE (e.g. with MnO_2).

Results from this study thus allow to reassess the REE external cycle. Indeed, the river input to the oceans has relatively flat REE patterns without Ce anomalies, whereas oceanic REE patterns exhibit strong negative Ce anomalies and HREE enrichment. Indeed, the processes at the origin of seawater REE patterns are commonly thought to occur within the ocean masses themselves. However, the results from the present study illustrate that seawater-like REE patterns already occur in the truly dissolved pool of river input. This leads us to favor a partial or complete removal of the colloidal REE pool during estuarine mixing by coagulation, as previously shown for dissolved humic acids and iron. In this latter case, REE fractionation occurs because colloidal and truly dissolved pools have different REE patterns. Thus, the REE patterns of seawater could be the combination of both intra-oceanic and riverine processes. Eventually, the Atlantic continental shelf could be considered as a potential REE trap and shelf sediments would, similar to metalliferous deep sea sediments, represent a REE potential resource and guide for exploration. This latter hypothesis will be further tested by analysing various fractions (detrital, Fe-Mn oxides, organic compounds) of sediments deposited in river estuaries at the Western Atlantic margin.

On calculating phase equilibria for metamorphic systems

POWELL R[1*]

[1] School of Earth Sciences, University of Melbourne, Vic. 3010, Australia, powell@unimelb.edu.au (* presenting author)

Mike Brown has overseen a revolution in metamorphic geology, as an organiser of meetings, journal creator and editor, supporter of people and contributor to the science itself. I would like to give a personal view of an important part of that revolution—the calculation of metamorphic phase equilibria: where we are, what the challenges are, and what might be the way forward. This will be done via consideration of methodological aspects of what is needed for such calculations: 1) An extensive internally-consistent thermodynamic dataset for the end-members of minerals, fluids and melts; 2) Activity-composition relationships for these phases, extending into parts of composition space where there is little or no experimental control; 3) Methods, for example for calculating phase diagrams, that take into account the "natural" variables that are likely to be critical in metamorphic systems; 4) Software that implements these methods, using the current best thermodynamic descriptions of phases; and 5) An appropriately nuanced appreciation of reaction in metamorphic rocks, for example regarding length-scales, and the likely boundaries of application of equilibrium thermodynamics in the study of metamorphism.

Hydromagnesite-magnesite playas: A model for carbon storage

IAN M. POWER[1*], SIOBHAN A. WILSON[2], GREG M. DIPPLE[1], AND ANNA L. HARRISON[1]

[1]The University of British Columbia, Vancouver, Canada, ipower@eos.ubc.ca (* presenting author), gdipple@eos.ubc.ca, aharriso@eos.ubc.ca

[2]Monash University, Clayton, Australia, sasha.wilson@monash.edu

Hydromagnesite-magnesite playas (hectare-scale) are found near the town of Atlin, British Columbia, Canada. The playas were first described in 1916 by Young [1] and, most recently, characterized in the context of a biogeochemical model for CO_2 sequestration by Power et al. [2,3]. The weathering of ultramafic bedrock results in Mg-rich groundwaters that discharge into topographic lows where microbial, geochemical and physical processes mediate carbonate precipitation. The playas may be thought of as a natural repository of CO_2. Although magnesite [$MgCO_3$] is the most stable Mg-carbonate mineral, its precipitation is kinetically inhibited as a consequence of the strong hydration of Mg^{2+} ions [4]. As a result, the playas consist of a complex assemblage of hydrated Mg-carbonate mineral phases.

Aragonite [$CaCO_3$], dypingite [$Mg_5(CO_3)_4(OH)_2{\cdot}5H_2O$], and nesquehonite [$MgCO_3{\cdot}3H_2O$] may precipitate directly from surface and ground waters, which undergo diagenesis post-deposition. Playa sediments at depth (up to ~3 m) were collected along a transect (90 m) at 5 and 10 m intervals. The sediments are mainly composed of hydromagnesite [$Mg_5(CO_3)_4(OH)_2{\cdot}4H_2O$], but also contain magnesite. The abundance of magnesite at the surface ranges from 7 to 40 wt.% across the playa. The water table (~1 m depth) coincides with a hard crust containing up to 10 wt.% lansfordite [$MgCO_3{\cdot}5H_2O$]. Below ~1 m, the abundance of magnesite typically increases and may be up to 87 wt.% with hydromagnesite being the remainder. The Mg-carbonate sediments overlay Ca-carbonate sediments containing aragonite and dolomite [$CaMg(CO_3)_2$], which overlay glaciolacustrine sediments. Electron microscopy shows that magnesite forms as a distinct mineral phase and does not show intergrowth with hydromagnesite (Figure 1); meaning that it likely does not form from dehydration of hydromagnesite. The current focus is on understanding the geochemical conditions of low-temperature magnesite formation, which has implications for the long-term storage of anthropogenic CO_2 as Mg-carbonate minerals.

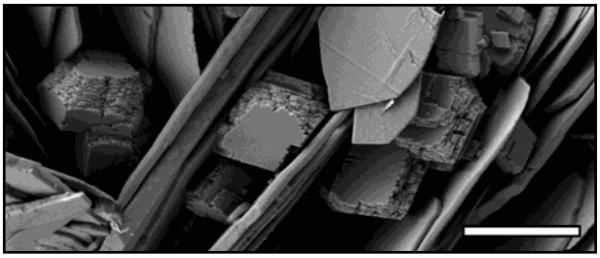

Figure 1: Low-temperature magnesite (rhombohedral crystals) forming between hydromagnesite plates (1 µm scale bar).

Records of atmospheric Pb deposition along the St. Lawrence Valley, Quebec

S. PRATTE[1*], A. MUCCI[1], M. GARNEAU[2]

[1] GEOTOP & Dept. of Earth and Planetary Sciences, McGill University, Montreal, Qc, Canada H3A 2A7 (*correspondence: steve.pratte@mail.mcgill.ca)

[2] GEOTOP & Département de Géographie, Université du Québec à Montréal, Montreal, Qc, Canada

Ombrotrophic peat bogs provide reliable historical records of atmospheric metal deposition, in particular lead [1]. To date, most studies were carried out in Europe and served to document various periods of anthropogenic activities. In contrast, records of atmospheric metal deposition in North America are still scarce. The objective of this study was to reconstruct the recent history of atmospheric metal deposition (Pb, As, Cd, Ni and Zn) along the St. Lawrence Valley (SLV).

Cores (50 to 100-cm long) were collected in four peat bogs along the SLV. They were sub-sampled at 1 to 5-cm intervals and analyzed for their trace metal contents (Pb, As, Cd, Ni and Zn). Here, we present the vertical distributions of Pb and its stable isotopes (204, 205, 206, 207) in the four cores. Core chronologies were established using ^{210}Pb for the surface horizons and ^{14}C for the deeper sections. Regional, natural background metal concentrations and isotopic signatures were established from the analysis of samples taken from the bottom of the bogs. When the latter were not available, values from the upper continental crust (UCC) values were used [2]. Variations from these values within the cores were compared to the isotopic composition of North American major lead-bearing ores (used for the synthesis of gasoline additive) and modern aerosol for U.S. and Canada (1994-1999).

Preliminary results show that anthropogenic Pb concentrations increased sharply from the start of the 19th through the 20th century to reach a maximum between 1940-1970. The age and amplitude of this peak vary spatially along the SLV and, in some cases, can be associated with specific anthropogenic activities (e.g. smelting) or the convergence of different air masses. Since the 60's, lead concentrations have decreased rapidly, following the ban on leaded gasoline, but they have not reached pre-anthropogenic levels. Results show that the southwestern SLV has been more impacted by anthropogenic Pb.

Stable lead isotopes analyses are ongoing and will help discriminate between different anthropogenic and natural sources of atmospheric Pb at the study sites.

CONTAMINATION, MELTING AND SULPHIDE MINERALISATION IN THE BASAL RIVER VALLEY COMPLEX, CANADA

PREVEC[1*], STEPHEN A. AND VILJOEN[1], GREG

[1]Dept of Geology, Rhodes University, P.O. Box 94, Grahamstown, South Africa, 6140, s.prevec@ru.ac.za*

The River Valley Complex (RVC) is a Palaeoproterozoic mafic intrusion lying astride the ca. 1.0 Ga Grenville Front Tectonic Zone (GFTZ). The Complex is the easternmost member of a regionally extensive pod of mafic intrusions, with contemporaneous volcanics and dykes which comprise the Huronian magmatic suite. The RVC is the first member of this suite to show ore-grade prospects for PGE-sulphide mineralisation, as well as the sole instance of ultramafic cumulus rocks. The ores are associated with the Marginal Zone, which is transected by a cross-cutting near-basal unit (the awkwardly named "Inclusion/Autolith-bearing zone") which hosts both autolithic and (more rarely) exotic xenolithic blocks, and has been interpreted [1], on the basis of PGE and HFSE geochemistry, as the product of a late, chemically-boninitic melt, distinct from any other yet reported in this magmatic suite. A xenolithic fragment found in the South Zone of the Dana Lake showing, displaying apparent cumulus layering (only otherwise found higher in the lithostratigraphic sequence), a partial mantle of leucocratic selvage, and sulphide mineralisation, was sampled.

The xenolith is characterised by major and trace element geochemistry comparable to that of a granitoid (e.g., SiO_2 ranging from around 56 wt.% up to nearly 80 wt.%), and features quartz and alkali feldspar prominently. Conversely, the host rock is olivine normative, shows relict cumulus textures, and has REE and other HFSE abundances about an order of magnitude lower than those in the xenolith. Sm-Nd isotopic compositions show a range between $\varepsilon_{Nd}^{2.45}$ of around -1 to -2.3, typical of relatively uncontaminated Palaeoproterozoic mafic rocks regionally. However, the matrix values range between +3.2 and 0, representing the first direct evidence for depleted mantle in the Canadian Palaeoproterozoic. The sulphide mineralogy (po-cpy-py-pn ± sp) varies in mode across the traverse, with fracture-hosted cp-pn dominant in the xenolith, and po-pn-cp in the host rock. Normalised PGE profiles show a PPGE-enriched pattern typical of magmatic sulphide-controlled PGE in both the host rock- and xenolith-hosted sulphides, with the added feature of a negative Ru anomaly. A model involving infiltration metasomatism of fluid-rich crustal (footwall) melt is tentatively proposed to facilitate sulphide liquid precipitation and incorporation.

Geochemical Mapping of Mantle Flow between Samoa and the Lau Basin

ALLISON A. PRICE[1*], MATTHEW G. JACKSON[1], PAUL S. HALL[1], JOHN M. SINTON[2], MARK D. KURZ[3]

[1] Boston University, Dept. of Earth Sciences, Boston, MA, 02115 (Price@bu.edu)

[2] University of Hawai'i at Manoa, Dept. of Geology and Geophysics, Honalulu, HI, 96822

[3]Woods Hole Oceanographic Institution, Dept. of Marine Chemistry, Woods Hole, MA, 02543

The juxtaposition of the Samoan plume and the Tonga Trench provides a unique setting for the study of upper mantle flow. The Samoan plume is located only 200 km east of the northern terminus of the Tonga trench. North of the terminus, the Pacific plate "tears," and the resulting tear creates a slab "window" allowing Samoan mantle to flow southward beneath the Vitiaz lineament--which separates the Pacific from the Lau Basin--and into the shallow mantle of the Northern Lau Basin. The presence of high $^3He/^4He$ (up to 28 times atmospheric (R_A)) and latitudinal gradients in trace element and isotopic (Sr-Nd-Pb) enrichment in the N. Lau Basin have been attributed to the southward flow of mantle material from the nearby Samoan hotspot through the slab window. High $^3He/^4He$ ratios (up to 28.1 R_A) have been reported in a swath within the northern Lau Basin but drop rapidly to both the South (~400km south of Peggy ridge) and East (Lupton, 2009.) However, $^3He/^4He$ ratios have not been reported in the region to the West or North of the region of the infiltrating plume, so the geochemical "map" of Samoan plume material in the Lau Basin is incomplete.

We present He, Pb, Sr, and Nd isotopic analyses as well as trace element analyses for glasses in the region just to the west of the location where the highest $^3He/^4He$ ratios were reported. The samples, which span the North Lau and North Fiji Basins, as well as submarine samples from Wallis Island, located just north of the Lau Basin, have $^3He/^4He$ ratios that vary between 6 and 15 R_A. The highest of the new $^3He/^4He$ occur in submarine lavas from Wallis Island, located between the northernmost portion of the Rochambeau Ridge (28.1 R_A) and the Samoan hotspot (up to 35 R_A.) The new data indicate that the Samoan-plume high $^3He/^4He$ mantle does not spread to the west in the Lau Basin, but is confined to a narrow corridor in the Northern Lau Basin that extends from Samoa, through Wallis and into a narrow region of the N. Lau Basin. However, Sr, Nd and Pb isotopic evidence are consistent with low 3He/4He Samoan plume material "leaking" into the N. Fiji basin as far west as Pandora Ridge. This observation places important constraints on changing mantle flow due to the evolving geometry of plume-trench juxtaposition.

The α-particle dose of the solubility threshold for detrital epidote-group grains from the Yangze River delta

JASON R. PRICE[1*], MICHEAL TUBRETT[2], AND DEREK WILTON[3]

[1]Department of Earth Sciences, P.O. Box 1002, Millersville University, Millersville, PA 17551-0302, USA, Jason.Price@millersville.edu (* presenting author)
[2]CREAIT Network, Memorial University of Newfoundland, St. John's, NL, A1B 3X5 Canada, mtubrett@mun.ca
[3]Department of Earth Sciences, Memorial University of Newfoundland, St. John's, NL, A1B 3X5 Canada, dwilton@mun.ca

The epidote-group minerals are common accessory phases in silicate rocks. These calc-silicate minerals may contain substantial quantities of Th, and concomitantly U. The radioactive decay of ^{232}Th, ^{238}U, ^{235}U to their daughter nuclides results in the radiation-induced transformation from a periodic to an aperiodic structure termed metamictization [1]. Metamictization of epidote-group minerals can increase their solubility and thus these minerals can be important sources of Ca in pore and stream waters that drain silicate terranes [2]. On geologic timescales, dissolved Ca and bicarbonate ions from silicate mineral dissolution are carried by streams to the oceans where they are sequestered in Ca-carbonate minerals [3]. Therefore, the weathering of metamict epidote-group minerals is capable of consuming atmospheric CO_2 and potentially influencing the long-term global climate.

The extent of epidote-group mineral metamictization is a function of age, and Th and U content, which together yield the α-particle dose of the grain [4]. To determine the solubility threshold of epidote-group minerals, the α-particle dose of grains from the Yangtze River delta in China have been calculated. These detrital grains are resistant to chemical weathering and persist into fluvial sediments. Delta sediments from such a large river system provide a suite of epidote-group minerals that approximate the compositional range and radiation damage commonly observed in nature for grains resistant to dissolution. The grain(s) with the highest α-particle dose thus reflect the solubility threshold for the epidote-group minerals.

The Th, U, and Pb isotopic compositions of each grain were measured by laser ablation-inductively coupled plasma-mass spectrometry. ^{232}Th-^{208}Pb ages were corrected for common Pb using an iterative technique [5]. End-member epidote grains contain sufficiently low Th and U concentrations to prevent quantification of an α-particle dose, explaining, at least in part, why they are so resistant to chemical weathering. End-member allanite grains are relatively radioactive, reflect at least four sources of allanite to the delta, and yielded a maximum α-particle dose of ~3.6 x 10^{15} α-decays mg^{-1}. This dose compares very favorably with that of ~3.5 x 10^{15} α-decays mg^{-1} reported for Amazon detrital zircons [6].

Light activation of steady state copper uptake in marine diatoms

NEIL M. PRICE[1*] AND JUN-WOO KIM[2]

[1]McGill University, Department of Biology, Montreal, Canada, neil.price@mcgill.ca
[2]McGill University, Department of Biology, Montreal, Canada, jun-woo.kim@mail.mcgill.ca (* presenting author)

Marine diatoms of the Thalassiosirales use either a Cu-containing plastocyanin (PC) or an Fe-containing cytochrome (cyt) c_6 to transfer electrons from cyt b_6f to photosystem I in the light reactions of photosynthesis. Growth assays confirm that the PC-containing strains require higher concentrations of Cu for cell division and contain roughly 2-3 times more cellular Cu (30.8 fmol Cu' L^{-1}) than strains with cyt c_6. Under steady state conditions, Cu uptake rates are a linear inverse function of Cu-limited growth rates and not significantly different among PC and cyt c_6-containing strains. Thus, despite having greater cellular demand for Cu, diatoms that use PC are unable to acquire extra Cu. In the presence of high light, however, Cu uptake rates of PC-containing species are increased by 2-10 fold, suggesting that Cu acquisition is somehow light-activated. Steady state Cu uptake rate is proportional to irradiance at both high and low Cu concentrations (Fig. 1). We are currently examining how light affects extracellular Cu(II) reduction in a number of PC and cyt c_6-containing *Thalassiosira* species.

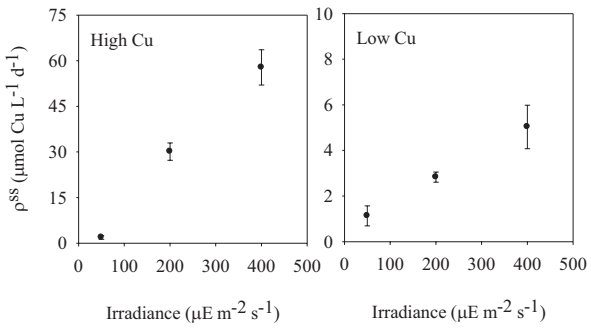

Figure 1: Steady state Cu uptake rate of *Thalassiosira oceanica* normalized to cellular volume as a function of growth irradiance. Values are means of 3-5 replicates and error bars ± 1 std.

Interfacial tension and nucleation behaviour of minerals (revisited)

MANUEL PRIETO[1*], DIONISIS KATSIKOPOULOS[1], AND ANGELES FERNÁNDEZ-GONZÁLEZ[1]

[1]Department of Geology, University of Oviedo, Oviedo, Spain, mprieto@geol.uniovi.es (* presenting author)

According to the classical nucleation theory (CNT), the nucleation rate depends strongly on the interfacial tension (σ), which in aqueous systems is related to the solubility by the rule that the higher the solubility, the lower σ. Indirect estimations of σ from nucleation experiments [1] are typically used to account for crystallization in natural aqueous systems [2] and to model the precipitation in sequential order of lesser and lesser soluble isochemical mineral phases according to the Ostwald step rule. In a related way, when solid solutions crystallize from supersaturated aqueous solutions the distribution of the substituting ions between the solid and the fluid phase usually differs from the equilibrium values [3]. "More soluble" solid solution compositions are kinetically favoured and tend to nucleate even though the aqueous solution is less supersaturated for these compositions than for less soluble members. This effect has been modelled by considering a linear variation of σ with composition [4]. However, to the authors knowledge, there is no empirical study on the compositional evolution of σ in solid solution systems.

In this work we revisit the concept of interfacial tension in the light of recent findings that challenge the tradictional picture of crystal nucleation, at least in the case of the $CaCO_3$-H_2O system [5]. Our point is that, in the CNT framework, the interfacial tension must be considered more an "artificial" fitting parameter than a measurable magnitude with a precise physical meaning. We show the dependence of CNT-derived σ values on the speciation model, the expression chosen for the driving force, and the shape chosen for the nuclei. Special attention is paid to the polymorphic precipitation of $CaCO_3$ phases. Finally, we determine the CNT-σ parameters for intermediate members of a number of binary (virtually ideal and non-ideal) solid solutions. Our results show a good correlation between the deviations from the ideal mixing behaviour, the solubility, and the obatined CNT-σ values. Positive deviations from ideality (positive enthalpy of mixing) correlate with negative deviations of σ from a linear trend, whereas negative deviations (tendency to ordering) correlate with positive deviations of σ. In each case, the obtained σ values are used to model non-equilibrium distribution coefficients, the results being in good agreement with experimental measurements reported in the literature.

Precipitation of $MgCO_3$ at elevated temperature and CO_2 pressure

VALENTINA PRIGIOBBE[1*]

[1] ETH Zurich, Institute of Process Engineering, Zurich, Switzerland. *Current address:* Dept. of Petroleum and Geosystems Engineering, University of Texas at Austin, Texas, U.S.A. valentina.prigiobbe@mail.utexas.edu (* presenting author)

Introduction and methods

Mineral carbonation is a Carbon Capture and Storage (CSS) technology that consists in fixing CO_2 into stable carbonates, e.g., magnesite ($MgCO_3$) which can be either disposed of or reused [1]. Hydrated phases can initially form which then transform into the stable carbonate [2]. If carbonates are designed to be reused, the precipitation process must be carried out under well-constrained conditions which are still unknown or not fully defined [3,4,5]. Here, we present the results from a $MgCO_3$ precipitation study at 90ºC, 120ºC, and 150ºC and at 100 bar of CO_2 [6]. Batch experiments were performed using a $MgCl_2$-CO_2-Na_2CO_3 aqueous system and monitored with online Raman spectroscopy. Precipitation was modeled using a population balance equation (PBE) [7] coupled with a geochemical model. Nucleation and growth rates were described by empirical equations based on classical nucleation theory and the birth-andspread growth mechanism and the kinetic parameters were estimated by fitting Raman spectroscopy measurements using multivariate kinetics modeling [8].

Results and conclusions

Two types of mechanisms were verified. At all investigated temperatures and at low magnesium concentration (C_{Mg}) $MgCO_3$ precipitated directly (Fig. 1.a). At 120 and 150ºC and at high C_{Mg}, $MgCO_3$ formed simultaneously with hydromagnesite which then transformed into $MgCO_3$ (Fig. 1.b). The kinetics showed no sensitivity to C_{Mg}, small sensitivity to temperature, and a significant sensitivity to supersaturation with respect to $MgCO_3$ (S_M). This allowed the formulation of general rate equations for nucleation and growth given by, respectively,

$$J = 4\times10^{8} e^{(-19/\ln^2 S_M)}, \quad (1)$$

$$G = 29\times10^{-9}(S_M - 1)^{2/3} \ln^{1/6} S_M e^{(-19/\ln^2 S_M)}, \quad (2)$$

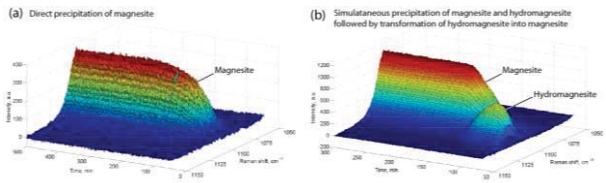

Figure 1: Online Raman spectroscopy measurements.

An early Neoproterozoic dynamic sulphur cycle: evidence from the Shaler Supergroup

JOHN K. G. PRINCE*[1], BOSWELL A. WING[2], ROBERT H. RAINBIRD[3], GALEN P. HALVERSON[4]

[1]Carleton University, Ottawa, Canada, jprince2@connect.carleton.ca (* presenting author)

Abstract:

The Neoproterozoic (1000-542Ma) is a dynamic era of Earth history, punctuated by super continental break-up, global glaciations, and the evolution of metazoan life [1,2,3]. During the early to mid-Neoproterozoic, Earth's redox budget was in a state of flux, the evidence for which is preserved in the isotopic records of sulphur and carbon [4]. In order to constrain the initiation of this dynamic behaviour, we described and sampled 3 outcrop stratigraphic sections and a drill core at ~3m intervals through the Minto Inlet Formation of the Shaler Supergroup, which is exposed in the Minto Inlier of NW Victoria Island, NWT.

The Minto Inlet Formation is >250m thick and hosts well-preserved Neoproterozoic sulphate-rich evaporites deposited in a periodically restricted intra-continental marine basin. The Minto Inlet Formation was deposited between ~900Ma and ~800Ma based on detrital zircon geochronology and stratigraphic correlation with well-calibrated sections in the northern Cordillera [4]. We measured multiple sulphur isotopes ($\delta^{34}S$, $\Delta^{33}S$) of the sulphate fraction in all of the stratigraphically controlled dataset of 67 samples.

Current understanding of the sulphur isotope record suggests that the fraction of S buried as pyrite relative to sulphate evaporites was high, approaching 1 for most of the Proterozoic, through the Ediacaran, and into the early Phanerozoic [5]. We used multiple sulphur isotope measurements of Minto Inlet Formation evaporites to constrain models of S fluxes into and out of the ocean prior to the onset of the Cryogenian (720-635Ma). This approach suggests that the relative burial fraction of S as pyrite was extremely low (≈0.2) during the earliest stages of the deposition of the Minto Inlet Formation. Previously, pyrite burial fractions this low had been recorded only at Permian-Triassic time, more than ≈600 Ma after the deposition of the Minto Inlet Formation [5]. Our results indicate large scale variations in ocean redox conditions and a dynamic sulphur-cycle were initiated during the early-Neoproterozoic.

Earths Icy Biosphere as a Model for the Microbiology of Other Icy Worlds

JOHN C. PRISCU[1*], KEVIN P. HAND[2]

[1]Montana State University, Land Resources and Environmental Sciences, jpriscu@montana.edu
[2]Jet Propulsion Laboratory, Pasadena, California, kevin.p.hand@jpl.nasa.gov

Antarctic terrestrial environments were initially thought to be devoid of life. However, discoveries of microbial life in Antarctic lake ice, and within and under Antarctic glacial ice have all provided information on the diversity and biogeochemical importance of biology to icy environments. We now know that polar microbiology plays a major role in biogeochemical processes on Earth and offers new insights into the evolution and biodiversity of life on our planet. The discovery of viable microorganisms in icy environments has extended what we know about the limits of life on Earth and provides strong evidence to show that life has successfully radiated into virtually all habitats on our planet containing "free" liquid water. Icy worlds beyond Earth may harbor the greatest volume of habitable space in the Solar System. For at least five of these worlds, considerable evidence exists to support the conclusion that oceans or seas may lie beneath the icy surfaces. The total liquid water reservoir within these worlds may be some 30 to 40 times the volume of liquid water on Earth. For example, data obtained from orbiters have revealed a deep ocean of liquid water beneath a thick chaotic ice cover on Europa where organic matter derived from comets and oxidants provided by radiation from Jupiter's magnetosphere may yield a habitat for life and a reservoir of endogenous and exogenous substances. This vast quantity of liquid water begs the question: Can life emerge and thrive within ice and the cold, lightless oceans beneath many kilometers of ice? To address this broad question, information on water activity, metabolic energy sources, nutrient availability, the ability of the physical environment to support growth and reproduction, and the origin of the biological seed must be known. Studies of Earth's subzero environments will continue to play a crucial role in informing our understanding of habitability on other frozen worlds in our Solar System and guide our development of the robotic tools needed to investigate those distant environments. We will present combined laboratory, numerical, analytical, and field investigations from Earth's polar regions to define the potential habitability of icy worlds beyond Earth.

Tracing industrial emissions in the Athabasca oil sands region (Alberta, Canada) using stable isotope techniques

BERNADETTE PROEMSE[1*], BERNHARD MAYER[1], AND MICHAEL WIESER[2]

[1]Department of Geoscience, University of Calgary, 2500 University Drive NW, Calgary, AB, T2N 1N4, Canada bcpromse@ucalgary.ca (*presenting author)

[21]Department of Physics and Astronomy, University of Calgary, 2500 University Drive NW, Calgary, AB, T2N 1N4, Canada

The Athabasca oil sands region (AOSR) in northeastern Alberta, Canada, is one of the world's largest oil reservoirs. Its heavy oil will become increasingly important as conventional energy resoures decline. Due to the rapid industrial development in the AOSR, there have been increasing concerns about the impact of the emissions from the oil sands operations on the surrounding terrestrial and aquatic ecosystems. Stable isotope techniques may help to assess such impact in the case where industrial emissions are isotopically distinct from background components. In order to trace nitrogen (N) and sulfur (S) emissions released by the oil sands industry, we have determined chemical and isotopic compositions of various N and S compounds in emissions and several environmental receptors.

Potential source materials such as untreated oil sand, bitumen, elemental sulfur from the sulfur storage block, coke and the by-product ammonium sulfate were analyzed for either $\delta^{34}S$, $\delta^{15}N$ values or both. We also determined stable isotope ratios of sulfate ($\delta^{34}S$, $\delta^{18}O$), nitrate ($\delta^{15}N$, $\delta^{18}O$, and $\Delta^{17}O$) and ammonium ($\delta^{15}N$) of stack emitted $PM_{2.5}$ [1]. The nitrogen and triple oxygen isotopic composition ($\delta^{15}N$, $\delta^{18}O$, and $\Delta^{17}O$) of atmospheric nitrate in bulk deposition and throughfall as well as $\delta^{15}N$ of atmospheric ammonium, and $\delta^{18}O$ and $\delta^{34}S$ of atmospheric sulfate in throughfall and bulk deposition were also measured. Bio-indicators such as lichens and pine needles were collected and analyzed for total N content, $\delta^{15}N$, total S content and $\delta^{34}S$. Industrial N and SO_4 emissions were found to be isotopically distinct. $\delta^{18}O$ and $\Delta^{17}O$ of atmospheric nitrate deposition and $\delta^{18}O$ values of atmospheric sulfate deposition showed trends towards lower values with increasing nitrate and sulfate deposition rates allowing for the quantification of industrial contributions to atmospheric nitrate [2] and sulfate deposition in the AOSR. Lichens responded to elevated N and S deposition in close proximity to the oil sands operations, whereas chemical and isotopic compositions of N and S in pine needles showed no significant industrial impact.

In addition to "traditional" stable isotope techniques, we have investigated the suitability of $\delta^{98/95}Mo$ as an environmental tracer in the AOSR and determined its value in Athabasca bitumen and air filters. Preliminary results reveal that industrial activities are associated with Mo isotope fractionation, providing a potential new tracer for industrial activities in the AOSR.

Laser ablation ICPMS is a widely established method to directly monitor and image the elemetal distribution on solid surfaces with small lateral resolution. The minimal sample preparation and the fact that any solid surface can be analzed irrespective of its nature and composition, has made the method a versatile tool in many areas of science. In addition, the ability of detecting isotope specific information has increased the variety of applications sigificantly. E.g. human and animal teeth as well as otoliths are often used for migration studies.

Beside monitoring the natural isotopic variation, isotopically enriched spikes can be used in natural systems to monitor uptake and distribution of isotopic spikes by hard tissues after administration.

Here, we present the use of Sr isotope spikes for comparing calcium and strontium metabolism in the living organism and tracer distribution within hard tissues (i.e. bones, teeth, otoliths). Our results give new insights into Sr metabolism and turnover. The investigations bear an analytical challenge as spectral interferences have to be accounted for when analysing Sr and Ca isotope ratios with high spatial resolution using LA- ICPMS.

Nucleation and growth of acicular rutile in garnet: a case of open system precipitation

ALEXANDER PROYER[1*], GERLINDE HABLER[2], RAINER ABART[2], RICHARD WIRTH[3], KURT KRENN[1], AND GEORG HOINKES[1]

[1]University of Graz, Institute of Earth Sciences, Graz, Austria, alexander.proyer@uni-graz.at (* presenting author)
[2]University of Vienna, Department of Lithospheric Research, Vienna, Austria,
[3]GFZ Potsdam, Potsdam, Germany, wirth@gfz-potsdam.de

Crystallographically oriented precipitates of rutile grew within garnet in metapelites from the Greek Rhodope during exhumation and cooling from eclogite and granulite facies conditions. Homgeneous nucleation produced a three-dimensional array of mostly acicular rutile precipitates with aspect rations between 10 and 100. Rutile c-axes are inclined at an average angle of 27° to the needle long axes (oblique extinction), and EBSD analysis reveals a clear but complex crystallographic orientation relationship with the garnet host. TEM-imaging shows semi-coherent to incoherent phase boundaries and a small but significant lattice mismatch even along those phase boundaries with the best relative match. The "idiomorphic" rutile needles are terminated by low-index planes of garnet, the most common ones being (110), (100) and (112).

Another set of micrometer-sized rutile inclusions in the same garnets is more isometric and granular and is interpreted as resulting from heterogeneous nucleation at dislocations; TEM-data show very poor lattice match (complete incoherence along all interfaces). Garnet from another metapelite sample shows arrays of oriented rutile needles embedded in a very fine grained (nanometer-sized) "dust" – most likely a later generation of rutile precipitates – with clear zones free of "dust" around the needles and larger precipitate-free zones (also free of needles) along the garnet rims.

The mechanism of rutile precipitation from garnet is not trivial and in fact impossible stoichiometrically unless one assumes significant amounts of Ti^{4+} on the tetrahedral site in garnet [1, 2]; Yang et al, 2005). Hence, a mechanism called open system precipitation (OSP; Proyer et al. 2008, 2011) is invoked, defined as precipitation made possible by exchange of chemical components with external reservoirs such as the rock matrix and/or fluid inclusions). Several open system reaction equations can be devised, the most effective one being a redox reaction by which Fe^{2+} from the dodecahedral site is oxidized to Fe^{3+} and moves onto the octahedral site in order to replace exsolving Ti^{4+}, accompanied by diffusion of electrons and divalent cations. Part of Ti^{4+} may also be reduced to Ti^{3+} because many of the large primary rutile inclusions found in the same garnets display a colour change from brown to grayish-purple, which is typical for reduced rutile. In that case, Ti^{3+}-bearing overgrowths on primary rutile inclusions would be another type of heterogeneously nucleated precipitate.

Garnets with oriented acicular rutile precipitates are not uncommon from high-grade amphibolite, granulite and also eclogite facies rocks, but the typical garnets from such rocks are precipitate-free, and the actual geological significance – particularly the T-t information recorded by the various precipitate types, their size, spatial distribution and morphology – is yet unclear.

Stable Vanadium Isotope Fractionation During Differentiation

PRYTULAK, J[1,2*], SAVAGE, P.S[1,3], HALLIDAY, A.N[1]

[1]University of Oxford, Oxford, UK (Alex.Halliday@earth.ox.ac.uk)
[2]Imperial College, London, UK (*j.prytulak@imperial.ac.uk)
[3]Washington University, St. Louis, USA (savage@levee.wustl.edu)

Understanding and quantifying fractionation processes is key to the application and interpretation of both traditional and non-traditional stable isotopes. In this study we examine the effects of magmatic fractionation on the nascent stable vanadium (V) isotope system [1, 2]. Vanadium exists in multiple valence states and $\delta^{51}V$ should be strongly influenced by changing oxidation state. We present $\delta^{51}V$ of lavas from Hekla, Iceland [3]. Hekla is a fissure volcano with eruptive products ranging from basalt to rhyolite with remarkably coherent liquid lines of descent. The evolution from basalt to basaltic andesite can be clearly related to crystal fractionation [e.g., 4]. In addition to Sr, Nd, Pb, U-series, and O isotopes, Hekla lavas also boast studies of stable Si [3] Li and Fe [5] isotopes, making them arguably the best-characterized differentiation suite in terms of non-traditional stable isotopes. Hekla is therefore ideal to examine $\delta^{51}V$ against a wide backdrop of geochemical data.

We concentrate on basalt to basaltic andesite lavas where V concentrations decrease sharply from ~300 ppm to ~10 ppm. We find a large range in $\delta^{51}V$ of ~2 ‰, which co-varies with major and trace elements. The crystallising mineral phases are olivine, plagioclase, clinopyroxene and magnetite; with magnetite as the dominant V host.

Co-variation of $\delta^{51}V$ with indices of differentiation could implicate Rayleigh fractionation similar to that proposed for $\delta^{56}Fe$ variations at Hekla [5]. No mineral-melt isotope fractionation factors are available, and a bulk *f* must be assumed. However, unlike Fe, V is dominantly controlled by one phase. If Rayleigh fractionation is occurring, then magnetite must be extremely light in order to drive the lava to the observed heavy $\delta^{51}V$ compositions.

The incorporation of V into magnetite will depend partly on the oxygen fugacity of the system. Determining mineral-melt fractionation factors by measurement of $\delta^{51}V$ in both natural and experimental materials could pave the way for the use of magnetite as a unique single mineral tracer of oxygen fugacity.

22c. Applications of emerging geochemical and isotopic analytical techniques for integrated water resource management and environmental monitoring

Innovative mass spectrometry techniques make it possible to detect emerging contaminants, including pharmaceutical compounds and explosives, at concentrations that are environmentally relevant. Applications of these techniques are challenging because of the very low concentrations of these compounds and because of the complex matrices often encountered in the environment. Sample collection methods and analytical procedures must be refined to provide representative samples and analyses that can be used to assess the potential impacts of emerging contaminants.

Two case studies are used to illustrate steps required for the application of tandem mass spectrometry techniques. These studies involved refinement of sample collection techniques, analyte separation methods, analyte quantification, and modifications of instrument configurations.

A large nation-wide survey of explosives was conducted which initially involved the application of HPLC-MS/MS methods. The HPLC-MS/MS technique required inclusion of several isotope-labelled internal standards at multiple concentrations. Modification of the analytical procedure to an IC-MS/MS procedure resulted in decreased matrix suppression effects and improved analyte quantification. These modifications were particularly important for the analysis of groundwater and saline waters.

On-site wastewater disposal systems represent one of the largest volumes of contaminated water discharged to the subsurface. This wastewater contains elevated concentrations of dissolved organic matter, and nitrogen and phosphorus species. Interaction of this water with natural aquifer materials also can result in the presence of elevated concentrations of dissolved metals. The quantification of trace pharmaceutical compounds within this setting requires consideration of sample acquisition methods, sampling equipment materials, the interaction of these materials with the target compounds, and sample matrix effects. Analyses of a suite of pharmaceutical compounds in the low ng L^{-1} were made for samples collected from wastewater dicharge areas, groundwater and DOC-rich surface water. These studies required diligent use of isotope-labelled internal standards to optimize analytical results. Based on these results, mechanisms controlling transport of these compounds can be better delineated.

Early Earth: an insight from the combined Os-Nd-Hf isotope systematics of Barberton komatiites

IGOR S. PUCHTEL[1*], MATHIEU TOUBOUL[1], JANNE BLICHERT-TOFT[2], AND RICHARD J. WALKER[1]

[1]University of Maryland, College Park, MD 20742, USA, ipuchtel@umd.edu (*presenting author), mtouboul@umd.edu, rjwalker@umd.edu
[2]Ecole Normale Supérieure de Lyon, 69007 Lyon, France, jblicher@ens-lyon.fr

We report ^{190}Pt-^{186}Os, ^{187}Re-^{187}Os, ^{146,147}Sm-^{142,143}Nd, and ^{176}Lu-^{176}Hf isotopic, trace lithophile, and highly siderophile element (HSE) abundance data for remarkably well preserved komatiites from the Komati and Weltevreden Formations of the Barberton Greenstone Belt (BGB). These data provide new insights into the chemical evolution of the early Earth. The 3.48 Ga Komati lavas are mildly depleted in LREE and Th and show strong depletions in HREE, whereas the 3.26 Ga Weltevreden lavas are strongly depleted in LREE and Th and are enriched in HREE; both systems show positive Nb and Ta anomalies. The two komatiite systems are characterized by initial γ^{187}Os of +0.34±0.10 and -0.14±0.03 and ε^{143}Nd of +0.30±0.13 and +0.41±0.11, respectively ($2\sigma_{mean}$), indicating evolution of their sources with time-integrated near-chondritic Re/Os and slightly suprachondritic ^{147}Sm/^{144}Nd. The initial ε^{142}Nd in both systems are not resolvable from that in the terrestrial standard. At the same time, these systems have radiogenic initial ε^{176}Hf of +1.9±0.3 and +4.7±0.8, respectively, implying long-term evolution to the times of melting with suprachondritic ^{176}Lu/^{177}Hf. The Weltevreden system is also characterized by an initial ^{186}Os/^{188}Os of +0.22±0.03, indicating evolution of its source with a time-integrated suprachondritic Pt/Os (3.3±0.2 *vs.* 1.8 in chondrites). Finally, the sources of the two komatiite systems are calculated to have had distinct absolute HSE abundances, containing ~50% (Komati) and ~80% (Weltevreden) of the total HSE estimated for the modern Primitive Mantle. The combined data require early formation and long-term isolation of deep mantle domains enriched in majorite and/or perovskite; these domains served as the melting source regions for the BGB lavas. The isolation must have occurred after ^{146}Sm was no longer extant, but before the mantle accumulated the full complement of the HSE as a result of the late accretion. Our combined data also require deep-sourced formation for the BGB komatiites, most probably *via* dry melting in starting mantle plumes. The potential mantle temperatures calculated from the emplaced lava compositions are in excess of 1800ºC, thus providing evidence for extremely hot conditions that existed in the early Archean mantle.

Exploring the Geomicrobiology of the Río Tinto subsurface Mars analog by using a life detector biochip

FERNANDO PUENTE-SÁNCHEZ[1*], MERCEDES MORENO-PAZ[1], PATRICIA CRUZ-GIL[1], LUIS RIVAS[1], MARINA POSTIGO[1], MANUEL J. GÓMEZ[1], MIRIAM GARCÍA-VILLADANGOS[1] AND VICTOR PARRO[1]

[1]Centro de Astrobiología (INTA-CSIC), Madrid, Spain, puentesf@cab.inta-csic.es (*presenting author)

Introduction:

The Iberian Pyritic Belt (IPB) is one of the largest massive pyrite deposits in the world, and is considered as a Martian analog. Several studies [1][2] of the acidic, heavy metal rich-Tinto river in the IPB have revealed a surprisingly rich extreme ecosystem, yet little is known about the geomicrobiology of its subsurface. In a previous work [3] we described an antibody microarray which contains more than 200 antibodies against bacterial strains, different fractions of natural extracts, proteins, etc. and reported its usefulness for immunoprofiling of environmental samples and for the detection of biomarkers with different range of universality.

Results and conclusions:

Here we show the results obtained by using LDChip200 (Life Dectector Chip) for immunoprofiling the whole depth of a drill in the IPB at the Tinto river origin. From 0,5 to 1 g of samples from cores up to 160 m depth were processed for a quick analysis with the LDChip200. The results showed the presence of Gram-positive bacteria and peptides or proteins from the ferritin superfamily which might be involved in tolerance to the high iron concentrations present in the IPB subsurface. Biodiversity was also assessed by DNA extraction and analysis with a phylogenetic oligonucleotide microarray for prokaryotes [4], and by cloning and sequencing of the PCR-amplified bacterial 16s rRNA gene. Members of the Gram-positive Firmicutes group of bacteria were detected by the oligonucleotide microarray and sequencing. Sequencing also revealed sequences similar to those of nitrate and sulphate reducing bacteria. Those results allowed us to build a preliminary model of the ecosystem and provided an initial insight into the biology of the deep subsurface of the Iberian Pyritic Belt.

Ar-39 dating of groundwater: How limiting is underground production?

ROLAND PURTSCHERT[1]

[1]Climate and Environmental Physics, University of Bern, Switzerland, purtschert@climate.unibe.ch

With a half-life of 269 years is ^{39}Ar an ideal tracer for groundwater dating in the age range 50-1000 years [1]. Ground water resources beyond the dating range of transient tracers such as ^{3}H/^{3}He, Sf_6, CFC's and ^{85}Kr become increasingly important due to contamination and overexploitation of shallow and young groundwater's. A potential limitation of ^{39}Ar dating of groundwater, besides the difficult sampling protocol, is the possibility of underground production due to neutron activation of potassium [2]. Over modern ^{39}Ar concentrations have for example been observed in U- and Th- rich crystalline rocks [3]. Another important factor is the escape path and probability of ^{39}Ar from the rock matrix into the water permeable pore space. In this review paper the importance of underground production of ^{39}Ar is assessed. Data collected over the last decade in numerous porous and fractured aquifers woldwide are discussed.

Abstract

Resolving the timing of the last deglaciation in the Southern Hemisphere can aid discrimination among proposed mechanisms for the last glacial termination. Here, we present records of glacier behavior from three former glacier catchments of the Southern Alps, New Zealand, during the last glacial termination. We used ^{10}Be surface-exposure dating and detailed glacial geomorphologic mapping to produce chronologies of well-preserved glacial landforms tracking the last deglaciation in the Southern Alps. We implemented a glaciological model to derive magnitudes and rates of paleo-snowline changes from our ^{10}Be-dated geomorphological record of glacier behavior. Our glacier/palaeo-snowline reconstruction indicates that Southern Alps ice recession and warming took place in two rapid pulses, separated by an interval of cooling and glacier resurgence during late-glacial time. The timing of these warming pulses coincided with the initiation of stadial conditions in the North Atlantic Ocean. In this regard, we discuss the possible role of a bipolar seesaw mechanism for initiating and sustaining the last glacial termination in the southwest Pacific sector of the Southern Hemisphere.

Transient porosity as an integral aspect of microstructural development during fluid-mineral reaction.

A. PUTNIS[1*], C.V. PUTNIS[1] AND H. AUSTRHEIM[2]

[1]Institut für Mineralogie, University of Münster, Münster, Germany , putnis@uni-muenster.de (* presenting author), putnisc@uni-muenster.de
[2] PGP, University of Oslo, Norway, h.o.austrheim@geo.uio.no

Whenever an aqueous solution interacts with a mineral with which it is out of equilibrium the resultant dissolution process is likely to result in an interfacial solution composition that is supersaturated with respect to different mineral or mineral solid solution phases. At this stage the transport properties of the solution and the probability of nucleation within this interfacial aqueous solution will determine the subsequent behaviour of the system. If the rate-determining step in the dissolution-transport-nucleation process is the dissolution rate, the nucleation of the new mineral phase will take place at the dissolving interface. The microstructural evolution of this solid-fluid two-phase product of the interface reaction depends on the possibility that it can continue to grow at the expense of the parent phase i.e. that the fluid can maintain contact with the parent phase at the migrating reaction interface. This will be the case if the volume of the product solid formed is less than the volume of the parent phase dissolved, allowing the fluid phase to occupy the difference. The solid volume deficit depends on both the molar volumes of parent and product phases and their relative solubility in the interfacial fluid [1]. The volume occupied by the fluid in this two-phase reaction product can be described as a porosity in the product solid. The product solid, together with the porosity which may be on a nanoscale, forms a microstructure characteristic of the reaction mechanism. As with all microstructures this is may be a transient phenomenon and subsequent textural equilibration (recrystallisation) in the presence of fluid may eventually eliminate the porosity. In contrast to microstructures formed in solid-solid reactions, the closure temperature at which no further reaction takes place may be as low as room temperature.

Examples of the microstructural development in natural and experimental fluid-mineral reactions will be given to illustrate these general principles [2].

The most important consequence of this mechanism is that it allows pervasive fluid flow through an initially low permeability rock and the transformation of one mineral assemblage to another [3]. A further aspect of this mechanism is the fact that within micropores a fluid can maintain a higher supersaturation than in a free fluid, and furthermore, the rate of dissolution of the parent phase will define a rate of change of supersaturation in the pores at the migrating interface. These two factors define the threshold supersaturation at which nucleation of the product phase takes place [4]. Taken together with the fact that the fluid composition within the porous parent phase will evolve in time depending on the mass transport though the interconnected porosity, modelling such an interface-coupled dissolution-precipitation process has proven to be a challenge.

The mechanism of leached layer formation during mineral dissolution

CHRISTINE V. PUTNIS[1*], ENCARNACION RUIZ-AGUDO[2], CARLOS RODRIGUEZ-NAVARRO[2], AND ANDREW PUTNIS[1]

[1]Institut für Mineralogy, University of Münster, Münster, Germany, *putnisc@uni-muenster.de, putnis@uni-muenster.de (*presenting author)

[2]Department of Mineralogy and Petrology, University of Granada, Granada, Spain, encaruiz@ugr.es, carlosrn@ugr.es

Many minerals and glasses dissolve non-stoichiometrically, i.e. the elemental ratios measured in the fluid during dissolution experiments are different to those in the solid. This phenomenon results frequently in the formation of the so-called leached layers, which are chemically and structurally altered zones at the fluid–solid interface depleted in some elements relative to the bulk mineral composition [1,2]. The mechanism of non-stoichiometric dissolution and leached layer formation has been a subject of significant research over the past decades, due to its relevance to a wide range of natural and technological weathering processes, as well as being critical to define kinetic laws for mineral reactions. In this study, *in-situ* nanoscale Atomic Force Microscopy (AFM) observations have been made of reacting surfaces during the dissolution of two minerals: 1) a carbonate (dolomite, $CaMg(CO_3)_2$) and; 2) a silicate (wollastonite, $CaSiO_3$), both of which are known to dissolve non-stoichiometrically under acidic conditions and/or to develop leached layers upon dissolution. Combined with chemical analyses of both the output solutions and the reacting surfaces, AFM observations lead to a clearer understanding of the reaction mechanism.

Our study gives clear evidence that a leached layer is formed via an interface-coupled dissolution-precipitation mechanism [3] in a two step process: stoichiometric dissolution of the pristine mineral surfaces and subsequent precipitation of a secondary phase (a Si-rich and Mg-rich surface precipitate, respectively) from a supersaturated boundary layer of fluid in contact with the mineral surface, and not by preferential leaching of cations as postulated by most currently accepted dissolution models. Furthermore, this study demonstrates that *in situ*, direct observations of the reacting mineral surfaces are important to unambiguously ascertain the kinetics and mechanism of mineral dissolution. The kinetics of the process can be quantified from the measurement of etch pit spreading rates, which are unaffected by the formation of a secondary precipitate, whose existence has been neglected or simply not observed in the past.

Abstract

The transport of metal ions under hydrothermal conditions such as formation of ore bodies and as corrosion products in nuclear reactors are strongly influenced by temperature, pressure, and the type of complexing ligands. It is difficult to make speciation measurements under extreme conditions, and the interpretation of the measurements is not always unambiguous. *Ab initio* calculations have been shown to be very useful in the interpretation of the spectra of aqueous solutions of metal ions in the presence of complexing ligands, for example Sc^{3+}-Cl^- [1], Zn^{2+}-Cl^- [2] and Zn^{2+}-Br^-[3]. We present here our studies of cobalt(II) in the presence of water, chloride, hydroxide, and ammonia ligands, including predictions of the Raman spectra [4], and compare with recent experimental Raman measurements carried out at the University of Guelph. We will also discuss the stability of mixed OH^-/Cl^- complexes.

Petrogenesis of Quaternary volcanic rocks in the Halaha River and Chaoer River area in Daxing'an Mountain range,North China

QICHENG FAN*, YONGWEI ZHAO, JIANLI SUI

Institute of Geology, China Earthquake Administration, Beijing 100029, email: fqc@ies.ac.cn

The Halaha River and Chaoer River area (HC for short), middle of the Daxing'an Mountain range, is in the north of the North-South Gravity Lineament. 28 Quaternary volcanoes, which scattered along a Quaternary NE strike fault, are found in this area. Based on studies of the volcanic field characteristics, in conjunction with geological dating by K-Ar, it is identified that the volcanism occurred in four periods: Early Pleistocene, Middle Pleistocene, Late Pleistocene and Holocene. Quaternary volcanic rocks in this area, mainly alkaline basalt, cover an area of ca. 1000 km^2. Based on studying of the geochemistry with the Quaternary volcanic rocks in HC, this paper attempts to bring mantle sources and magma genesis in this area to light. The volcanic rocks in HC is of alkali one in sodium series, dominated by alkali olivine basalts. They resemble alkali basalts in Datong, as shown by trace elements distribution patterns, and generally exhibit OIB-like characteristics. They show nearly homogeneous Sr-Nd-Pb isotopic compostition similar to the prevalent mantle. All data show that bsalts of HC have a garnet lherzolite mantle source, low degree partial melting in which at different depth result in the primitive magma. Regional extension triggered asthenospherie upwelling, which may lead to the genesis of magma and subsequent volcanism.

Theme 23: General Geochemistry Sessions
Geochronology: the role of fluids

Our primary purpose to date fluid inclusions by ^{40}Ar/^{39}Ar *in vacuo* crushing was to develop a new approach to obtain ore-forming ages of hydrothermal deposits. We suceeded in dating the mineralization ages of W-Sn, Au, Cu and Pb-Zn deposits using this novel technique on quartz, siliceous breccia and sphalerite [1-4]. Our results indicate that the ^{40}Ar/^{39}Ar stepwise crushing technique is very useful to determine the ore-forming ages, however, some samples probably contain too low K-concentrations to be analysed.

Since 2000, we've been investigating the fluid evolution of the Dabieshan eclogites during UHP metamorphism and retrograde metamorphism by the ^{40}Ar/^{39}Ar progressive crushing on garnet, amphibole and quartz [5-7]. The fluid inclusions of garnet revealed the age messages of the Paleozoic UHP metamorphism, and the amphibole and quartz recorded that the retrograde metamorphism of the Dabieshan eclogites occurred from Permian to early Jurassic.

Due to the lack of suitable minerals for dating, the timing of hydrocarbone charging of reservoirs is one of the most difficult problems in geochronology. We recently applied the ^{40}Ar/^{39}Ar progressive crushing into dating the natural gas emplacement in the Songliao Basin, NE China. The igneous quartz from the Cretaceous volcanic rocks that host the gas reservoir contains abundant secondary fluid inclusions with high K contents and high methane pressures, providing an excellent closed system for ^{40}Ar/^{39}Ar dating. The dating results of the igneous quartz by crushing precisely constrained the gas emplacement at 42.4±0.5 Ma [8].

The crushers were improved again and again to make the crushing tubes and dropping pestles shorter and smaller in diameters. It is very important to crush the mineral grains as homogeneously as possible to obtain a good dating result. ^{40}Ar/^{39}Ar geochronology of fluid inclusions is very useful for us to understand various geological processes with fluids.

Experimental study of the kinetics of CO_2-sequestration by olivines and Hawaiian picrites

LIN QIU[1]*, ZHENGRONG WANG[1], SHUN-ICHIRO KARATO[1], JAY J. AGUE[1], MICHAEL ORISTAGLIO[1], EDWARD BOLTON[1], AND DAVID BERCOVICI[1]

[1]Department of Geology and Geophysics, Yale University, New Haven, CT, USA

*presenting author: lin.qiu@yale.edu

Mafic/ultramafic rocks have been suggested as promising candidates to store anthropogenic CO_2 permanently. In this study, we employed an experimental approach to quantitatively evaluate the carbonation reaction kinetics as CO_2-rich fluids react with olivine (Fo_{90}) and high-Mg basalts (Hawaiian picrites).

Gem-quality olivine grains, olivine powders (10-20μm) and basalt powders (10-40μm) reacted with CO_2-containing solutions (e.g., 1M and 3M $NaHCO_3$ solution) in gold capsules placed in a hydrothermal autoclave over durations of 1-7 days at 200 ^oC and 150 bar. Dissolution experiments for these samples have also been carried out at three pH values (4.1, 6.9 and 9.3) to understand dissolution kinetics. After completion of experiments, gold capsules were checked for leaks, experimental run products were examined using SEM and electron microprobe, and the solution was analysed for alkalinity and major and trace element compositions at Yale University.

Our preliminary results show that carbonation rates of olivines and basalts are a function of the chemistry of the solution (e.g., concentration of $NaHCO_3$), the grain size, the mineralogy of the solid, and the duration of the experiments. We find that carbonation rates increase with increasing concentration of $NaHCO_3$ and decreasing grain size, but decease with time. For example, an increase of $NaHCO_3$ concentration from 1M to 3M raises the carbonation rate for olivine grain by a factor of 6, and the carbonation rate for 10- 40μm olivine powders with 1M $NaHCO_3$ solution is an order of magnitude greater than that for single olivine grains. Carbonation rates of olivine and basalts in the first day are significantly higher than that of the subsequent days and slow down after 3-days of reaction. A dissolution and precipitation model is formulated to quantitatively simulate this process.

The clumped isotope geothermometer in soil and paleosol carbonate

JAY QUADE[1*], JOHN EILER[2], MATHEIU DAERON[3], AND DAN BREECKER[4]

[1]University of Arizona, Geosciences, quadej@email.ariozna.edu (* presenting author)

[2]California Institute of Technology, Geological and Planetary Sciences, eiler@gps.caltech.edu

[3]CNRS, Science du Climat et de l'Environment, mathieu.daron@gmail.com

[4]Univerisity of Texas at Austin, Geological Sciences, breecker@jsg.utexas.edu

We studied both modern soils and buried paleosols in order to understand the relationship of temperature estimated from clumped isotopes in carbonates ($T°C_{clumped}$) to actual surface and burial temperatures. Carbonates from modern soils in a broad range of climates were sampled from Arizona, Nevada, Tibet, and India. $T°C_{clumped}$ obtained from these soils shows that soil carbonate only forms in the very warmest months of the year, largely in the afternoon, and probably in response to intense soil dewatering. The highest $T°C_{clumped}$ obtained from modern soil carbonate are <40°C On average, $T°C_{clumped}$ significantly exceeds mean annual temperature by 10-15°C due to (1) summertime bias in soil carbonate formation, and (2) sensible heating of soil. Secondary controls on $T°C_{clumped}$ are site aspect, but especially soil depth and shading.

Site mean annual temperature (MAT) across 0-30°C is highly correlated with $T°C_{clumped}$ from soils, following the equation:

$$MAT(°C) = 1.20*T°C_{effective\ air\ T\ from\ clumped} - 21.72 \qquad (r^2=0.92) \qquad (1)$$

where $T°C_{effective\ air\ T\ from\ clumped}$ is the effective air temperature at the site estimated from $T°C_{clumped}$. The effective air temperature represents the air temperature required to account for the $T°C_{clumped}$ at each modern soil site. The highly correlated relationship in equation (1) permits mean annual temperature in the past to be reconstructed from $T°C_{clumped}$ in paleosol carbonate, though it should be noted that soil carbonates appear to principally reflect warm season temperatures and so the proxy might be more precisely used as a measure of warm season climate or, in combination with other mean annual temperature proxies, of seasonality.

We also measured $T°C_{clumped}$ from long sequences of deeply buried (≤5 km) paleosol carbonate in the Himalayan foreland in order to evaluate potential diagenetic resetting. We found that paleosol carbonate faithfully records soil $T°C_{clumped}$ down to 3-4 km burial depth, or ~100°C. Deeper than this and above this

Biogeochemical cycles of metals have been deeply modified by anthropogenic activities since the industrial revolution [1]. Since the end of the 90's, the development of metal isotopic ratios analysis provides crucial information about their biogeochemical behaviour. In the case of mining or smelter activities, extracted metals can be clearly followed through their isotopic signatures [2; 3]. Only few publications [4; 5] report the use of Ni isotopes for environmental studies, in spite of its high potential for tracing anthropogenic Ni. The combination of isotopic tools with microspectroscopic techniques (μSRXF and XAS), to unravel metal local distribution and speciation, should improve our understanding of Ni behavior and predict its mobility and bioavailability.

Samples from the ultramafic massives of Barro Alto and Niquelândia (Goiás State, Brazil), constitued in ores, fly ash, slags and natural and waste impacted soils were characterized for their Ni speciation and isotopic signatures. Ni concentrations range from 0.5 to 22.9 $g.kg^{-1}$

Ni K-edge XAS data were collected in bulk and microbeam modes for Ni ore, pristine pyrometallurgical wastes (fly ash and slags) before and after leaching (TCLP and DTPA procedures), to evaluate Ni extractability. TCLP or DTPA leaching leads to the extraction of 0.3 to 8.1% of Ni depending on samples. XANES spectra show that Ni is octahedrally coordinated. Linear Combination Fitting of EXAFS oscillations suggests that Ni in the ore is mainly involved in Ni-phyllosilicates and less than 20% in Ni bearing goethite. The Ni speciation in wastes is dominated by olivine and ferronickel, and leaching procedures only slightly impact Ni speciation.

The relatively high temperature processes occurring during pyrometallurgy processes may be responsible of strong isotopic fractionation [2]. Hence, Ni species from slags and fly ash should be easily distinguished from natural Ni species by their different isotopic signatures. Thus, all anthropogenic materials (ores, fly ash and slags) and soils will be carefully studied for isotopic signatures, in order to trace anthropogenic Ni in this ecosystem.

Insights into biomineral growth from atomistic simulations of clusters and nanocrystals

DAVID QUIGLEY[1*], MATT BANO[2] AND P. MARK. RODGER[2]

[1]Department of Physics, University of Warwick, Coventry. United Kingdom, d.quigley@warwick.ac.uk (* presenting author)

[2]Department of Chemistry, University of Warwick, Coventry, United Kingdom.

Introduction

The common biomineral calcium carbonate ($CaCO_3$) appears in nature as a variety of crystalline polymorphs and morphologies, exhibiting structure on a hierarchy of length scales which cannot be reproduced synthetically. Molecular simulation has a key role to play in elucidating the earliest stages of biomineral growth where length scales prohibit direct observation by experiment.

Nanoparticle simulations

Our previous free energy calculations based on metadynamics [1,2] have established that amorphous structure is energetically competitive with crystalline calcite for particles smaller than 2nm, with calcite structure increasingly preferred at sizes of 5nm and larger. This confirms experimental evidence that $CaCO_3$ growth can proceed via amorphous precursor phases.

Substantial improvements in the quality of force-fields for $CaCO_3$ [3] are enabling new questions to be addressed. Specifically water content and dehydration of the amorphous phase, and the stability of nanocrystals with aragonite or vaterite structure. The latter of these questions is a necessary step in elucidating the mechanisms of polymorph selection during nucleation and growth.

The traditional method of generating atomic representations of crystalline nanoparticles is the Wulff construction, in which a bulk crystal is cleaved such that the total surface energy is minimised. Our most recent work has demonstrated that such an approach fails for models which correctly capture the $CaCO_3$-water interfacial energetics. Surface *enthalpies* are found to be negative, with the entropic penalty of tightly-bound surface water being sufficient to generate a net interfacial free energy penalty.

We have developed an alternative Monte-Carlo method for generating nanocrystal configurations and applied this to the three $CaCO_3$ polymorphs. A discussion of magic-number effects will be presented, along with simulations comparing the energetics of these particles over a range of sizes in explicit water. Some progress toward simulating transitions between nano-crystalline polymorphs will be presented, along with challenges to calculation of transition kinetics.

Pre-nucleation clusters

Improved atomistic models have also allowed larger scale simulations to probe the earliest stages of ion aggregation, suggesting an explanation for the formation of stable pre-nucleation clusters [4]. This talk will present recent attempts to capture this phenomenon in simple lattice models of nucleation and growth.

Nucleosynthetic anomalies of Ni and other transition metals in chondrites and possible carrier phases

QUITTÉ G.[1*] AND POITRASSON F.[2]

[1]CNRS UMR 5276, ENS de Lyon, Université Lyon 1, Lyon, France, Ghylaine.Quitte@ens-lyon.fr (* presenting author)
[2]GET, CNRS - UPS – IRD, Toulouse, France.

Introduction

The numerous nucleosynthetic anomalies found in refractory inclusions, presolar grains and particular phases carried by chondrites suggest that the matter constituting the solar system results from a mixing between different sources. Over the last few years, Ni isotope heterogeneities – among other elements – have been reported in various meteorites. Many samples including ureilite silicates, CAIs, CB metal nodules fall on a mixing line between an s-process and a e-process components [e.g. 1-2] ; altogether it is clear that meteorites come from at least 3 isotopically distinct Ni reservoirs [2-3]. However, the carrier phases of these nucleosynthetic anomalies have not been fully identified yet.

Leachates of carbonaceous chondrites

Focused studies of specific components or stepwise dissolution of carbonaceous chondrites are powerful tools to characterize the fine-scale isotope heterogeneities of the solar system, even if leaching procedures may induce some mixing between the various nucleosynthetic components. Acid leachates of carbonaceous chondrites already display anomalies for a variety of elements [e.g. 4-5]. A stepwise dissolution procedure similar to those previously used in other studies has been applied to facilitate the comparison of the isotopic results. Nickel is a suitable element to resolve the different nucleosynthetic components as ^{61}Ni is overproduced by s-process (AGB stars) when excesses of ^{62}Ni and ^{64}Ni witness nucleosynthesis in a neutron-rich environment (e.g. supernova explosion). Powdered whole rock samples of Allende, Murchison, and Orgueil were sequentially digested with reagents of increasing acid strength. Nickel is not isotopically uniform among the various host phases. Murchison and Orgueil show similar patterns, with widespread deficits in neutron-rich Ni isotopes. Allende is quite different: most leachates are slightly enriched in those isotopes. In Orgueil, the ^{62}Ni-deficit increases with increasing acid strength, which is consistent with the s-process component being carried by acid-resistant SiC presolar grains. Besides, most of the Ni is dissolved by concentrated acetic acid and nitric acid confirming that metal is a major carrier phase. As ^{58}Fe is the most neutron-rich Fe isotope, a correlation is expected with the neutron-rich Ni isotopes: hint towards negative $\varepsilon(^{58}Fe/^{54}Fe)$ values indeed exists in Orgueil fractions [6]. Isotope measurements of Cu and Zn in the same leachates are in progress with the aim of combining data for several elements from the "iron peak group". Correlations, if any, will potentially bring stronger and more precise constraints on the astrophysical setting where the nuclides have been produced, and help better identify the carrier phases of the isotope anomalies.

[4]University of Kiel, Kiel, Germany

Deep convective mixing is thought to play a key role in glacial-interglacial cycles in atmospheric CO_2 by providing a pathway for carbon between the deep ocean and the atmosphere. Such mixing is inhibited in the subpolar North Pacific by very low surface water salinity [1], and as a result the North Pacific is not typically thought to play a direct role in glacial-interglacial CO_2 change [2]. Here we challenge this assumption with new boron isotope and radiocarbon data, that track the behaviour of carbon in the deep North Pacific over the last deglaciation. We show that over the last deglaciation deep water formed to 3600 m in the North Pacific. This is supported by experiments with an earth system model, which show that deep mixing in the North Pacific can account for a significant proportion of atmospheric CO_2 rise during deglaciations.

Early diagenesis of As and P in tropical deltaic systems

SHAILY RAHMAN[1*] AND ROBERT C. ALLER[1]

[1]School of Marine and Atmospheric Sciences, Stony Brook University, Stony Brook, New York, USA,
sharahma@ic.sunysb.edu (*presenting author)
raller@notes.cc.sunysb.edu

In a comparative study of the diagenetic cycling of As in tropical shelf systems, vertical profiles of dissolved and solid phase arsenic were measured in the Guianas mudbelt, a coastal extension of Amazon delta deposits, and in the clinoform delta of the Gulf of Papua, Papua New Guinea. Both tropical systems are highly energetic, sedimentary depocenters with little anthropogenic contaminant input. Some of the highest concentrations of dissolved arsenic in the world are found in the French Guiana porewater samples, with maxima ranging from 5μM (375ppb) up to 13μM (975ppb). Mudbank As concentrations are typically higher than those found in the upstream Amazon delta (~2 – 4 μM). In contrast, porewater samples from the Gulf of Papua overall exhibited lower As maxima than Amazon-Guianas deposits, most often below 1μM, though in Bamu estuary sediments, concentrations exceeded 5μM. At most sites in the upper 10 – 15cm, dissolved arsenic and SRP appears to correlate with dissolved iron, suggesting concomitant release via dissolution of a solid Fe carrier phase, most likely Fe – oxyhydroxide.

In both the Amazon delta and French Guiana mudbank sediments, high As concentrations extend several decimeters downcore, in some cases showing little sign of attenuation (i.e. KS00-17 LC). In the Gulf of Papua, however, after reaching a subsurface maximum, there is little dissolved As remaining in solution with depth in most cores analyzed to date. Sequential solid phase extractions of French Guiana deposits indicate high amounts of As, reaching 300 nmol/g dry sediment. Solid phase As in the Gulf of Papua is ~10x lower than in the Amazon – Guianas mudbelt. Dissolved and solid phase phosphate were measured in several cores from Kourou – Sinnamary mudbank. Total solid phase phosphate (boiling aqua regia leach) measured between 10 - 19 μmol/g, and showed a marked correlation (r2 ranging from 0.7 – 0.95) with total solid phase iron downcore. Maximum dissolved P, SRP, ranged up to 150 μM. Total P at several Gulf of Papua sites were ~20 – 30 μmol/g.

Derivation of an accurate force-field for the simulation of carbonates

PAOLO RAITERI[1,*], RAFFAELLA DEMICHELIS[1] AND JULIAN D. GALE[1]

[1]Curtin University, Department of Chemistry, PO Box 1987, Perth WA 6845, Australia, p.raiteri@curtin.edu.au (* presenting author)

In recent years computational methods have become increasingly important in the study of geochemical processes due to the atomistic insight they are able to provide. In particular, force-field simulations are arguably the natural candidates to study processes that occur at the nano-scale due to their ability to approach the experimental conditions. However, the predictive power of force-field simulation strictly depends on the empirical parameters used in the simple formulae that mimic the atomistic interactions, which need to be derived with considerable care.

This work presents the approach followed in our group to derive force-field parameters based on a combination of static and free energy calculations, which are able to reproduce the thermodynamics of minerals in water [1]. Advantages and limitations of this approach will be illustrated, also in view of possible errors in the experimental thermodynamc quantities that are used to train the force field. The application of this approach to the study of carbonates in an aqueous environment will also be presented.

Although force field simulations do not naturally allow for chemical reactions, different approaches to simulate proton reactivity have been proposed in the past years. In this work an overview of two methods, ReaxFF[2,3] and MSEVB[4,5], is also presented.

Cenozoic boron isotope variations in benthic foraminifers

M. RAITZSCH[1*] AND B. HÖNISCH[2]

[1]Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany, raitzsch@awi.de (* presenting author)
[2]Lamont-Doherty Earth Observatory of Columbia University, Palisades, USA, hoenisch@ldeo.columbia.edu

Background

One of the proxies at the forefront of estimating past CO_2 from marine archives is the boron isotopic composition recorded in shells ($\delta^{11}B_c$) of surface-dwelling foraminifers [e.g. 1], which reflects surface seawater pH and relates to atmospheric CO_2. A prerequisite for translating $\delta^{11}B_c$ into pH is the knowledge of the $\delta^{11}B$ of seawater ($\delta^{11}B_{sw}$), which is essentially unknown prior to the Pleistocene. Whereas boron in seawater has a long residence time of 10-20 My, modeling results suggest that $\delta^{11}B_{sw}$ may have changed considerably over millions of years [2,3], thus restricting paleo-pCO_2 reconstructions beyond the Pleistocene to interpretation of relative shifts rather than quantitative estimates.

Estimating $\delta^{11}B_{sw}$ from $\delta^{11}B_c$

Our benthic foraminiferal $\delta^{11}B_c$ approach is based on (i) the observation that deep-sea pH is quasi-constant below 1000 m water depth and (ii) the assumption that past variations in deep-sea pH were muted compared to surface seawater, similar to the dominant control of ice volume on the oxygen isotopic composition of benthic foraminifer shells. Because the distribution of dissolved boron and its isotopes in seawater is conservative, ocean-wide changes in benthic $\delta^{11}B_c$ should thus primarily reflect changes in $\delta^{11}B_{sw}$. The synthesis of multiple individual estimates from spatially distant core locations thus avoids bias due to regional variations in carbonate chemistry, which likely differed between ocean basins. However, modeling studies based on independent evidence from the CCD history of the ocean and atmospheric CO_2 estimates suggest that deep-sea pH has not remained constant over the Cenozoic. To scale our averaged benthic $\delta^{11}B_c$ record to $\delta^{11}B_{sw}$, we therefore account for a linear 0.45 units pH-increase [4] from 50 Ma until today.

Results & Conclusions

Our 50 My benthic foraminiferal $\delta^{11}B_c$ stack, composed of seven core sites from all ocean basins and various water depths, yields a remarkably consistent record. Although a general influence of whole ocean pH-variation has to be accounted for, the history of CCD-variations is not uniform in all ocean basins [5] and would have caused non-uniform changes in pH and thus in benthic $\delta^{11}B_c$. We do not observe such inter-basin differences in $\delta^{11}B_c$ and hence conclude that our record primarily reflects secular variations in $\delta^{11}B_{sw}$. Accordingly, our estimates suggest that $\delta^{11}B_{sw}$ increased by ~2.5‰ since the late Eocene, superimposed on oscillating variations with amplitudes of up to 2‰ over the entire record.

The Influence of Geology and Substrate on Plant Life in Northeastern North America

NISHANTA RAJAKARUNA

[1]College of the Atlantic, Bar Harbor, ME 04609, USA
nrajakaruna@coa.edu

7f. Critical zone processes: their role in ecology and evolution

Within a given climate, geology plays a central role in the distribution and ecology of plant species and their associated biota. The most significant causes of localized or unusual plant distributions are discontinuities in geology. Abrupt changes in geologic conditions can also set the stage for processes generating plant diversity. The study of plants growing on unusual geologies and substrates has contributed much to ecological and evolutionary theory. While much attention has been paid to the influences of geology and substrate on plant life worldwide, such literature for eastern North America is scant. The work we are currently pursuing on the flora of serpentine and granite outcrops, seabird guano deposits, and metal-enriched mine tailings in Maine suggests a unique substrate effect on the regional flora at taxonomic, physiological, and community levels. Our research highlights the need to better document the floras of other under-explored substrates of the region, including limestone, dolomite, and gypsum, and soils overlying metal-enriched geologies, including mine tailings and waste rock piles. These island-like habitats with unusual chemical and physical soil features can provide unique settings for the assembly of distinct plant communities, consisting of rare and endemic species and physiologically distinct ecotypes of more regionally common species. Such edaphically-restricted plants and their associated biota can provide ample opportunities for descriptive and experimental studies in ecology and evolution, ranging from cellular and organismal to population, community, and ecosystem levels.

Bioremediation of Heavy Metals using Transgenic Microalgae

Microalgae account for most of the biologically sequestered trace metals in aquatic environments. Their high metal binding affinities coupled with efficient metal uptake and storage systems make them efficient metal chelators. These factors combined with their large surface: volume ratios aid them bind up to 10% of their biomass as metals. In addition to essential trace metals required for metabolism, microalgae can efficiently sequester toxic heavy metals which often compete with essential trace metals for binding and uptake into cells. We have developed transgenic approaches to further enhance the heavy metal specificity and binding capacity of microalgae with the objective of using these microalgae for the treatment of heavy metal contaminated wastewaters and sediments. These transgenic strategies have included the over expression of enzymes whose metabolic products ameliorate the effects of heavy metal-induced stress and expression of heavy metal chelating protein such as Metallothionein (MT) to sequester heavy metals. The most effective strategies have substantially reduced the toxicity of heavy metals allowing transgenic cells to grow at wild-type rates in the presence of lethal concentrations of heavy metals. In addition, the metal binding capacity of transgenic algae has been increased five-fold relative to wild-type cells. Recently, fluorescent heavy metal biosensors have been developed for expression in transgenic *Chlamydomonas reinhardtii*. These fluorescent biosensor strains can be used for the detection and quantification of bioavailable heavy metals in aquatic environments. Furthermore, we discuss strategies for utilizing these transgenic algae for applications including sequestration of heavy metals in aquatic sediments.

Carbonaceous aerosols from biomass burning emissions in Northern India: Chemical characterization and temporal trends

PRASHANT RAJPUT[1]*, M. M. SARIN[2], DARSHAN SINGH[3] AND DEEPTI SHARMA[4]

[1]Physical Research Laboratory, Ahmedabad, India, prashant@prl.res.in (*presenting author)
[2]Physical Research Laboratory, Ahmedabad, India, sarin@prl.res.in
[3]Punjabi University, Patiala, India, dsjphy@yahoo.com
[4]Punjabi University, Patiala, India, deeptisharma271286@gmail.com

Introduction

The impact of biomass burning emissions on atmospheric chemistry and climate has been well recognized in the present–day scenario of rapid increase in the concentration of carbonaceous aerosols. Furthermore, mixing state of carbonaceous aerosols with other chemical species in the atmosphere leads to degradation of regional air–quality. Recent studies from south and south–east Asia have led to diverging views on the sources of carbonaceous aerosols, suggesting dominance of biomass burning emissions vis-à-vis fossil–fuel combustion [1–3]. It is, thus, important to document spatial and temporal variability in the chemical characteristics of carbonaceous aerosols through ground–based measurements from source regions in the Indo–Gangetic Plain (IGP). A large stretch of the IGP in Northern India is influenced by emissions from biomass burning during the wintertime.

Materials and Methods

$PM_{2.5}$ samples were collected (twice a week from October 2008 to May 2009 and from October 2010 to May 2011) from a sampling site (Patiala: 30.2° N, 76.3° E, 250 m asl) using a high–volume sampler. The sampler was operated at a flow rate of ~1.2 m^3/min for ~12 hours to filter about 1200 m^3 of air through tissuquartz filters (20 x 25 cm^2). EC and OC were determined on EC–OC analyzer, using a thermal–optical transmittance protocol [3, 4]. PAHs were extracted by accelerated solvent extraction (ASE), followed by matrix purification on a silica cartridge and quantification on GC–MS [4].

Results and Conclusion

Our comprehensive study on the atmospheric abundances of $PM_{2.5}$, EC, OC, WSOC and PAHs from two distinct post–harvest biomass burning emissions (paddy–residue burning during October–November and wheat–residue burning in April–May) show large temporal and inter–annual variability. This is attributable to the source strength and combustion efficiency of the two biomass burning events in the IGP. Relatively, high mass fraction of OC (Av: 0.33) and low contribution of EC (0.03) in $PM_{2.5}$ are associated with the paddy–residue burning (with high moisture content) compared to wheat–residue burning ($OC/PM_{2.5}$: 0.26; $EC/PM_{2.5}$: 0.07). The OC/EC ratio (Av: 10) for paddy–residue burning is about three times higher than that associated with wheat–residue burning emissions. However, the WSOC/OC ratio (range: 0.41–0.91) exhibits similar characteristic for paddy– and wheat–residue burning emissions.

The ΣPAHs/EC ratio of 4.2 mg g^{-1} is significantly higher from paddy–residue burning than that from wheat–residue (1.2 mg g^{-1}). The particulate concentrations of 5– and 6–ring isomers (normalized to EC) from paddy–residue burning are also about 3–6 times higher. The cross plot of PAHs isomer ratios show distinct dominance of agricultural–waste burning emissions in Northern India [4]. This study brings to focus temporal trends in the dominance of carbonaceous aerosols from biomass burning emissions during the two post–harvest seasons and have implications to atmospheric radiative forcing on a regional scale.

Substrates for anaerobic microbial activity in oil sands tailings ponds

ESTHER RAMOS-PADRON[1]*, LINDSAY N. CLOTHIER[1], SANDRA L. WILSON[1], GERRIT VOORDOUW[1], AND LISA M. GIEG[1].

[1]University of Calgary, Biological Sciences, eramospa@ucalgary.ca (*presenting author)

Alberta, Canada, is home to vast fossil energy reserves in the form of heavy oil or bitumen. Surface mining of the oil sands to recover bitumen using a caustic hot water extraction process generates a large volume of solid and liquid waste that is deposited in large storage areas or tailings ponds. The ponds are managed to promote solids densification so that surface water can be recycled. Surface water contains aerobic microbial communities, while the remaining tailings material at depth harbors anaerobic microorganisms. Such microbial communities can potentially affect gas emissions (H_2S and CH_4), solids densification, and the biodegradation of oil-associated compounds in the tailings such as bitumen, naphtha (a low molecular weight mixed hydrocarbon diluent), and naphthenic acids (NA). We previously measured sulfate reduction and methanogenesis rates with depth in tailings ponds and found that these activities are ongoing at discrete intervals [1]. Microbial community analysis showed that sulfate reducers and methanogens were abundant along with other anaerobes like nitrate and iron reducers [1]. However, the carbon sources driving such indigenous tailings pond communities remained unknown.

Thus, to determine the key substrates driving anaerobic microbial processes in tailings ponds, we established enrichments under a variety of anaerobic conditions using anaerobic tailings as inoculum. The incubations were amended with either bitumen, naphtha, or NA as potential carbon sources. Concentrations of nitrate, sulfate, Fe(II) and methane were determined over time in the substrate-amended incubations relative to substrate-free controls as indicators of anaerobic microbial activity. In some cases, substrate concentrations were also determined by liquid or gas chromatography.

In laboratory incubations, bitumen did not serve as a carbon source for anaerobic communities. However, naphtha and NA did drive several anaerobic activities. Incubations established under methanogenic conditions with naphtha showed enhanced levels of methane relative to substrate-free controls, and that this acitivity was ongoing after transfers of the enrichment. Several naphtha components disappeared over time in the naphtha-amended cultures relative to controls. Naphtha components such as low molecular weight alkanes have been shown to drive methanogenesis in samples collected from other tailings ponds [2], thus naphtha is an important carbon source in diverse tailings ponds. Incubations amended with commercially available model NA showed enhanced levels of nitrate reduction, Fe(III) reduction, and methanogenesis relative to substrate-free controls. Natural NA (extracted from tailings pond water) also stimulated Fe(III) reduction and methanogenesis in laboratory incubations. Little is known about the anaerobic transformation of NA in tailings ponds, but our data suggests that in addition to naphtha, NA may also be an important carbon source for the indigenous anaerobic communities.

Reconstruction of the Indian Summer Monsoon at weekly to sub-weekly resolution using terrestrial Giant African Snail *Lissachatina fulica* from northern India.

RAVI RANGARAJAN[1*], PROSENJIT GHOSH[1]

[1]Centre for Earth Sciences, Indian Institute of Science, Bangalore, India. *ravi@ceas.iisc.ernet.in., pghosh@ceas.iisc.ernet.in. (*presenting author),

Reconstruction of the ISM (Indian Summer Monsoon) at weekly to sub-weekly scales using terrestrial land snails is attempted here. Terrestrial mollusc *Lissachatina fulica* belonging to the Giant African Land Snails (GAL's) are endemic to the African sub-continent and have become an invasive species in most parts of the world. In this study, the stable isotopes of oxygen from the carbonate shells of *L.fulica* are used as a proxy to infer the variation in the ISM during the time period at the beginning of the last century. To establish and validate the suitability of the proxy for monsoon reconstruction, *in vitro* growth rate monitoring and present day comparison of precipitation and shell oxygen isotope has been carried out. The in vitro growth rate experiments showed a high growth rate (2.5 mm/week). Further, the dormancy/aestivation periods associated with non-monsoon time were also defined to explore the possibility for weekly reconstruction of ISM precipitation. The $\delta^{18}O$ of present day shells collected from Kolkata were compared with the already available precipitation isotopic data [1]. The $\delta^{18}O$ values ranged from -2 to -6‰ across the growth period of 3 years with marked cyclicity (Figure 1). The approach was then tested with museum specimens that were collected in the year 1918 from the same region. The $\delta^{18}O$ profile of the archived shells showed a higher depletion of ~1 to 2 ‰ than the present day shells, confirming the variation in the amount of precipitation.

Figure 1: Comparative $\delta^{18}O$ plot of the snail shell carbonates of two individual shell specimens along with the cumulative rainfall data of the region.

Fractional crystallization of the Lunar Magma Ocean

JENNIFER F. RAPP[1,2*], DAVID S. DRAPER[2]

[1]Lunar and Planetary Institute, Houston, TX, USA, jennifer.f.rapp@nasa.gov (* presenting author)
[2]Astromaterials Research Office, ARES Directorate, NASA Johnson Space Center, Houston, TX, USA, david.draper@nasa.gov

The current paradigm for lunar evolution is that of the crystallization and differentiation of a Lunar Magma Ocean (LMO) [1]. In this model, the crystallization of the LMO gave rise to the plagioclase-rich ferroan anorthosite highlands crust, due to flotation of less dense plagioclase in the mafic magma ocean; and to mafic cumulates rich in olivine and pyroxene, which were later re-melted to produce basaltic magmas such as mare basalts and picritic pyroclastic glasses. LMO crystallization also produced KREEP, which represents the very late-stage incompatible element enriched liquid resulting from magma ocean crystallization, and is thought to have later hybridized with the ascending basaltic magmas (or their source rocks) resulting in specific minor and trace element enrichments seen in lunar basalts.

Numerical simulations have been used to predict the crystallization sequence of the LMO, the extent of fractional crystallization versus bulk crystallization [2], and the density profile of the resultant cumulate pile [3]. However these models, on which a large portion of lunar petrological research is predicated, remain largely untested experimentally. The Snyder model [2] features crystal suspension in the magma ocean due to vigorous convection, and equilibrium crystallization for the majority of LMO crystallization followed by fractional crystallization of the residual magma ocean. This model has been tested experimentally [4], and found to produce a different cumulate assemblage from that predicted by Snyder. We are experimentally simulating fractional crystallization from the outset of LMO solidification, as an alternative end-member model of lunar differentiation. We find that fractional crystallization of the lower portion of the LMO produces a divergence of residual liquid compositions from that of the equilibrium crystallization process, with liquids being somewhat more orthopyroxene-normative, and trending strongly towards plagioclase after approx. 50 volume % of the magma ocean has crystallized. We also find that spinel crystallizes, in small but significant quantities, in our cumulate pile deeper than predicted by previous models [2-4]. These differences are likely to be more pronounced as fractional crystallization proceeds, leading to concomitant differences in crystallizing assemblages including a lack of garnet in the lunar interior, which has implications for the potential thickness of the anorthosite crust. It remains to be seen whether this melt composition will evolve to produce sufficient plagioclase to account for the lunar crust, with a residuum representing KREEP. The outcome of this experimental investigation will enable us to put further constraints on the mechanisms by which the Moon evolved, in particular the extent, if any, to which equilibrium crystallization played an active role in LMO crystallization.

Abstract

New advances in microprobe technology at beamline X26A, at the National Synchrotron Light Source at Brookhaven National Laboratory, are allowing rapid and high resolution imaging of the distribution and concentration of elements in a sample. With this technique, called a fly-scan, we collect high resolution images in few hours that with conventional XRF scans would take a day. Currently the beam size is approximately 6 x 9 microns, giving a practical limit for the sampling interval of 4 -6 microns. The output of the fly-scan contains the full energy spectra for every detector at each point. To create an image, at each point, a window around the desired spectral peak is summed from each detector. This stacking helps eliminate noise, and provides an additive effect to the sampling time. Thus images of the distribution and concentration of any element whose florescence spectra is within the detection range of the sensors can be created after the data has been collected (Fig. 1).

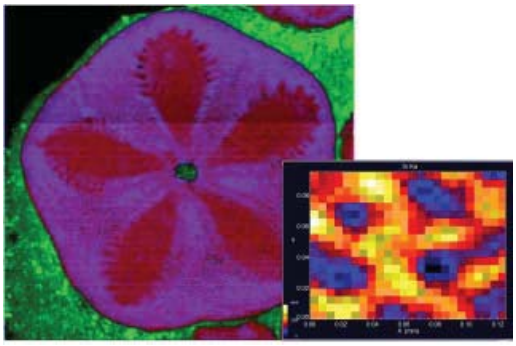

Figure 1: Flyscan image of echinoderm fossil showing distribution of Ca (red) Fe (green) and Sr (blue). Inset of high resolution Sr map from conventional XRF scan showing the typical ossicle structure where the shell is high Sr and the ferroan calcite cement is low Sr.

Carbonate fossils, such as echinoderms, can be used as proxies for the Sr/Ca and Mg/Ca ratios in paleoseawater. However diagenesis and other factors can change the composition of the carbonates. Echinoderm ossicles have a complex porous structure that can rapidly fill with encapsulating cement. This encapsulating cement protects the original carbonate material and creates a microscopic time capsule of the original chemistry [1]. We use fly scan imaging to identify extremely well preserved samples of fossil echinoderms, and measure the composition of the fossil stereom. We then calculate the Sr/Ca ratio of seawater then the fossil was formed. Our results confirm the observations that Sr changes inversely with Mg, and the total strontium concentrations is seawater have fluctuated by a factor of 5, throughout the Phanerozoic [2].

The petrogenesis of monogenetic volcanoes inferred from Lunar Crater Volcanic Field, Central Nevada

[3]Department of Geoscience, University of Nevada, Las Vegas, USA, gene.smith@unlv.edu

The origin of chemical and isotopic variability observed over small spatial scales in basaltic monogenetic volcanic fields is highly controversial, and may be attributed to mantle heterogeneity [1] or to shallow lithospheric assimilation [2, 3], or both. The Lunar Crater volcanic field provides an opportunity to address the importance of shallow versus deep processes in the petrogenesis of basaltic monogenetic volcanoes and the nature of their mantle sources. We have performed Sr, Nd, Pb, Hf and Os isotopes measurement on 19 basaltic lavas from four closely spaced volcanic centers in the northern LCVF. Three eruptive centers (named YMB, OPB and PB [4]) are located within ~500 m of each other; the Marcath volcano, which represents the youngest eruptive center in the field, is located ~6 km SW of these cones. Detailed isotopic studies of the volcanic rocks show a limited range in Nd and Hf isotope ratios, but significant heterogeneity in Sr and Pb isotopes, and superchondritic Os isotope ratios. The lavas are characterized by $^{87}Sr/^{86}Sr$ ranging from 0.7030-0.7037, $^{143}Nd/^{144}Nd$ 0.51286-0.51291, $^{176}Hf/^{177}Hf$ 0.28293-0.28298, $^{206}Pb/^{204}Pb$ 19.16-19.49, $^{207}Pb/^{204}Pb$ 15.55-15.61 and $^{208}Pb/^{204}Pb$ 38.44-38.82. Os concentrations vary from 2 to 241 ppt and $^{187}Os/^{188}Os$ ranges from 0.1336 to 0.61. The lavas produce a well-defined negative correlation between Sr and Pb isotopes that could be attributed to lower crust assimilation. However, the lack of correlation of Sr, Nd or Os isotopes with indices of fractionation (e.g. MgO) suggests a limited role for crustal assimilation. In addition, high (OIB-like) Nb/U ratios and a positive correlation of $^{187}Os/^{188}Os$ with Nb/U argue against an important role for either upper or lower crustal assimilation. These data suggest instead that the basalts are generated by tapping a heterogeneous, enriched mantle source, consistent with trace element chemistry [5]. The HIMU-like trace element patterns and Sr and Pb isotope signatures of the OPB and PB lavas are consistent with derivation from an enriched mantle source with a component of recycled oceanic crust. In contrast, the relatively high Ba, Rb and Cs coupled with lower $^{206}Pb/^{204}Pb$ and higher $^{87}Sr/^{86}Sr$ of the Marcath and YMB lavas are consistent with derivation from an EMI-like mantle source that may be produced by a component of recycled oceanic crust plus sediment. These data indicate that the mantle in this region is characterized by chemical and isotopic heterogeneity over very small spatial scales.

Archean laboratory models possessing photosynthetic microbial mats

MAIJA RAUDSEPP[1+*], NEIL R. BANERJEE[1] AND GORDON SOUTHAM[1]

[1]Department of Earth Sciences, The University of Western Ontario, London, Canada mraudsep@uwo.ca (*presenting author)

Introduction

Geochemical signatures of oxygen oases are preserved in late Archean shallow marine environments several hundred million years before the globally recorded great oxygenation event at 2.45 Ga [1]. We have created two possible Archean environments to observe geochemical changes in an oxygen oasis over several months. In both experiments a consortium of cyanobacteria, aerobic heterotrophs, iron reducing bacteria, sulphate reducing bacteria, and methanogens were grown on an olivine substrate. In the first experiment no additions were made to the system; in the second experiment ferrous iron equivalent to 0.01mM, a low estimate for an Archean ocean concentration, was added daily.

Results

Microbial growth in both experiments was dominated by oxygenic photosynthesis until the system became limited by inorganic carbon (Fig.1). $H_{2(g)}$ from low temperature serpentinization may have supported small amounts microbial growth.

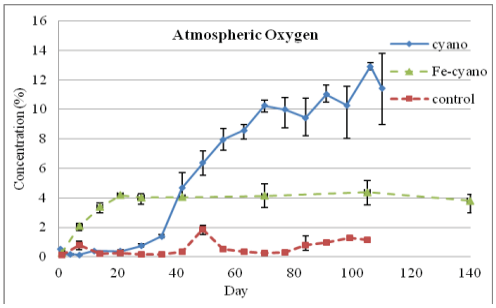

Figure 1: Oxygen accumulation from cyanobacteria mat (cyano), established cyanobacteria mat with iron additions (Fe-cyano) and un-innoculated system with no iron addtions (control).

In the low iron system, scanning electron microscopy showed some sections of mat were mineral free, whereas, other sections had dense accumulations of 0.5-20µm Mg-rich phyllosilicates. Different microbial communities were established on Fe-rich olivine versus Mg-rich olivine. In the high iron system lower oxygen resulted from the oxidation of $Fe^{2+}_{(aq)}$ producing <1µm ferric hydroxides particles. Ferric hydroxides densely covered the cyanobacteria and attached to heterotrophs. Mat growth was not hindered by the addition of iron but greater amounts of exocellular polymeric substances were produced.

Conclusion

This study demonstrates that bacteria in an Archean oxygen oasis had the potential to be fossilized by iron hydroxide minerals. Phyllosilicates, produced in part by biogenic alteration most, likely did not preserve bacteria morphology.

Anthropogenic alteration of dissolved inorganic carbon fluxes from watersheds

PETER RAYMOND[1]

[1]Yale School of Forestry and Environmental Studies, New Haven, United States, peter.raymond@yale.edu

Section Heading

Introduction. Stream and River dissolved inorganic carbon fluxes represent a key linkage between major reservoirs in the global carbon budget. Over geologic time scales changes in inorganic carbon fluxes from land to sea can cause changes in atmospheric CO2. On shorter time scales alterations in these fluxes can be important to terrestrial carbon budgets, soil chemistry, and the buffering capacity of receiving waters. Here I will discuss what is known about the influence of human's on DIC fluxes from watershed.

Speckled zircon from mafic granulite: mechanism and meaning

N.M. RAYNER[1*], D. E. MOSER[2], M. SANBORN-BARRIE[1]

[1]Natural Resources Canada, Ottawa, Canada, nrayner@nrcan.gc.ca (* presenting author)

[2]Western University, London, Canada, desmond.moser@uwo.ca

Located in northern Hudson Bay, Southampton Island, Nunavut, is uniquely situated to provide critical insight into the assembly and evolution of northeast Laurentia. Archean and Paleoproterozoic plutonic rocks with 3.0-3.6 Ga Nd model ages dominate the eastern half of the island and include a layered ultramafic complex of which gabbroic anorthosite makes up a minor component. Mineral assemblages and thermobarometry record evidence of granulite-facies metamorphism with peak conditions of 900°C and 10kbar [1]. Zircons recovered from the gabbroic anorthosite are characterized by a distinct speckled zoning pattern in cathodoluminesence (CL) images (Figure 1).

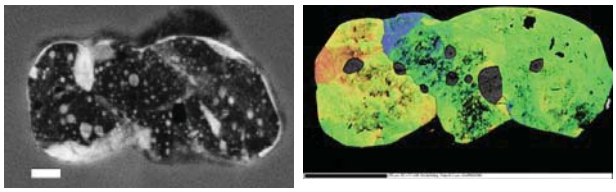

Figure 1: (Left) CL image showing speckled texture in zircon from mafic granulite. Scale bar 20µm. **(Right)** EBSD texture map (after re-polishing) showing relative crystallinity and low angle (up to 4°) misorientation of zircon lattice. Plagioclase inclusions show in grey.

Detailed geochronology, imaging, microstructural analysis and trace element geochemistry are applied to characterize the mechanism(s) responsible for this texture. SHRIMP U-Pb results define a discordia with an upper intercept of ca. 3.0 Ga and a lower intercept of ca. 1.87 Ga. Two interpretations of these results are feasible; the upper intercept may represent the crystallization age of the anorthosite or an inherited component. Accordingly, the lower intercept may record the timing of granulite-facies metamorphism or its crystallization age. EBSD mapping reveals that bright CL 'speckles' are subhedral domains of highly crystalline, unstrained zircon within a zircon matrix exhibiting finer-scale microstructure. Subgrains have rotated by several degrees across transverse, low -angle boundaries, possibly annealed fractures. The latter are sites of zircon recrystallization, suggesting a dynamic deformation and thermal annealing process. This combined isotopic, geochemical and microstructural study allows us to evaluate the two end-member tectonic scenarios; whether the mafic intrusive complex was emplaced and cooled within the deep crust (ca. 30km) during the Paleoproterozoic or whether Paleoproterozoic deep-crustal burial of a Mesoarchean layered complex produced the 'speckled' zircon microstructure and host granulite-facies mineralogy.

The French Radioactive Waste Management National Agency (Andra) is preparing submission of a license to build application for a high level and long lived radioactive waste repository in the Callovo-Oxfordian geological formation in the eastern Paris basin. In this context, flow and solute transport modelling is carried out at the Paris Basin scale in order to understand past and predict future hydrogeological behaviour. The past to present transport characteristics of the basin must be understood to constrain this model. Cl, He and their stable isotopes are considered as good natural tracers to be used for investigating the transport processes and behaviour within a multi-layered aquifer system at regional and local scales. Synthesis of data resulting from over 20 years of study and covering the entire Paris basin provides valuable information which was used to constrain and consolidate a conceptual model of basin evolution.

Chloride transport is dominated by vertical diffusion from the halite level of the Keuper formation in the east of the basin. The mix between primary and secondary brines associated with this level moved laterally into the rest of the basin since the early cretaceous due to uplift of the east border of the basin, generalizing the upward diffusion of chloride from Triassic levels to the entire system. Paleo circulation occurred two times in Dogger and Rhetian at -149±6My and -99±2Ma [1] before general uplift of the basin at the beginning of the Paleogene. Chloride spatial distribution indicates local activities of faults which induced hydraulically conductive links between Triassic, Liassic and Dogger formations.

Helium transport also appears to be dominated by global vertical diffusion from crust to the top of the sedimentary pile in the central and western parts of the basin. This system is separated into two independent domains in the east of the basin by the Keuper halite levels which act as a barrier to diffusion. In the vicinity of present Triassic outcrops in the east of the basin, $^{3}He/^{4}He$ ratios are characteristic of a mantel-derived ^{3}He contribution, quickly changing to a crustal-type $^{3}He/^{4}He$ ratio further along the flow path. The $^{3}He/^{4}He$ ratio in the centre of the basin corresponds to a binary mixing of a southern mantel-derived component and an eastern crustal component.

Simplified 1D modelling of He, Cl, Br and δ37Cl for last 70 My suggests that current lateral advection in the Oxfordian and Dogger formations over and underlying the Callovo-Oxfordian are active since 20 My and 5 My respectively, in the sector considered for the radioactive waste repository.

Mineral Precipitation Between Solutions Flowing in Parallel

GEORGE REDDEN*, DON FOX, JAMES HENRIKSON, LUANJING GUO, HAI HUANG, YOSHIKO FUJITA

Idaho National Laboratory, Idaho Falls, ID,USA (George.Redden@inl.gov, Don.Fox@inl.gov, Luanjing.Guo@inl.gov, James.Henriksen@inl.gov, and Hai.Huang@inl.gov (* presenting author)

Engineering mineral precipitation in the subsurface requires generating supersaturated conditions in order for desired minerals to nucleate or grow. For multi-component precipitation reactions, reactants must become mixed at the molecular scale. Different strategies can be used to mix reactants, either prior to introduction into the subsurface or *in situ*. Due to the strong coupling between reactant transport, mixing, and nucleation/growth processes, different mixing strategies will produce different spatial and temporal distributions of precipitates in the subsurface, with distinctly different outcomes with respect to the location of precipitates, changes in media properties and volume averaged rates of reactions. We have been studying the formation of precipitation reaction fronts that are generated by transverse mixing across the interface between solutions flowing in parallel.

Using a flow cell with a homogeneous sand packing, separate solutions containing calcium and carbonate were injected upward in a parallel flow configuration (Figure 1). The solutions, if mixed directly, would create strongly supersaturated conditions for calcite. The objectives were to quantify: 1) the dimensions of the precipitation zone, 2) changes in transverse permeability with distance along the zone, and 3) transient changes in the chemical properties (e.g., pH) on either side of the zone. In addition, we investigated the influence of differences in density of the two solutions on the position of the precipitation zone. The precipitation zone was found to be on the order of 1-2mm across. (This is in contrast to related experiments that involved mixing by double diffusion without advection, where the width of the precipitation zone was >1cm.) A low pH wedge formed on the side containing unbuffered calcium. Formation of asymmetric chemical conditions was consistent with expectations based on the $CaCO_3$ precipitation reaction stoichiometry and the properties of the solutions; however an anticipated disappearance of the pH wedge due to reduced permeability in the precipitation zone was not observed. A two-dimensional numerical model has been developed to simulate the nonlinearly coupled processes of flow, transport, and reaction in the system. Different scenarios with varying flow rate and solution concentrations (engineering controls) have been tested.

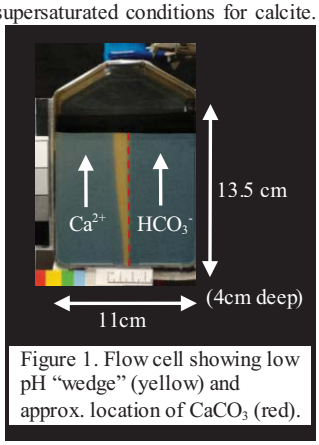

Figure 1. Flow cell showing low pH "wedge" (yellow) and approx. location of $CaCO_3$ (red).

Bioaccessibility of arsenic in soil: method evaluation, comparison to *in vivo* primate data, and influence of soil chemistry

JIM REDWINE[1]*, NICK BASTA[2], RONA DONAHOE[3], MARY MCLEARN[4], AND JAMIE RICHEY[5]

Several studies have shown relatively limited human and animal absorption of arsenic from contaminated soils. Extensive efforts are presently underway to develop less expensive laboratory (*in vitro*) tests that simulate *in vivo* results, and validate them against live animal data. In this study, *in vitro* tests using three common methods were performed on soils for which *in vivo* primate data were available. *In vitro* and *in vivo* test results were then compared. The same soils were treated with iron amendments, to determine if iron treatment reduced arsenic bioaccessibility. Prior to testing, soils were extensively characterized to enable better interpretation of the results of the *in vitro* tests. *In vitro* data by all three methods correlates poorly with primate data. Specifically, with the exception of one iron-rich soil, *in vitro* tests over-estimate bioavailability by factors ranging from 1.3 to 16.7. The presence of calcium carbonate or iron in soil affects the results of the *in vitro* tests. The largest *in vitro* over-estimate occurred for calcium carbonate soils, and iron binds arsenic such that it is less extractable in the *in vitro* tests. As expected, iron treatment significantly reduced arsenic bioaccessibility in the soils studied. A large data base of physical and chemical information was generated for these soils, and with more detailed analysis, could be used to help determine other geochemical influences on arsenic bioavailability and bioaccessibility.

X-ray pair distribution function and NMR studies of biogenic amorphous calcium carbonate

RICHARD J. REEDER[1*], MILLICENT P. SCHMIDT[1], LAURA M. KUBISTA[1], YUANZHI TANG[2], BRIAN L. PHILLIPS[1]

[1]Stony Brook University, Geosciences, Stony Brook, NY, USA rjreeder@stonybrook.edu (* presenting author), millicentpschmidt@gmail.com, lkubista@gmail.com, brian.phillips@sunysb.edu

[2]Harvard University, Engineering and Applied Sciences, Cambridge, MA, USA tang.yuanzhi@gmail.com

Introduction and Approach

Amorphous calcium carbonate (ACC) is known to serve multiple functions during biomineralization processes: as a transient precursor to crystalline $CaCO_3$, as structural components of functional hard parts, and as temporary storage of calcium. Minor additives play important roles in stabilization of ACC as well as in transformation to crystalline forms. Yet, the specific interactions of the additives with the ACC remain largely unknown. One of the main limitations in understanding ACC stabilization and transformation mechanisms is a lack of knowledge of short- and medium-range structure in the amorphous phase. Recent application of synchrotron total X-ray scattering and pair distribution function analysis has allowed characterization of short- and medium-range structure extending up to length scales of 15 Å in synthetic hydrated ACC [1]. NMR studies provide insight to the role of hydrogen bonding in the local structure. We have applied these same experimental approaches to examine structure in hydrated biogenic ACC to provide a comparison with synthetic ACC. American lobsters produce gastroliths that are composed almost entirely of hydrated ACC.

Results and Conclusions

X-ray PDFs for gastrolith ACC exhibit a weak, sharp peak at 1.3 Å and a strong, sharp peak at 2.4 Å, resulting from first-shell C-O and Ca-O bonds. A weak peak is also evident at ~2.9 Å, appearing as a small shoulder to the 2.4 Å peak. In addition, there are two broad peaks of lower amplitude centered at ~4 and ~6 Å, with even weaker oscillations extending up to ~12 Å. Comparison with the PDF for synthetic hydrated ACC shows essentially identical features, in both position and amplitude. Reverse Monte Carlo refinement has shown that the broad features at 4 and 6 Å represent dominantly Ca-Ca and Ca-O pair correlations [2]. NMR data likewise closely resemble those for synthetic ACC, showing a broad ^{13}C peak near +169 ppm, 3.6 ppm FWHM. Phosphorus present at minor concentrations in the gastrolith yields a ^{31}P NMR peak at 2.8 ppm, similar in position to phosphate in crystalline $CaCO_3$ but much broader (5.5 ppm FWHM), indicating a wide range of local environments. ^{31}P-detected ^{1}H NMR spectra contain a broad sideband envelope characteristic of rigid structural water, similar to ^{1}H spectra of synthetic ACC, suggesting intimate association of phosphate in the gastrolith ACC.

The role of lead (Pb) in highly saline fluids of a deep geothermal system: complexation and precipitation

SIMONA REGENSPURG [1]*, RUDOLF NAUMANN [2], ELVIRA FELDBUSCH[1], FIORENZA DEON[1]

[1]GFZ German Research Centre for Geosciences, International Centre for Geothermal Research, Potsdam, Germany, regens@gfz-potsdam.de (* presenting author)

[2]GFZ German Research Centre for Geosciences, Section 4.2 Inorganic and Isotope Geochemistry, Potsdam, Germany rudolf@gfz-potsdam.de

At the geothermal in situ laboratory in Groß Schönebeck (North German Basin) fluid of a Permian sandstone reservoir is produced from about 4.4 km depths, where the temperature is about 150°C at 45 MPa pressure. The brine is characterized by a very high salt content of 265 g/L total dissolved solids, which is mainly composed of NaCl and $CaCl_2$ [1]. During the initial testing phase of the geothermal fluid loop between April and October 2011, fluid was produced from one well at temperatures below 100 °C. After passing a gas seperator and two filter units (< 20 µm), the fluid was re-injected into a second well. During that phase, fluid samples were collected with a special sampling device, allowing to take fluid at in-situ pressure and temperature from the above ground installations after the production well. Fluid samples were collected at various temperatures between 20 and 100 °C. Addionally, filter residues as well as mineral scalings, which precipitated within the well bore have been collected and analyzed. One of the compounds of interest both in fluid and in solid phase is lead (Pb), which was found to be highly enriched (up to 1 mM) in the fluid solution as well as in most of the solid samples.

Solid samples were analyzed by X-ray diffraction (XRD), Scanning Electron Microscopy (SEM) and, after acid extraction by ICP-MS or OES for total elemental composition. Although a large quantity of the material was weakly crystalline or amorphous, some crystalline phases were identified in the samples. Lead occured in different minerals such as laurionite (PbOHCl), galena (PbS), native Pb and PbO, indicating that redox processes play an important role in the borehole.

Fourier Transform Infrared Spectroscopy (FTIR) spectra were collected both on samples of the geothermal brine and on synthetic Pb containing solutions of various composition to identify Pb complexation in the solution.

The aim of these investigations was to understand Pb mobility and the factors affecting Pb solution and precipitation at geothermal conditions.

Extracellular reduction of uranium via *Geobacter* conductive pili as a protective cellular mechanism

GEMMA REGUERA*

Michigan State University, Department of Microbiology and Molecular Genetics, East Lansing, USA, reguera@msu.edu

Abstract

The in situ stimulation of Fe(III) oxide reduction by *Geobacter* bacteria leads to the concomitant precipitation of U(VI) from groundwater. Despite its promise for the bioremediation of uranium contaminants, the biological mechanism behind this reaction has remained elusive for almost two decades. Because Fe(III) oxide reduction by *Geobacter* requires the expression of their conductive pili, the contribution of the pili to uranium reduction was investigated in strains of *Geobacter sulfurreducens* with various levels of piliation and in pili-defective strains [1]. Pili expression significantly enhanced the rate and extent of uranium reduction per cell and resulted in the immobilization of the soluble, hexavalent uranium, U(VI), along the pili as a mononuclear tetravalent uranium, U(IV), complexed by carbon containing ligands and with coordinations consistent with a biological mechanism. There was also a direct correspondence between the levels of piliation, the cell envelope respiratory activities, and the cell viability. In contrast, the pili-defective strains preferentially reduced the uranium in the periplasm and had reduced respiratory activities and viability. Furthermore, the degree of periplasmic mineralization in the pili-deficient strains correlated well with their outer membrane *c*-cytochrome content.

It is unlikely that cytochromes released from the outer membrane could have associated with the pili and contributed to the reductive precipitation of uranium, because direct probing of the pilus filaments by scanning tunneling microscopy did not reveal any electronic features resulting from the contribution of cytochrome heme groups [2]. Rather, they show topographic and electronic features intrinsic to the pilus shaft [2]. Furthermore, there was no correlation between the amount of uranium reduction and the cytochrome content of any of the strains tested [1].

Conclusion

The polymerization of the micrometer-long conductive pili on the cell envelope increases the redox-active surface area available for binding and reducing uranium outside the cell. Not only do the pili enhance the reductive precipitation of the soluble U(VI), but also prevent it from penetrating inside the cell, thus preserving the vital respiratory activities of the cell envelope and the cell's viability. Hence, the results support a model in which the conductive pili function as the primary mechanism for the reduction of uranium and cellular protection.

Carbonate alteration of dolerite intruding coal seams: a natural example of carbon sequestration during fossil fuel combustion and relevance to industrial solutions involving mineral carbonation

DAVID REID[1*], MOTSHIDISI NGWAGWE[1], TENDAI MATHIVHA[1], NICOLE MEYER[1], JACQUES VOGELI[1]

[1]Department of Geological Sciences, University of Cape Town, South Africa, david.reid@uct.ac.za (* presenting author)

Coal seams within the Karoo sequence of South Africa are variably intruded by numerous dolerite dykes and sills that have not only produced a thermal metamorphic effect in the surrounding coal but have themselves been altered by fluids sourced from the original magma and surrounding country rock sediments. While the most significant effect in the adjacent coal is widespread devolatilisation and occasional burning, probably brought about by the heat migrating from the cooling magma, there appears to be a protracted period of hydro- and carbo-thermal fluid activity.

Carbonate alteration of the dolerite is restricted to where the intrusions cut the coal measures and is characterised by pseudomorphic replacement of the primary igneous mineralogy. Olivine and pyroxenes are the first to be replaced, followed by Fe-Ti oxides and finally plagioclase. The degree of replacement varies from essentially complete at the contacts but reduces inwards, with dykes wider than about 3m retaining unaltered interiors. Sills tend to track up and down the stratigraphic sequence along strike so their alteration can vary considerably, depending on proximity to the individual coal seams.

Carbonate replacing the igneous minerals have ternary Ca-Mg-Fe compositions that reflect their hosts, although the correlation is by no means close. There appear to be three broadly defined compositional groups: calcites, dolomites and siderites, that have developed in textural patches dominated by plagioclase, pyroxene and Fe-oxides respectively. These compositional patterns do however confirm the in situ replacement origin by fluids migrating into the solidified dolerite.

Carbon and Oxygen isotope ratios in the carbonates are indicative of a mixture between magmatic and coal sources but require a significant component of the latter, thereby confirming an internal closed system consistent with built in sequestration. Judging from the distribution of dykes through the mine lease area and the proportion of which is carbonated, we estimate that the order of 100s of tonnes of CO2 were taken up by these intrusions. Extending this estimate to incorporate the effect of the sills and to project across the entire coal field is fraught with uncertainty but may involve a factor of 100x. Consequently the natural process probably involved only modest quantities of CO2 and associated C-H-O fluid components.

It is clear that for dolerite to absorb CO2 produced by coal metamorphism, the process was enhanced by near magmatic temperatures, abundant fluid and prolonged geologic time. Low cost energy proxies have to be found for any industrial process that is to be based on the natural phenomenon. However, there are abundant mineral reservoirs with similar bulk composition that are available in South Africa and even worldwide that could be utilised for mineral carbonation.

Iron is integral to global biogeochemical cycling, and is increasingly studied in marine systems based on both speciation as well as size distribution. However, to date, the size-associated distribution of iron species in freshwater lakes has not been investigated. The physico-chemical properties of a lake, as well as interaction with suspended particles, bed sediments, and floc, affect the stability and bioavailability of iron compounds. Iron compounds and trace metals may be present within several operationally defined size fractions, each representing a pool that can differ in bioavailability, sorption reactivity, and mobility. In addition to trace metal concentrations, iron species and abundances are likely to change with depth as well as along creek-lake transects, indicating finer depth scale assessment will provide a more accurate picture of iron-metal dynamics in freshwater systems. Here, the objective is to gain a more thorough understanding of iron distribution within (1) a stratified, anoxic water column as well as (2) along a wetland-lake transect, (Algonquin Park, ON), by determining the relative proportion of iron species in four operationally defined size fractions: particulate (>0.45 um), large colloidal (0.45>0.2 um), small colloidal (0.2>0.02 um), and dissolved (< 0.02 um). Samples from ten depths within the Coldspring Lake water column (July 20-21, 2011) and twelve sites along the Costello Creek - Lake Opeongo transect (August 25-28, 2011) were sequentially filtered into four size fractions, and preserved for trace metal analysis by ICP-MS, and $Fe^{2+/}Fe^{3+}$ quantification by the Ferrozine method. Results assessing Fe^{2+}/Fe^{3+} speciation and abundances, with linkages to trace metal concentrations, in each of these systems will be presented..

OXIDATIVE WEATHERING ON THE EARLY EARTH

CHRISTOPHER T. REINHARD[1*], STEFAN LALONDE[2], TIMOTHY W. LYONS[1]

[1]Dept. of Earth Sciences, Univ. of California, Riverside, CA 92521 USA (*correspondence: christopher.reinhard@ucr.edu)

Recently accumulating evidence suggests that the biological production of oxygen in Earth's surface oceans preceded the initial accumulation of large amounts of oxygen in the atmosphere by 100 million years or more. However, the potential effects of oxygen production on surface ocean chemistry have remained little explored, and questions persist regarding both the potential role of oxidants other than molecular oxygen and the locus of oxidation of crustal material (i.e., subaerial and/or submarine settings). Here, we revisit the notion of transient and/or spatially restricted 'oxygen oases' in the Archean surface ocean by employing a simple steady-state box model of the surface ocean in a coastal upwelling system, and explore the plausibility that such a system could support the widespread oxidation of reduced crustal minerals. We find that although it is possible to establish strong air-sea gas exchange disequilibrium with respect to O_2, there is an apparent timescale mismatch between the kinetics of oxidative dissolution and the rate at which reduced minerals delivered physically to shallow marine sediments will be buried below the zone of oxidant penetration. In addition, the circum-neutral pH of marine environments places stringent constraints on the efficacy of Fe^{3+} as an oxidant for crustal sulfides, rendering the most important sulfide oxidant in modern weathering systems ineffective. Estimated dissolution timescales compare more favorably with typical timescales of soil development, despite the much lower dissolved oxygen concentrations inferred for a subaerial environment at gas exchange equilibrium with atmospheric pO_2. We suggest that, although the production and accumulation of dissolved O_2 in the Archean surface ocean is probable under certain conditions and should be explored as a biogeochemical agent, it is unlikely that extensive oxidative weathering of chalcophile elements such as Mo, Re, and S occurred within the marine realm.

Sorption of uranium(VI) and radium(II) at trace level onto kaolinite and montmorillonite

ESTELA REINOSO-MASET*, DELPHINE HAINOS, JACQUES LY

CEA Saclay, DEN/DANS/DPC/SECR/Laboratoire de Mesures et de Modélisation de la Migration des Radionucléides, 91191 Gif-sur-Yvette, France (*estela.reinoso-maset@cea.fr)

Clays are one of the main components of soils and sediments, and are known to have the distinctive property of retaining ions, generally with a high affinity for cationic species. Since retention processes confer a retardation effect on the migration rate of contaminants, the clay content and the intrinsic properties of clays will determine the prevailing process during the transport of contaminants through subsurface environments.

Uranium and the long-lived decay product radium-226 are abundantly present in the vast mine waste produced during uranium extraction activities. However, in the case of release to the surrounding environment, these radionuclides would be found at trace level compared to major cations present in interstitial waters; and hence, the extent of radionuclide sorption will be conditioned by the predominant occupancy of surface sites by the latter solutes. Therefore, the aim of this work was to study the sorption of trace level uranium(VI) and radium(II) on two common phyllosilicate minerals, kaolinite and montmorillonite, alongside with the sorption of sodium, potassium, calcium and magnesium at higher concentration.

Batch type experiments using chemical and radiochemical analytical techniques were carried out to obtain the intrinsic ion-exchange properties of both clay minerals and the ion-exchange equilibria occurring at the mineral-solution interface with the associated selectivity coefficients for Na/H, K/H, Cs/H, Ca/H and Mg/H ion couples. Sodium, K, Cs, Ca and Mg were introduced in sufficiently high amount in separated batches containing the respective homo-ionic clay forms and the adsorbed cation concentration was measured as a function of pH. The results enabled to determine the clay surface sites characteristics (i.e. the number and concentration of sorption site types) and to confirm the multi-site ion-exchanger properties of these clay minerals, as previously observed for montmorillonite [1]. The sorption of U(VI) and Ra(II) at trace level was determined through distribution coefficient (K_d) measurements at different pHs.

Finally, the sorption data for both clays was processed according to a general multi-site sorbent / multi-species sorbate model which has already been applied to successfully describe the sorption reactions on mineral surfaces [2, 3]. The modeling results will provide with fundamental sorption equilibria stoichiometries and constants crucially needed for the calculation of the interfacial chemistry to be coupled to transport in predictions of radionuclide migration rates.

Reevaluating osmium isotopes as tracers of glacial-interglacial cycling

LAURIE REISBERG[1*], DOMINIQUE BLAMART[2], AND CATHERINE ZIMMERMANN[1]

[1]CRPG-CNRS, Université de Lorraine, reisberg@crpg.cnrs-nancy.fr (* presenting author); Vandoeuvre-lès-Nancy, France
[2] LSCE (CEA-CNRS-UVSQ), Dominique.Blamart@lsce.ipsl.fr, Gif-sur-Yvette, France

Over the past 15 years, several studies [1-5] have demonstrated correlations between the Os isotopic compositions of hydrogenous marine sediments and glacial-interglacial variations. These are often attributed to decreased continental erosion during glacial episodes. However, the short Os marine residence time (< 5ka) inferred from these rapid variations is inconsistent with that derived from mass balance considerations (~25 to 40 ka, [6-8]). This observation has prompted the proposal that rapid weathering during deglaciations produces transient spikes in the concentration and/or isotopic composition of Os delivered to the ocean, thus arguing that the riverine flux and the oceans are far from steady state equilibrium [9].

Nevertheless, these interpretations rest on the assumption that the available Os isotopic records faithfully reflect the past Os compositions of global seawater. However, many records may be biased by basin isolation, detrital input, and low sedimentation rate. To obtain a reliable, high resolution record of Quaternary marine Os isotopic variations, we are analyzing sediments from ODP Leg 175, Site 1084, drilled beneath the Benguela Upwelling System (BUS) off Namibia. As an open ocean site with rapidly deposited (~ 18 cm/kyr) organic rich sediments, it should be unaffected by the problems noted above. Results from 24 samples analyzed to date, spanning the past ~130 ka, show much less variability ($^{187}Os/^{188}Os$ =1.037 ±.026; 2σ) than that found in previous studies (~10%), and no correlation with glacial-interglacial variations. Instead, the uniformity of the BUS Os record ressembles that of an early Pleistocene record from the equatorial Pacific Ocean [9]. One explanation for the discrepancy between the BUS results and other late Quarternary records may be that the latter reflect local, rather than global, processes. However, while this explanation seems logical for sediments deposited in semi-isolated near-shore basins [2-4], local effects are unlikely to modify the Os compositions of open ocean sites [1,5]. Instead, we consider the fact that dissolved Os may be present in several oxidation states, and experimental studies suggest that it is difficult to pass from one to another [11]. Os incorporated into metalliferous sediments [1] or planktic foraminifera [5] under oxidizing conditions may not be in the same form as that incorporated under the reducing conditions prevailing in the BUS. Thus it may be too simplistic to consider that all of the Os present in the oceans is contained within a single uniform reservoir with a well-defined residence time.

The vapour-liquid fractionation of Cu stable isotopes: a new tool for porphyry research

KIRSTEN U. REMPEL[1,2*], ROLF L. ROMER[1,3], AXEL LIEBSCHER[1,4]

[1] GFZ German Research Centre for Geosciences, Potsdam, Germany
[2] rempel@gfz-potsdam.de (* presenting author)
[3] romer@gfz-potsdam.de , [4] alieb@gfz-potsdam.de

Copper is an essential element for green technologies such as long-life Cu batteries, thin films and other highly conductive materials, while porphyry Cu-Mo deposits are a major source of other metals crucial to green industry (Mo and Re). The formation of these deposits typically involves a two-phase magmatic fluid comprised of aqueous vapour and liquid, and significant quantities of Cu may be transported in both of these phases. The stable isotope signature of Cu in each fluid phase could be of use in tracking the evolution of the fluid system, or in identifying zones of a porphyry deposit formed from the vapour- and liquid-dominated fluid regimes. In order to investigate these possibilities, we have conducted an experimental study of the vapour-liquid (V-L) fractionation of Cu and its stable isotopes ($^{65}Cu/^{63}Cu$).

Closed-system V-L fractionation was measured experimentally at P-T conditions applicable to porphyry formation (up to 450°C and 400 bar) by the removal of V and L sample pairs from a batch of bulk fluid contained within an autoclave, with each pair taken at successively lower total pressure. For most sample pairs, the isotopic compositions of the vapour and liquid were equal within uncertainty.

However, from the intial compositions of the bulk start solutions to those of the final, lowest-pressure V and L sample pairs extracted from the autoclave, a shift to heavier values of $\delta^{65}Cu$ was seen. Specifically, between the starting compositions and those of the lowest-pressure vapour samples, the increases in $\delta^{65}Cu$ values were 0.16, 0.69 and 0.10‰ (all ±0.07‰) at 350, 400 and 450°C, respectively. This compositional shift is roughly proportional to the volume of vapour extracted between sample pairs in order to decrease total pressure (6-35% of the total bulk fluid removed as vapour), indicating that $^{65}Cu/^{63}Cu$ fractionation may be described by a Rayleigh distillation process.

These results suggest that in a closed, boiling hydrothermal ore-forming environment, Cu isotopes exhibit conservative fractionation, and coexisting V and L will preserve the isotopic signature of the fluid source. However, in a structurally open system in which periodic vapour removal occurs, the movement of the escaped vapour outward from the magmatic source will result in cooling and condensation of liquid droplets with heavier $\delta^{65}Cu$ values. This process will give the evolving vapour a progressively lighter $\delta^{65}Cu$ than the residual fluid near the source, although individual liquid droplets will be only marginally heavier in composition than the vapour from which they condensed. It follows that V and L fluid inclusions trapped at shallower depths (e.g., epithermal vein systems), or primary Cu(I) minerals deposited from those fluids, will have lighter $\delta^{65}Cu$ values than their deeper magmatic counterparts and the ore fluid source.

Glacial-interglacial simulations of ε_{Nd}

JOHANNES REMPFER[1,2,*], THOMAS F. STOCKER[1,2], FORTUNAT JOOS[1,2], JEAN-CLAUDE DUTAY[3]

The Atlantic Meridional Overturning Circulation (AMOC) is an important component of the climate system. Reconstructions of past changes in AMOC are possible via records of paleocirculation proxies that reflect the distribution of water masses or the rate of ocean circulation and that can be measured in sediment cores. However, their interpretation is not unequivocal in some cases.

Covariation of Nd isotopic composition (ε_{Nd}) with salinity and potential temperature, indicates the potential of ε_{Nd} as a complementary water mass tracer [1]. Variations of ε_{Nd} can be reconstructed from sediment cores and are interpreted as past water mass changes [2].

Numerical simulations may contribute to the quantitative interpretation of such reconstructions. However, to date only few simulations of past ε_{Nd} are available [3]. Systematic studies of its paleoceanographic potential were limited by computational costs. We have included Nd isotopes (^{143}Nd and ^{144}Nd) into a cost-efficient climate model of intermediate complexity [4] with which we run 125,000-year simulations of ε_{Nd}.

In this study we present results of the first glacial-interglacial simulations of ε_{Nd}. Simulated ε_{Nd} is in good qualitative agreement with the few available reconstructions from the Atlantic Ocean. Inferences on changes in the AMOC during the entire last glacial cycle are therefore possible. However, our results indicate that relationships between variations in ε_{Nd} and overturning strength in the North Atlantic, or in the deep South Atlantic, are not straightforward during the entire last glacial cycle.

Besides allowing to further constrain changes in pattern and strength of the AMOC during the last glacial cycle, our results therefore provide important new insight into the paleoceanographic potential of ε_{Nd}.

Reactivity of chemically synthesized *versus* biomineralized Fe^{II}-Fe^{III} green rusts with both organic and inorganic pollutants

REMY PAUL-PHILIPPE, HAZOTTE ALICE, SERGENT ANNE-SOPHIE, HANNA KHALIL, JORAND FREDERIC *

*LCPME UMR 7564 CNRS-University of Lorraine, Jean Barriol Institute, 405 rue de Vandoeuvre, 54600 Villers-lès-Nancy, France (*correspondence: frederic.jorand@univ-lorraine.fr)

Green rusts (GR) are mixed ferrous–ferric hydroxides that have layered structures consisting of alternating positively charged hydroxide layers and hydrated anion layers. These compounds can be obtained by chemical co-precipitation of Fe^{II} and Fe^{III} species or from bioreduction of ferric oxides by iron reducing bacteria. Due to the spatial configuration of structural Fe^{II}, green rusts show high reactivity against both organic and inorganic pollutants. While numerous works were mainly focused on the reactivity of a chemically synthesized GR, no report has appeared on the reactivity of biogenic GR with environmental pollutants. In the case of biogenic GR, the presence of exo-polymeric substances, bacterial cells, etc. could contribute to enhance GR stability. This work is devoted to compare the reactivity of chemically synthesized and biogenic GRs towards two pollutants: Methyl Red (MR) and cationic mercury, Reductive transformation of MR was monitored by spectrophotometric method and cationic mercury by ICP-AES. Results show that both abiotic and biotic carbonated GR can reduce Hg^{II} and MR. The effect of stabilizing agents such as phosphate and silicate on the GR reactivity was also tested.

Studies of surface ocean nitrate utilization in the Subarctic North Pacific using multiple nitrogen isotope recorders in the surface sediment

H. Ren[1*], R. F. Anderson[1], A. S. Studer[2], S. Serno[1], D. M. Sigman[3], G. Winckler[1], R. Gersonde[4] and G. H. Haug[2]

[1]Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY, USA, hren@ldeo.columbia.edu (* presenting author)
[2]Geological Institute, ETH Zurich, Zurich, Switzerland
[3]Department of Geosciences, Princeton University, Princeton, NJ, USA
[4]Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany

In this study, we map and compare spatial patterns of three nitrogen isotope recorders: bulk sedimentary $\delta^{15}N$, diatom frustule-bound $\delta^{15}N$ (DB-$\delta^{15}N$), as well as planktonic foraminifera test-bound $\delta^{15}N$ (FB-$\delta^{15}N$) from 37 multicore core-top sediments across the open Subarctic North Pacific (SNP) and the Bering Sea between 60°N and 35°N, which were obtained during the INOPEX cruise in 2009. Both the bulk sedimentary $\delta^{15}N$ and the DB-$\delta^{15}N$ vary between 4 and 8‰, with increasing values towards the more nitrate-deplete lower latitudes, generally consistent with changes in the surface ocean nitrate consumption in the SNP. Bulk sedimentary $\delta^{15}N$ is more variable, which could be due to sedimentary processes altering or contaminating the isotopic signal. Consistent with previous studies [1], the $\delta^{15}N$ of both recorders are 2~4‰ higher than the expected $\delta^{15}N$ of the sinking flux, calculated using the World Ocean Atlas 09 summer surface ocean nitrate concentration in a Rayleigh model, assuming the same nitrate source (with the mean deep ocean nitrate concentration and $\delta^{15}N$), and the fractionation factor during nitrate assimilation as a function of the summer mixed layer depth [2]. The diatom-to-sinking flux offset is constant around 2‰ in the Bering Sea and the southwestern zonal transect, but is greater (around 4‰) in the northwestern and eastern regions. While basin-wide measurements of the $\delta^{15}N$ of the surface nitrate and the sinking flux will be needed to evaluate the offset, we suspect that the changes in the offset may be due to variations in the nitrate source $\delta^{15}N$: higher subsurface nitrate $\delta^{15}N$, originating from the eastern Pacific, has been observed in the northward coastal current off of British Columbia, and may penetrate westward as in the polar half of the North Pacific gyre, while lower nitrate $\delta^{15}N$ from N fixation in the North Pacific subtropical gyre may influence stations along the southern margin of the gyre. The lack of spatial patterns in the $\delta^{15}N$ differences between opal size fractions argues against large effects from variations in diatom assemblage; however, the assemblage effect will be directly analyzed once diatom species counts are completed. While we have limited FB-$\delta^{15}N$ data, the $\delta^{15}N$ of *N. pachyderma* (mostly sinistral) appears most similar to the DB-$\delta^{15}N$, within 1‰.

[3]Department of Engineering Science, University of Oxford, Parks Road, Oxford, OX1 3PJ, United Kingdom, Richard.Darton@eng.ox.ac.uk

Spontaneous abiotic carbonate precipitation in the oceans is substantially inhibited by the presence of dissolved magnesium and sulphate [1] so that seawater is ≈supersaturated with respect to calcite and aragonite without precipitation occuring. Concern over ocean acidification has let to considerable efforts to understand the impact of lower seawater saturation on (particularly biogenic) carbonate precipitation. But there has been less effort to constrain the impact of increased saturation levels on carbonate precipitation since the early 1990s [e.g. 2]. This issue remains important, however. Recent ideas have suggested a role for changing ocean alkalinity (and therefore saturation state) as a mechanism to drive past glacial-interglacial atmosphereic CO_2 changes. And a range of geoengineering schemes rely on increased ocean alkalinity through carbonate, hydroxide or silicate mineral addition to the surface ocean to induce uptake of atmospheric CO_2 into seawater [3]. The efficiacy of these geoengineering approaches is dependent on a comprehensive understanding of abiotic carbonate precipitation.

Here we present results from laboratory experiments which are specifically designed to investigate the spontaneous precipitation of $CaCO_3$ as saturation state increases in seawater under controlled P_{CO2} and alkalinity. Solutions of seawater were continuously dosed with $Ca(OH)_2$ and $Mg(OH)_2$ over an extended period in a closed system in which the CO_2 concentration in the gas phase was continuously monitored. CO_2 was drawn into solution and pH was measured at discrete intervals. Through analysis of trace-metal incorporation into carbonate phases, we determine the saturation state and rate at which carbonate precipitation occurs, complimenting existing techniques that analyse changes in major element composition.

Mesoarchean TTG melt formation and migration in the Skjoldungen region of South-East Greenland

BARRY L. RENO*[1,2], TOMAS NÆRAA[1] AND LEON BAGAS[3]

[1] Geological Survey of Denmark and Greenland, Copenhagen, Denmark, blr@geus.dk (*presenting author)

[2] Institute for Geography and Geology, University of Copenhagen, Denmark

[3] Centre for Exploration Targeting, University of Western Australia Perth, Australia

The Skjoldungen region of South-East Greenland exposes a well-preserved section of Mesoarchean mid- to lower-continental crust that provides a unique window into crustal evolution and differentiation processes during the Archean. The central portion of the region comprises a sequence of mafic granulite rocks exhibiting clear textural evidence for having been subjected to in-situ partial melting, and subsequent generation of TTG melt. These rocks exhibit an aerially extensive network of former melt-bearing veins that preserve evidence of TTG melt generation in the lower crust and transport from mm-scale leucosomes within the mafic granulite to m-scale dikes that are structurally discordant to the mafic granulites and appear to be feeding larger-scale mid-crustal TTG bodies.

The Px–Pl-bearing mafic granulites have a LREE-enriched calc-alkaline basaltic protolith. Metamorphism and TTG-melt formation and migration occurred either during a crustal differentiation event at ca. 2.86 Ga or during collisional orogenesis at 2.8 – 2.7 Ga [1]. Leucocratic layers within the mafic granulite are characterized by cm-scale peritectic Opx, and form a large-scale network of former melt-bearing veins, in which smaller mm-scale foliation-parallel leucosomes are petrographically continuous with larger cm-scale structurally-discordant former melt-bearing channels which are texturally consistent with having fed large TTG sheets. The cm–m scale TTG layers exhibit enrichment in the most incompatible elements, HREE depletion, and are characterized by strong Pb enrichment, a subchondritic Nb/Ta ratio and higher Mg-number (~50). Trace element systematics are broadly consistent with these TTGs falling in the medium-(to high-) pressure sodic TTG groups of Moyen [2], suggesting partial melting of the mafic granulites occurred at pressures around ~1.5 GPa. Some of the larger-scale TTG dikes in exposures of structurally higher crustal levels exhibit similar geochemical characteristics, suggesting that partial melting of Px-Pl mafic granulites is one source of TTGs in South-East Greenland.

The energetic and kinetics of uranyl reduction on pyrite, hematite, and magnetite surfaces: a powder microelectrode study

D. RENOCK[1]*, M. MUELLER[2], R.C. EWING[2], AND U. BECKER[2]

[1]Dept. of Earth Sciences, Dartmouth College, Hanover, NH., USA, Devon.J.Renock@Dartmouth.edu (* presenting author)

[2] Dept. of Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI., USA, ubecker@umich.edu

There are many studies describing the influence of parameters such as pH, pCO_2, and complexing ligands on the sorption of aqueous uranyl ions on mineral surfaces. However, few of these studies describe the reduction reaction mechanisms and the factors that influence the rate of reduction, despite the fact that the oxidation state of uranium is the most important factor controlling the mobility of uranium. In this study, the energetics and kinetics of the U(VI) reduction half-reaction on pyrite, hematite, and magnetite were investigated by electrochemical methods using a powder microelectrode (PME) as the working electrode. Anodic and cathodic peaks corresponding to the 1 e^- reaction redox couple, U(VI)/U(V), were identified in cyclic voltammograms of pyrite, hematite, and magnetite at pH 4.5. A second oxidation peak, corresponding to the oxidation of U(IV), was identified and provides evidence for the formation of reduced uranium phases on the mineral surfaces. In addition, uranium-containing precipitates were identified on pyrite surfaces after polarization in a PME. High Tafel slopes (> 220 mV/dec on all minerals evaluated) suggest that uranyl reduction is mediated by insulating oxide layers that are present on the semiconducting mineral surfaces. The onset potential for uranyl reduction was determined for pyrite (>0.1 V *vs*. Ag/AgCl), and hematite and magnetite (between -0.02 and -0.1 V *vs*. Ag/AgCl). The onset potential values establish a baseline kinetic parameter that can be used to evaluate how solution conditions (*e.g.*, dissolved reductants, complexing ligands, and polarizing ions) affect the kinetics of uranyl reduction.

In addition, this is the first study that uses a PME, instead of a conventional mineral electrode, to evaluate redox processes on mineral surfaces. Stable and reproducible voltammograms obtained for pyrite, hematite, and magnetite were obtained with minimal electrode preparation. The results of this study demonstrate the feasibility of using PME's to evaluate redox energetics, kinetics, and mechanisms for other environmentally-relevant, mineral-analyte systems.

^{238}U-^{230}Th equilibrium in arc magmas: Implications for the time scales of fluid transfer in subduction zones.

Reubi O[1*], Sims KWW [2], Bourdon B[3]

[1] IGP, ETH Zurich, Switzerland (olivier.reubi@erdw.ethz.ch)

[2] University of Wyoming, USA; [3] LGL, Ecole Normale Supérieure de Lyon UCBL and CNRS, France

The transfer of fluids in subduction zone can be fingerprinted in the chemistry of erupted magmas. However, there remain uncertainties regarding the processes and location of material transport from the subducting plate to the mantle wedge. Constraints on the timing of transfer relative to mantle melting are essential to understand the processes at play and the volatile cycles. Large excesses in ^{238}U and ^{226}Ra measured in some arc magmas are taken as indicating short time scales (hundreds to thousands of years) and, therefore, direct causality between slab fluid fluxes and mantle melting. A large proportion of arc magmas are, however, in or close to ^{238}U-^{230}Th equilibrium. This is generally interpreted as resulting from "buffering" of the young slab-fluid U-series signal by an older sediment component in secular equilibrium (i.e. >400 kyr).

Samples from Volcan de Colima, Mexico demonstrate that magmas in ^{238}U-^{230}Th equilibrium can have significant ^{231}Pa and ^{226}Ra excesses. Chemical modelling indicates that, in this case, the U-Th contribution from the sediments is not sufficient to offset the ^{238}U excesses produced by slab fluids. Melting of a mantle source that returned to secular equilibrium after addition of the slab components (time interval >400 kyr) and production of ^{231}Pa and ^{226}Ra excesses during melting is the most likely scenario at Colima. Compilation of U-series data suggests that this scenario is common in arc settings, implying that the time span and consequently the causal relationship between slab-fluid addition and mantle melting are variable at regional and global scales.

Solubility of scorodite and 6-line ferrihydrite with sorbed arsenic in the presence of *Shewanella* sp. CN32 and *Shewanella* sp. ANA-3 in a chemically defined growth medium containing various phosphate concentrations

E. REVESZ[1*], D. PAKTUNC[2], AND D. FORTIN[3]

2. CANMET Mining and Mineral Sciences Laboratories and Dept. Earth Sciences, University of Ottawa, Ottawa, Canada Dogan.Paktunc@NRCan-RNCan.gc.ca
3. Dept. Earth Sciences, University of Ottawa, Ottawa, Canada, dfortin@uottawa.ca

Scorodite ($FeAsO_4 \cdot 2H_2O$) is a common As-rich mineral found in mining environments. In addition to its low solubility, it is relatively stable under oxidizing conditions, but its stability in the presence of known iron- and arsenic-reducing bacteria is poorly understood, especially under environmentally relevant conditions such as mine tailings. We investigated the reduction of synthetic scorodite in the presence of *Shewanella* sp. CN32, an iron and arsenic reducer, and *Shewanella* sp. ANA-3, a well-known arsenic reducer in a chemically defined medium containing various phosphate concentrations (15μM to 400 μM). The average initial rates of reaction found for arsenic reduction are 10.1 fmol/(cell·day) for ANA-3 and 5.4 fmol/(cell·day) for CN32 indicating that ANA-3 is a more efficient arsenate reducer than CN32. The concentration of dissolved Fe(II) is significantly lower than the concentration of dissolved As(III), and these concentrations are inversely related to the phosphate concentration. The solid phase post-reduction by-products were characterized by XRD, SEM, HRTEM and XAFS. Results so far for bacterial reduction of scorodite indicate that the residue is largely amorphous with domains that are rich in either iron or arsenic.

Preliminary results of reductive, bacterial assisted dissolution of 6-line ferrihydrite containing sorbed As in a chemically defined growth medium will also be discussed.

Sr-Nd-Pb isotope composition of Greenland river sediment constrains provenance of silt on the Eirik Drift

ALBERTO REYES[1*], ANDERS CARLSON[1], BRIAN BEARD[1], DAVID ULLMAN[1], ROBERT HATFIELD[2], AND JOSEPH STONER[2]

[1]University of Wisconsin-Madison, Geoscience, avreyes2@wisc.edu (* presenting author), acarlson@geology.wisc.edu, beardb@geology.wisc.edu, ullman@geology.wisc.edu

[2]Oregon State University, Earth Ocean and Atmospheric Sciences, rhatfield@coas.oregonstate.edu, jstoner@coas.oregonstate.edu

The Sr-Nd-Pb isotope composition of silt in the Eirik Drift off south Greenland can be used as a proxy for the presence/absence of ice on southern Greenland bedrock terranes. This approach requires characterization of different bedrock sources that can be compared with marine sediment core records. We present an updated dataset of Sr-Nd-Pb isotope composition for over 50 silt samples from rivers draining large subglacial basins under the Greenland Ice Sheet.

Distinct differences in the age and crustal evolution of major southern Greenland bedrock terranes are largely mirrored in the isotope composition of sediment in meltwater streams draining the ice sheet. Silt from rivers draining the Archean Block, the oldest south Greenland terrane, have the lowest $^{207}Pb/^{206}Pb$ and ε_{Nd}, and the highest $^{87}Sr/^{86}Sr$; in contrast, the young Paleogene volcanics of southeast Greenland and Iceland yield silt with the highest ε_{Nd} and lowest $^{87}Sr/^{86}Sr$. Silt from the Proterozoic Ketilidian Mobile Belt, in southernmost Greenland, is distinguished by very high $^{206}Pb/^{204}Pb$. Rivers draining the Nagsuggtoqidian Mobile Belt, comprising largely Archean rocks affected by Proterozoic metamorphism, have silt loads with relatively low ε_{Nd} and low $^{87}Sr/^{86}Sr$.

Suspended sediment discharged from the southern Greenland Ice Sheet during deglacial and interglacial intervals is transported via the Western Boundary Undercurrent to the Eirik Drift, where several long (>400 ka), well-dated marine sediment cores have been collected. The stream sediment isotope data presented here are used as end-members in a four-component mixing model, which allows us to determine the fractional contribution of silt from south Greenland bedrock terranes in the marine sedimentary record and, ultimately, to estimate the extent of the southern Greenland Ice Sheet during Pleistocene interglaciations.

Transformation of lead into pyromorphite by fungi

YOUNG JOON RHEE[1]*, STEPHEN HILLIER[2], AND GEOFFREY M. GADD[1]

[1]Division of Molecular Microbiology, College of Life Sciences, University of Dundee, Dundee DD1 5EH, Scotland, UK, y.j.rhee@dundee.ac.uk (*presenting author), g.m.gadd@dundee.ac.uk

[2]The James Hutton Institute, Craigiebuckler, Aberdeen AB15 8QH, Scotland, UK, Stephen.Hillier@hutton.ac.uk

Introduction

Lead is a serious environmental pollutant in all its chemical forms. Attempts have been made to immobilize lead in soil as the mineral pyromorphite using phosphate amendments (e.g., rock phosphate, phosphoric acid and apatite [1-2]). Lead metal, an important structural and industrial material, is subject to weathering, and soil contamination also occurs through hunting and shooting. Although fungi are increasingly appreciated as geologic agents [3-5], there is a distinct lack of knowledge about their involvement in lead geochemistry. We examined the influence of fungal activity on lead metal and discovered that metallic lead can be transformed into chloropyromorphite, the most stable lead mineral that exists. This is of geochemical significance, not only regarding lead fate and cycling in the environment but also in relation to the phosphate cycle and linked with microbial transformation of inorganic and organic phosphorus. In this contribution, we provide the first report of mycogenic chloropyromorphite formation from metallic lead and highlight the significance of this phenomenon as a biotic component of lead biogeochemistry, with additional consequences for survival in lead-contaminated environments and bioremedial treatments for lead-contaminated land.

Conclusion

The results from present study clearly demonstrate a previously unknown biogenic step in the biocorrosion of lead metal and transformation into pyromorphite through fungal action. This discovery represents an addition to our understanding of the biogeochemical cycling of lead, as well as phosphorus, and the importance of fungi as agents of geochemical changes (Rhee, Y.J., Hillier, S., and Gadd, G. M. (2012). Lead transformation to pyromorphite by fungi. Current Biology, doi:10.1016/ j.cub.2011.12.017).

Chemical zoning in calc-silicate rocks: stratigraphic control versus metasomatism (Northern Portugal)

MARIA AREIAS[1], MARIA A. RIBEIRO[1*], ARMANDA DÓRIA13

[1]Centro Geologia Universidade Porto, DGAOT-FCUP, R. Campo Alegre, 4169-007 Porto, Portugal (* presenting author: maribeir@fc.up.pt

Introduction

In a sheared gneiss-migmatite massif, in the border of a sin-tectonic variscan granite (coastal area of NW Portugal), metatexites and diatexites occur associated with metapelitic and calc-silicate rocks. Calc-silicate resisters (decimetric to metric bodies) are abundant mostly in the metatexitic zones, with ovoid or ellipsoidal geometry resulting from stretching and boudinage, associated with the shear foliation. The calc-silicate bodies are sub-parallel to the migmatitic foliation, striking N20° to N160°, with sheet folds [1].

Results and conclusion

The calc-silicate nodules present an internal structure with three zones: (i) core zone (CZ) with Wo+Cpx+Cal+An+ Qtz+Sph+/-Ep+/-Clzo; (ii) intermediate zone (IZ) where amphibole occurs and clinopyroxene disappears, and (iii) an external zone (EZ) with Bt+Qtz+Plg_{An50}+/ ilm. Taking into account field, petrographic and geochemical data, the IZ may be the result of mass transfer processes between different protoliths, coeval with de metamorphism, migmatization and deformation: the CZ represents a metagreywacke, with some carbonate concretions; the EZ a metapsamite and the IZ represents the metasomatic edges of the CZ. The chemical composition of the three zones is consistent to this explanation. In relation to the CZ, the IZ is richer in Na, K, Fe, Mg, P, LILE, Sc, Nb and Ta. In relation to the IZ, the EZ is enriched in Na and LILE and has less concentration at HSFE and transition metals. With support in these data it is considered that the IZ has input from the EZ (Mg, Fe, Na, K, P, LILE, Sc, Nb and Ta) and from CZ (HSFE). The geometry, internal structure, petrographic and geochemical composition of the calc–silicate boudins points to a model of diffusional metasomatism promoted by chemical potential between the CZ and the EZ - boundary metasomatism [2].

Mixture of phases "phlogopite-talc" in the emerald deposit of Santa Terezinha de Goiás, Brazil.

ANA MARIA RIBEIRO-ALTHOFF*

Laboratório de Geologia Isotópica, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil
ana.althoff@yahoo.com.br

Introduction – General Geology

The emerald deposits in Brazil represent a particular type of mineralization hosted mainly Proterozoic volcano-sedimentary sequences. The K-Ar and Ar/Ar geochronology of emerald mineralization from Santa Teresinha of Goias resulted in very disturbed spectra with significant variations in age values. This work deals with the different factors that may have caused the observed perturbations.

The emerald deposit of Santa Teresinha is the result of two processes (Giuliani et al., 1990): the first is the regional metamorphism responsible for the formation of carbonated talc-schists; the second is the infiltration of hydrothermal fluids that originated the phlogopite-schists hosting the emeralds (650-600 Ma, Brasiliano Orogeny).

Characterization of the phlogopite-talc mixture

The petrographic and X-ray diffraction examination of samples of phlogopite-talc-schists showed a great heterogeneity in the distribution of the association phlogopite + talc (+ chlorite). This heterogeneity was also observed in $^{40}Ar/^{39}Ar$ analysis: the age spectra of the three grains of phlogopite presented very different results.

Two single grains Sta11g provided upward-convex spectra with ages ranging from 530-635Ma (Sta11g-a) and 530-545Ma (Sta11g-b) while Sta11a provided a plateau age of 520 + 2Ma with 97% of ^{39}Ar released.

Excess argon in the talc

The presence of talc could explain the observed perturbations in the age spectra. As theoretically potassium is not part of talc composition, it is believed that the residual ^{40}Ar found in talc is a consequence of diffusion from neighboring minerals during a Proterozoic thermal event.

^{40}Ar degasing in talc was studied in a quadrupole spectrometer by continuous heating and temperature steps: maximum degasing occurs close to 1000°C (with H_2O and CO_2).

To evaluate the effects of the mixing on the K-Ar age, a mixing-model from degasing curves with the integrated K-Ar age was established. In this way it was possible to determine the age range based on the mixture (Ribeiro-Althoff, 1997).

Conclusion

The irregular shape of the age spectra obtained for the phlogopite could be explained by the mixing of varying proportions of two ^{40}Ar components: a radiogenic component (phlogopite) and an inherited component (talc), with different degasing curves. The apparent-age difference between the single grains indicates that the excess Ar varies from one grain to another.

The origin of mineralising brines in unconformity-related U deposits: Insights from noble gases and halogens in fluid inclusions

ANTONIN RICHARD[1*], MARK A. KENDRICK[2] AND MICHEL CATHELINEAU[1]

[1]G2R, Université de Lorraine, Vandoeuvre-lès-Nancy, France
antonin.richard@univ-lorraine.fr (* presenting author)
michel.cathelineau@univ-lorraine.fr

[2]The School of Earth Sciences, The University of Melbourne, Aus.
mark.kendrick@unimelb.edu.au

In the Proterozoic Athabasca Basin (Canada) unconformity-related UO_2-ores are associated with U-rich fluid inclusions (FIs) that are either NaCl-rich or $CaCl_2$-rich, and are hosted by quartz and dolomite [1, 2]. In order to constrain the origin of these brines we analysed the naturally occurring isotopes of Ar, Kr and Xe, together with halogens (Cl, Br and I), K, Ca and U in samples containing representative FIs. This was achieved by in vacuo crushing of irradiated samples using extended ^{40}Ar-^{39}Ar methodology [3].

The FIs have molar Br/Cl ratios from 7×10^{-3} to 13×10^{-3}, and I/Cl ratios from 2×10^{-6} to 12×10^{-6}. These compositions are consistent with the fluids deriving the bulk of their salinity by sub-aerial evaporation of seawater, beyond the point of halite saturation. The low I/Cl ratios do not favour fluid interaction with organic matter, or hydrocarbons, as a reductant for localizing U mineralisation.

One sample collected adjacent to high-grade U ore (~40 wt % U) has a less than atmospheric $^{40}Ar/^{36}Ar$ ratio of 180-220. This is ascribed to nucleogenic production of ^{36}Ar from ^{35}Cl in the FIs, due to an exceptionally high neutron fluence in the immediate (<1m) vicinity of the high-grade ores.

The majority of samples contain FIs with age-corrected $^{40}Ar/^{36}Ar$ of between the modern atmospheric value of ~300 and 450. These values are considered representative of the fluids initial composition and are typical of upper crustal sedimentary formation waters. The $^{40}Ar/^{36}Ar$ ratio is correlated with $Cl/^{36}Ar$ in several of the samples and defines $^{40}Ar_E/Cl$ values of between 6×10^{-5} and 10^{-7}. Combined with the salinities (25-35 wt.% salts), the $^{40}Ar_E/Cl$ values, indicate fluid $^{40}Ar_E$ concentrations of 7×10^{-10} to 200×10^{-10} mol.g^{-1} ($^{40}Ar_E$ denotes crustally-derived excess ^{40}Ar).

The FIs non-radiogenic $^{84}Kr/^{36}Ar$ and $^{129}Xe/^{36}Ar$ ratios are intermediate of air and air-saturated brines. The fluids have elevated ^{36}Ar concentrations of up to twenty times air-saturated seawater. The data are interpreted to reflect preferential acquisition of $^{36}Ar>^{84}Kr>^{129}Xe$ from sedimentary rocks. The lack of a strong enrichment in radiogenic ^{40}Ar and preservation of low $^{40}Ar/^{36}Ar$ ratios, suggests interaction of the brines with basement rocks occurred at high water-rock ratios or low temperatures (<200 ºC).

THEREDA – A thermodynamic database for increasing confidence in waste disposal

ANKE RICHTER[1*], FRANK BOK[1], AND VINZENZ BRENDLER[1]

[1]Helmholtz-Zentrum Dresden-Rossendorf e.V., Institute of Resource Ecology, Dresden, Germany, Anke.Richter@hzdr.de (* presenting author)

Motivation and Implementation

For geochemical modeling of scenarios for the disposal of radioactive and (chemo)toxic waste, comprehensive and internally consistent thermodynamic data are required as well as sorption data for the surrounding host rocks. The use of different databases renders it difficult to compare results of geochemical modeling, due to incompleteness, inconsistencies, resticted ranges of variation (temperature, density, pressure), limitations in solution composition (ionic strength) and last but not least missing sorption data.

Features of the Thermodynamic Database THEREDA

THEREDA (THErmodynamic REference DAtabase, www.thereda.de) – a cooperative project of leading research institutes in Germany – adresses these issues, providing full documentation, transparency of all data and a detailed quality assurance scheme [1,2]. THEREDA contains data for the three ion-ion interaction models extendend Debye-Hückel, Specific Ion Interaction Theory, and Pitzer model. At present, two datasets has been released: the oceanic salt system (Na^+, K^+, Mg^{2+}, Ca^{2+}, Cl^-, SO_4^{2-}, H^+, and H_2O(l) within a temperature range of 273.15–523.15 K) and Am/Nd/Cm (Am(III), Nd(III), Cm(III), Na^+, Mg^{2+}, Ca^{2+}, Cl^-, H^+, H_2O(l) at 273.15 K). Tailored parameter files for various geochemical modeling codes are provided (PhreeqC, ChemApp, EQ3/6, Geochemist's Workbench). Documented benchmark calculations allow comparisons with other databases as well as between the different geochemical codes. All data, documentation and references are freely accessible via the projects homepage. Additionally, a user forum allows direct contact with the THEREDA members.

Integration of Sorption Data of RES³T

A holistic view of geochemical processes in the context of a safety analysis requires the inclusion of sorption calculations. A thermodynamically consistent treatment of these processes is only possible with surface complexation modeling (SCM). Respective data are already compiled in the RES³T database [3] (www.hzdr.de/res3t), providing competing entries for many systems. An integration into THEREDA thus not only requires a synchronization of data structures but also a rigorous review process, leading to uniform recommended data sets for each sorbent-sorptive system. This data review process is already in progress.

Applications of Synthetic Uranium Reference Materials for Geochemistry Research

STEPHAN RICHTER[1*], HEINZ KŰHN[1], ROGER EYKENS[1]AND YETUNDE AREGBE[1]

[1]Institute for Reference Materials and Measurements (IRMM), Geel, Belgium, stephan.richter@ec.europa.eu (* presenting author)

Introduction

For many applications in geochemistry research isotope ratio measurements play a significant role. For instance, in geochronology isotope abundances of uranium and its daughter products thorium and lead are being used to determine the age and history of various samples of geological interest. For measuring the isotopic compositions of these elements by mass spectrometry, suitable isotope reference materials are needed in order to validate measurement procedures and to calibrate Faraday cup multi-collector and ion counting detector systems. IRMM is a well recognized provider for nuclear isotope reference materials to the nuclear industry and nuclear safeguards authorities, which are also being applied widely for geochemical applications.

Synthetic Uranium Reference Materials and their Applications

The preparation of several new synthetic uranium reference materials at IRMM during the recent five years has provided significant impacts on geochemical research. These synthetic isotope reference materials are prepared based on proven methods of purifying and gravimetrically mixing oxides or solutions from isotopically highly enriched uranium materials.

Firstly, the double spike IRMM-3636 [1] with a $^{233}U/^{236}U$ ratio of about 1:1 was prepared which allows an internal mass fractionation correction for high precision $^{235}U/^{238}U$ ratio measurements. The ^{234}U abundance of this double spike material is low enough to allow an accurate and precise correction of $^{234}U/^{238}U$ ratios, even for measurements of close to equilibrium uranium samples. This double spike has been used successfully for characterizing uranium isotopic ratios in various materials of geochemical interest [2] as well as natural consensus standards [3], i.e. NBL CRM 112A [4], and was found very valuable for U-Pb and U-Th geochronology.

Secondly, the application of the IRMM-074/1-10 series of isotopic of isotope reference materials [5] for linearity investigations of secondary electron multiplier (SEM) detectors will be discussed and new procedures introduced. This is of high relevance for U-Pb and U-Th geochronology by isotope mass spectrometric methods.

A general and historical overview about the preparation and certification of uranium isotope reference materials at IRMM will be given, including plans for future certification projects.

Tight coupling of life and metals throughout evolution

ROSALIND E. M. RICKABY*, TRISTAN J. HORNER, RENEE B. Y. LEE, GIDEON M. HENDERSON AND R. J. P. WILLIAMS

University of Oxford, South Parks Road, Oxford, OX1 3AN, UK, rosr@earth.ox.ac.uk (* presenting author)

The chemistry of the environment is intimately tied to the chemistry of life in a feedback system. The original reductive chemistry of life inexorably drove oxidation of Earth's surface. The contrast in solubility products between hydroxides and sulfides lead to a predictable sequence of altered environmental concentrations of metals. Some metals increased in availability: notably the latecomers, Cu and Zn, but others decreased e.g. Fe. Such changes are charted in the chemistry of ancient sediments.

Signals of the changing metal environment can also be found in the genomes of extant life. A rise in the number of Cu and Zn metal domains in proteins, fundamental to the advancement of life towards complexity and multicellularity, parallels the increasing Cu and Zn in the environment. This implies that the initial rise of oxidative products, and newly available metals, at first toxic to life, could be turned to advantage by leading to the emergence *de novo* of catalysts allowing increased complexity to evolve [1].

By contrast, a decrease in environmental availability of metals already exploited by enzymes, can drive substitution by new metals to perform old functions, at least in labile enzymes. An example is the change in metallocentre found in "cytochrome-c oxidase". The original protein was likely based on Fe only but later it became the copper-dependent, O_2-reducing enzyme cytochrome oxidase, seen today.

The recent identification of an unusual Cd/Zn carbonic anhydrase from the marine diatom *Thalassiosira weissflogii* [2] has revealed a biochemical function for Cd, substituting for Zn. This discovery holds the potential to explain the long-standing mystery as to why Cd, regarded as toxic to life, displays a nutrient-like profile in the modern ocean and isotopic ($^{114}Cd/^{110}Cd$) compositions which indicate removal into phytoplankton. We investigate whether this single known biological role for Cd can account for its apparent nutrient like behaviour by analysing the isotopic fractionation of Cd in the model bacteria, *Escherichia coli,* which have been transformed to express the CDCA1 gene. Our results demonstrate that whole cells accumulate and fractionate Cd regardless of CDCA1 expression. Our analysis of different cellular components suggest that, rather than direct use of Cd, it is detoxification in response to inadvertent Cd acquisition which is responsible for the fractionation of Cd isotopes. Such detoxification mechanisms are highly conserved across the diversity of life, and we conclude that detoxification acts as the driving force of the observed seawater Cd concentration and isotopic variations. In order to explain the negligible response of Cd uptake to expression of CDCA1, we shall explore if this unusual enzyme is a labile form of the conventional, non-exchanging carbonic anhydrases.

Interrogating >1Myr Time-Scale Controls On Ocean Chemistry In A 3D Model?!

ANDY RIDGWELL[1]*

[1]University of Bristol, Bristol, UK, andy@seao2.org (* presenting author)

Marine archives of paleo environments, particularly when encoded in deep-sea sediments, can be highly spatially hetrogeneous. Whilst box models have had success in interpreting environmental hetrogeniety on a basin-scale, fully 3D ocean-based models are required to resolve the geological record at any finer spatial resolution than this. However, the extreme scale contrast between the typical time-step required by dynamical ocean models – order days (or considerably shorter), and the 100 kyr time-scale of weathering feedback to >1 Myr residence time of many trace metal and isotope systems of interest, presents a seemingly insurountable barrier (unless one is prepared to wait the best part of a year for a model experiment to finish).

I will present a new methodology applied to a 3D Earth system model ('cGENIE') that involves alternating its behavior between fully 3D climate+carbon cycle and mass balance 'box' model modes. In so doing, solving the silicate weathering feedback can, for example, be accelerated by a factor of 10-100 compared to a fully dynamical calculation but with a virtually identical end result. To avoid boring you stupid with a discourse of pure technical model details, I will illustrate how the δ^7Li compostion of the ocean responds to massive CO_2 release and warming and how the encoding of this emerging weathering proxy in marine carbonates relates to more established proxies (e.g. wt% $CaCO_3$, $\delta^{13}C$) for tracking changes in global carbon cycling.

Ion adsorption on nanocrystalline anatase surfaces: Integrating experimental and theoretical studies through surface complexation modeling

MOIRA K. RIDLEY[1]*, JAMES D. KUBICKI[2], AND MICHAEL L. MACHESKY[3]

[1]Texas Tech University, Dept. of Geosciences, Lubbock, TX, USA, moira.ridley@ttu.edu (* presenting author)
[2]The Pennsylvania State University, University Park, PA, USA jdk7@psu.edu
[3]University of Illinois, Illinois State Water Survey, Champaign, IL, USA, machesky@illinois.edu

Detailed experimental studies have been undertaken to quantitatively examine particle-size effects on proton-induced surface charge and accompanying ion adsorption phenomena on a suite of nanocrystalline anatase (TiO_2) phases. Commercially available, crystalline, monodispersed anatase particles ranging in diameter from 3 to 40 nm were used in the study. Extensive characterization of these particles revealed that the [101] face predominates. Bulk surface titrations were completed in LiCl, NaCl, KCl, RbCl and $NaCF_3SO_3$ (NaTr) electrolyte solutions, over a wide range of ionic strengths (0.0005 to 0.3 *m*). Additionally, the specific adsorption of divalent ions (e.g., Sr^{2+}) has been investigated as a function of pH and loading in NaCl media.

Molecular simulation, DFT-MD, calculations were completed to complement the surface adsorption studies. Specifically, bonding geometries on the anatase [101] surface were predicted for the adsorption of cations and anions used in the experimental studies. The DFT-MD simulations show inner-sphere binding for all cations, with bidentate geometries predominating. Conversely, monovalent anions form outer-sphere complexes.

To integrate the experimental results with molecular-level insights gained from the simulation studies, surface complexation modelling (SCM) was performed. The CD-MUSIC model, coupled with a Basic Stern layer description of the electric double layer, was used to successfully provide a surface structural description of the ion adsorption data. All fitting parameters within the SCMs were constrained by the DFT simulation results. The resulting SCMs rationalize successfully the subtle differences observed in the surface reactivity of the anatase particles as a function of particle size. For example, the small decrease in pH_{znpc} values with increasing particle diameter are accounted for by slight differences in protonation constants, K_H. Similarly, binding constants for adsorbed ions and capacitance values for the EDL vary with particle size.

Anaerobic oxidation of methane coupled to iron reduction in deep marine sediments

Anaerobic oxidation of methane (AOM) is an important process in the global methane cycle and contributes to the regulation of methane release to the atmosphere. In sulfate depleted environments, methane can be oxidized anaerobically via microbial consortia tied to other electron acceptors.

Emphasizing the inorganic geochemistry, we explored the process of iron reduction coupled to AOM (Fe-AOM) in marine sediment samples from the Argentine Basin taken during RV Meteor expedition M78/3 (May – July 2009). The essential geochemical requirement for Fe-AOM is the juxtaposition of elevated methane concentrations and abundant reactive Fe(III) in anoxic sediments lacking reactive organic matter. These conditions are met in the Argentine Basin, where dynamic depositional conditions lead to the rapid burial of highly reactive metal phases. Additionally, reworked organic matter is delivered to deeper marine sediments resulting in the dilution by, and subsequent burial of, refractory organic carbon.

Our results show elevated dissolved iron concentrations in the pore water below the sulfidic zone accompanied by high amounts of highly reactive Fe (III) phases. This evidence indicates active iron reduction. In the same sediment, methane concentrations are high, while sulfate and sulfide are depleted. Low TOC contents (<0.8 wt%) throughout the sediment column and sulfate reduction rates close to or at the detection limit argue against the availability of highly reactive organic matter. This suggests that the refractory organic pool does not provide a sufficient energy source for dissimilatory iron reducing microorganisms in these deeper sediments. Thus, we propose that contributions from organo-clastic Fe reduction in these methane-rich sediments are minor. Instead, the concomitant occurrence of abundant methane and reactive ferric iron in the absence of sulfide argues for reduction of biologically available Fe(III) coupled to anaerobic oxidation of methane. The presence and release of dissolved iron and associated alteration of iron minerals in deep sulfate-depleted sediments has been observed in various marine environments, suggesting that Fe-AOM is important in the modern ocean, and, perhaps particularly so, in the sulfate-poor but highly methanic ancient ocean.

Session 13d. Geotraces, the international science program

Quantifying the flux of oceanic particles is central to understanding the coupling of carbon and nutrient cycles that control the functioning of the ocean ecosystems and ultimately the global climate. The natural ^{210}Po and ^{210}Pb nuclide pair affords a radiometric means to model scavenging particle fluxes in the ocean on seasonal to annual time periods.

Data on the dissolved (<0.2 μm), particulate (>0.2 μm, >53μm) and/or the total phases of ^{210}Po and ^{210}Pb has been gathered during two GEOTRACES cruises at the western (GA02, spring 2010) and eastern (GA03, fall 2010) basins of North Atlantic, that include entire (GA03) and upper (GA02) water profiles.

Excess of ^{210}Pb relative to its parent nuclide ^{226}Ra is observed in surface water indicating atmospheric inputs. These inputs are more significant in the subtropics, in association with Saharian dust deposition. In the sub-surface, ^{210}Pb activities decrease and generally attain either equilibrium or deficit with respect to ^{226}Ra, indicating ^{210}Pb removal by scavenging. The surface ^{210}Pb maximum generally corresponds to a minimum in ^{210}Po. Such surface ^{210}Po depletion reflects beside atmospheric input, large particle formation and export to deeper water, where ^{210}Po is regenerated in excess with respect to ^{210}Pb. The highest surface ^{210}Po depletion and deeper regeneration is encountered at the eastern boundary of North Atlantic. Evident here is the expression of enhanced surface production induced from nearby continental sources and upwelling off Africa, and benthic boundary processes.

Based on the ^{210}Po-^{210}Pb and ^{210}Pb-^{226}Ra disequilibria, the upper water profiles of ^{210}Po and ^{210}Pb will be modeled using a steady-state box model for the assessment of particle scavenging fluxes. These can then be compared to the shorter term rates using ^{234}Th nuclide from the same cruises over weeks to months. Thus scavenging rates of several important components such as particulate organic carbon can be assessed over different time scales. Based on the different biogeochemical properties of these nuclides, a distinction can be made between biogenic and lithogenic scavening associated with particle fluxes in both basins of North Atlantic. As important, these scavening rates can be compared to the legacy of modeling these nuclides over the past decades to assess transient changes in basin biodynamics.

Estimation of the mineral reactive surface area during CO_2 mineralization in natural hydrothermal fields.

19b Linking experimental and field observations of mineral carbonatation for in-situ long-term carbon storage

The quantitative description of fluid-rock reactivity in natural geothermal field is a useful tool in predicting become and fate of CO_2 artificially injected in natural geological reservoirs. The complex process of CO_2 mineralization involving a set of mineral dissolution and precipitation reactions is probably the best way to permanently storage CO_2. However the overall process strongly depends on the real amount of mineral able to react in the CO_2 mineralization process. In this work we report results of an original methodology able to estimate the Reactive Surface Area (RSA) of the minerals in the high CO_2 fluid geothermal system of Galicia (Spain). This field is characterized by fluids having pH ranging from 6 to 10 with corresponding pCO2 partial pressure varying from 10^5 to 1 Pa and CO_2 content linearly correlated to the variation of the major dissolved cations.

The methodology to estimate the variation of RSA during the CO_2 neutralization is based on an inverse model approach using the composition of springs and borehole fluids as input data. Assuming the continuum equilibrium condition, the irreversible mass transfer process has been described by the overall degree of reaction advancement using a set of polynomial equations solved independently of time scale. The apparent rate of mineral dissolution was estimated by the observed pH and equilibrium conditions. Calculations were carried out for albite, K-feldspar, biotite and calcite, assuming dissolved aluminum and silica activities controlled by quartz and kaolinite equilibriums.

We found that RSA of calcite, albite and K-feldspar increases by 2 orders of magnitude over the entire CO_2-fluid-rock interaction process, while RSA of biotite increases by 4 orders of magnitude. This shows that reactive surface area of minerals is not constant and changes by several orders of magnitude along the entire CO_2-water-rock process. Our work quantifying the evolution of this key kinetic parameter allows new constrains in modelling reactive transport of fluid-rock interaction processes and the safe mineralization of artificially injected CO_2 in natural reservoirs.

Bendego IC-Iron: HSE and Re-Os

DEBORA RIOS[1,2*], WILTON CARVALHO[2], RICHARD WALKER[3], DONALD DAVIS[1], AND ELIZABETH ZUCOLOTTO[4]

[1]Dept. Of Geology, University of Toronto, Toronto-ON, Canada, debora.rios@utoronto.ca (* presenting author)
[2]UFBA/FAPESB, Salvador-BA, Brazil, wilton@atarde.com.br
[3]University of Maryland, Maryland, USA.
[4]Museu Nacional/UFRJ, Rio de Janeiro-RJ, Brazil.

The Bendego Meteorite is a >5 ton iron found in Northeastern Brazil in 1784. Presently the main mass is hosted at the Brazilian National Museum, being the 16th largest specimen in the world. Bendego is a coarse octahedrite displaying kamacite bands (1.8 mm) of irregular Widmanstatten pattern and abundant Neumann lines. It belongs to the rare IC-group of (11) irons and contains abundant troilite, which occurs as macroscopic nodules as well as microscopic bands, both elongated and aligned. Macroscopic inclusions of cohenite exhibit internal nodules of troilite. Inclusions of plessite, schreibersite, rabdite, $[(Fe,Ni)_3P]$ polymorphs, and chromite were also recognized. It has 6.1-6.9% Ni, 0.40-0.51% Co, 600ppm Cr; 0.05% S; 54-56ppm Ga; 0.17-0.22ppm Ir; and smaller values of As (5.3-6.0ppm) and Au (0.69-0.80ppm), which are slightly different from values reported for other IC-group meteorites.

Re-Os and Highly Siderophile Element (HSE) analyses

This work reports the first Re/Os isotope results from the IC-group. Seven samples collected in different areas of Bendego were analysed at the University of Maryland. Iron meteorites are much richer in siderophiles (1284 < Re < 3249 ppt; 15 < Os < 48 ppb) than terrestrial crust and mantle rocks (Re ~390 ppt; Os ~50 ppt). Bendego has 99-114 ppb Os and 10-12 ppb Re. Ir, Ru, Pt and Pd concentrations were also measured. Normalized to the Orgueil meteorite (CI) these data result in a unique pattern (Figure) that differs from that of other magmatic iron meteorites and pallasites.

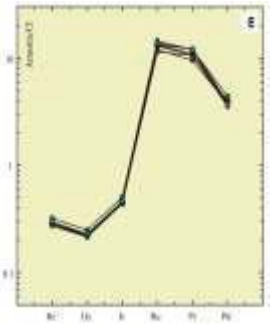

Figure: Bendego Meteorite HSE' multi-elementar diagram.

Concluding Remarks

IC-group meteorites are believed to have formed by magmatic processes similar to those of meteorites in groups IIAB, IIIAB and IVA, even they are thought to have formed on a separate parental body. Our data show: (i) negligible fractionation of highly siderophile elements over the volume of material sampled and (ii) a very distinct highly siderophile element pattern compared to the more voluminous iron groups. It is difficult to make any conclusions about crystal-liquid fractionation processes or the composition of the starting metal but the observed pattern clearly indicates a unique set of conditions compared to the other groups. The Re-Os isotopes of this sample are consistent with a primordial isochron, but given the essentially invariable Re/Os of all pieces analyzed, this cannot yet be confirmed. More samples from the same group will have to be analyzed for a better understanding of Bendego's HSE distribution and its relationship to a chondritic precursor.

The Nordic Seas in the Pliocene: A hot spot or not?

BJØRG RISEBROBAKKEN[1*], CARIN ANDERSSON[1,2], ERIN MCCLYMONT[3], AND LISBETH JENSEN[2]

[1]Bjerknes Centre for Climate Research, Bergen, Norway, bjorg.risebrobakken@uni.no (* presenting author), carin.andersson@uni.no
[2]Department of Earth Sciences, University of Bergen, Norway, lisbeth.jensen@student-uib
[3]Department of Geography, Durham University, England, erin.mcclymont@durham.ac.uk

Pliocene climatic and oceanographic conditions of the Nordic Seasneeds to be better constrained. Therefore, the Pliocenen section of ODP Site 642B (Eastern Nordic Seas, 1286 meter water depth) is studied with the aim to determine the role of the Nordic Seas as a gateway linking the North Atlantic and the Arctic Oceans. Site 642B is located underneath today's pathway of the Norwegian Atlantic Current, and will detect changes in polar heat transport within a current regime comparabla to the present. A multi-proxy approach is used to characterize surface, subsurface and bottom water conditions at the site throughout the Pliocene. The presented results is based on planktic and benthic oxygen and carbon isotopes, planktic foraminiferal counts and SST estimates, and alkenones.

The predominant conditions of the Nordic Seas changed at several occation through the Pliocene, e.g. with the surface water temperatures swiching between longer periods with 1-2°C warmer than present conditions to colder than present by 1°C. Occationally there is indications of strong fresh water influence at the surface, corresponding with reduced ocean-atmosphere gas exchange. However, strong ocean-atmosphere gas exchange or high productivity was the more normal Pliocene situation. Throughout the Pliocene large variability is seen within the mixed layer, however, independent of this variability colder and/or saltier than today's water is seen most of the time. The bottom water conditions at the site swiched between being comparable to and significantly saltier than at present. Reduced stratification between subsurface and bottom water characterize most of the Pliocene. The bottom water was less ventilated than presently through much of the Pliocene, however, conditions more similar to the present occurred towards the early to mid Piacenzian.

The oceanographic conditions of the Nordic Seas was distinctly different from the present day through much of the Pliocene. However, at no point through the Pliocene does our records show extreme polar amplification or strong deep convection and ventilation in the Nordic Seas.

Early mantle dynamics inferred from ^{142}Nd variations in Archean rocks from southwest Greenland

H. RIZO[1]*, M. BOYET[1], J. BLICHERT-TOFT[2], M. ROSING[3] AND J.-L. PAQUETTE[1]

[1] Université Blaise Pascal, 63038 Clermont-Ferrand, France (*H.Rizo@opgc.univ-bpclermont.fr)
[2]Ecole Normale Supérieure de Lyon, 69007 Lyon, France
[3]University of Copenhagen, Øster Voldgade 5-7, DK-1350 København K, Denmark

Because of the limited geological record, the composition and evolution of the silicate Earth during the Hadean/Eoarchean is widely debated and largely unknown. The short-lived ^{146}Sm-^{142}Nd chronometer applied to 3.7-3.8 Ga old rocks from Greenland has revealed excesses of ^{142}Nd (10-20 ppm) compared to modern samples and terrestrial Nd standards [1-7]. Since the parent isotope, ^{146}Sm, was extant only during the first few hundred million years of the Solar System, this implies that the Greenland samples were derived from a source formed in the Hadean. Combining ^{146,147}Sm-^{143,142}Nd systematics, we have estimated the differentiation age of the reservoir of Greenland rocks (amphibolites from the Isua region) to be between 4.53 and 4.42 Ga [1]. Here we present our ^{146}Sm-^{142}Nd data for a suite of mantle-derived samples with ages of 3.8, 3.7, 3.4 and 3.3 Ga, also collected in the Isua region. Covering over 500 million years of the early history of the Earth, they offer a unique opportunity to constrain the compositional evolution and dynamics of the early Earth mantle. The different groups of rocks were dated with the Sm-Nd and Lu-Hf isotope systems on whole-rocks, and by U-Pb analysis of rare zircons found in some of the samples. Preliminary results reveal ^{142}Nd anomalies in 3.4 Ga rocks, while the ^{142}Nd record of primordial heterogeneities in the Isua mantle source seems to have been completely erased after 3.3 Ga. Therefore, the chemical heterogeneities detected in the southwest Greenland mantle and inferred to have formed during the 4.53-4.42 Ga period appear to have resisted mixing by mantle convection until at least 3.4 Ga. These results add strong constraints on mantle dynamics during Earth's early history and the survival/mixing timescale of mantle heterogeneities.

Paleo-marine trace element partitioning relationships recorded in Precambrian Iron Formations

LESLIE J. ROBBINS[1*], STEFAN V. LALONDE[2], AND KURT O. KONHAUSER[1]

[1]University of Alberta, Edmonton, Canada, lrobbins@ualberta.ca (* presenting author), kurtk@ualberta.ca

Ancient metalliferous sediments such as Precambrian Iron Formations (IF) retain geochemical signatures of the composition of the seawater from which they precipitated. Recent efforts to back-calculate paleo-marine trace element abundances from these signatures [1,2,3] have utilized the distribution coefficient (K_D), a special case of the Freundlich isotherm where the Freundlich exponent equals one and sediment concentrations (c_s) are linearly related to aqueous concentrations (c) by the factor $K_D = c_s / c$. However, only a few IF-applicable K_D values have been proposed to date, all were adopted from modern seawater [1] or experimentally estimated [2,3], and their applicability to Precambrian oceans has been assumed. The growing IF trace element record itself has not been thoroughly evaluated for geochemical relationships that should exist after trace element adsorption to Fe oxides, for example scaling with Fe. Here we describe the analysis of a large IF geochemical dataset for evidence of partitioning relationships preserved by the rock record itself. As might be expected, insoluble elements such as Al, Ti, Hf, and Sc show inverse Fe scaling behaviour that follows crustal mixing lines, reaffirming their detrital origin. Many trace elements in IF of presumed seawater origin do indeed scale with Fe in a manner consistent with simple partitioning onto iron oxides. Fe scaling relationships are often best represented in the data at maximal c_s, where K_D-respecting trace element partitioning and open system conditions appeared to prevail. Apparent deviations below these maxima may signify that drawdown of trace elements occurred at times as the result of prolonged iron oxide precipitation. From our data it is possible to estimate the lumped factor K_D*c that directly characterizes paleo-marine elemental partitioning; we briefly evaluate the implication of these apparent factors for select trace elements. This work represents a first step towards a more vigorous exploration of metalliferous proxies for paleo-marine trace element evolution.

Magmatic Processes in the Bishop Tuff Rhyolitic Magma Based on Trace Elements in Melt Inclusions and Pumice Matrix Glass

J. ROBERGE[1]*, P.J. WALLACE[2], A.J.R. KENT[3]

[1]Instituto de Geofisica, UNAM, Mexico D.F., Mexico, robergejulie@gmail.com*
[2] University of Oregon, Eugene, USA, pwallace@uoregon.edu
[3] Oregon State University, Corvallis, USA, adam.kent@science.oregonstate.edu

Abstract

To investigate the origin of compositional zonation in the Bishop Tuff magma body, we have analyzed trace elements in the matrix glass of pumice clasts and in quartz-hosted melt inclusions. Our results show contrasting patterns for quartz in different parts of the Bishop Tuff. In all samples from the early part of the eruption, trace element compositions of matrix glasses are similar to but slightly more evolved than quartz-hosted melt inclusions. This indicates a cogenetic relationship between quartz crystals and their surrounding matrix glass, consistent with in situ crystallization. The range of incompatible element concentrations in melt inclusions and matrix glass from single pumice clasts requires 16-20 wt.% in situ crystallization. This is greater than the actual crystal content of the pumices (<15% crystals). In contrast to the pattern for the early pumices, pyroclastic flow samples from the middle part of the eruption show contrasting trends: in some clasts the matrix is more evolved than the inclusions whereas in other clasts the matrix is less evolved. In the late Bishop Tuff all crystal-rich samples have matrix glasses that are less evolved than the melt inclusions. Trace element abundances indicate that the cores of quartz in the late Bishop Tuff crystallized from more differentiated rhyolitic magma that was similar in many ways, yet distinct from, the early erupted Bishop Tuff. Our results are compatible with a model of secular incremental zoning (Hildreth and Wilson, 2007), in which melt batches from underlying crystal mush rise to various levels in a growing magma body according to their buoyancy. Early and middle erupted quartz crystallized from highly evolved rhyolitic melt, but then some parts of the middle erupted magma were invaded by less differentiated rhyolite such that the matrix melt at the time of eruption was less evolved than the melt inclusions. A similar process occurred but to a greater extent in magma that erupted to form the late Bishop Tuff. In addition, there was a final, major magma mixing event in the late magma that formed Ti-rich rims on quartz and Ba-rich rims on sanidine, trapped less evolved rhyolitic melt inclusions, and resulted in dark and swirly crystal-poor pumice that is a rare type throughout much of the Bishop Tuff.

$(^{231}Pa_{ex}/^{230}Th_{ex})_0$ records from a depth transect in the NE Atlantic 0-20 ka

N. L. ROBERTS[1]*, J. F. MCMANUS[2], A. M. PIOTROWSKI[1]

[1]University of Cambridge, Cambridge, UK, nr297@cam.ac.uk (* presenting author)
[2]Lamont-Doherty Earth Obervatory, Palisades, NY, USA

Paleoclimate proxy records of $(^{231}Pa_{ex}/^{230}Th_{ex})_0$ have been used to infer past changes in deep water-mass advection rates in the North Atlantic [1, 2]. However, data from several studies suggest changing particle flux and composition may cause complications to the use of the sedimentary $(^{231}Pa_{ex}/^{230}Th_{ex})_0$ solely as an advection rate proxy [3, 4, 5]. Modelling studies have also shown that values of $(^{231}Pa_{ex}/^{230}Th_{ex})_0$ recorded in shallow cores differ from deep cores [6, 7], and may also be a function of distance of a core from the deep-water formation region [6], as well as possible effects from sea-ice [8]. It is therefore essential to monitor changes in the local environment and sedimentary parameters as closely as possible in order to accurately interpret $(^{231}Pa_{ex}/^{230}Th_{ex})_0$ measured in marine sediment cores.

Here I will present $(^{231}Pa_{ex}/^{230}Th_{ex})_0$ records from four cores, spanning between 1 and 4 km water depth, in close proximity to each other in the eastern North Atlantic and thus approximating a true depth transect. All four cores have therefore experienced similar changes in productivity and particle composition through time. This allows us to easily account for shared changes in sediment production above the sites and to interpret these records in terms of depth-dependent water column processes. I will present sediment data, including opal and $CaCO_3$ fluxes, along with measured $(^{231}Pa_{ex}/^{230}Th_{ex})_0$ from the last glacial maximum (20 ka) to the present. I will interpret the $(^{231}Pa_{ex}/^{230}Th_{ex})_0$ results, some of which are above the production ratio, in the context of changing sedimentary parameters, changing environmental influences, and ocean advection rates, giving further insight into the controls on $(^{231}Pa_{ex}/^{230}Th_{ex})_0$ and its use as a geochemical proxy.

CONSTRAINING THE SIZE OF HEINRICH EVENTS USING AN ICEBERG/SEDIMENT MODEL AND A 3D ICE SHEET MODEL

W.H.G. ROBERTS[1*], P.J.VALDES[1], A.J.PAYNE[2]

[1]BRIDGE, School of Geographical Sciences, University of Bristol, U.K. (*william.roberts@bristol.ac.uk)

[2]Bristol Glaciology Centre, School of Geographical Sciences, University of Bristol, U.K.

Heinrich Layers, anomalously thick layers of ice borne sediment in the north Atlantic ocean, and the events that caused them have long been associated with abrupt climate changes during glacial times. However, there is still no consensus about either how much ice is needed to transport this sediment or how such a large volume of ice could be produced. Estimates for this ice volume do exist and may be broadly separated into two categories: estimates derived from ice sheet models, and estimates derived from isotope records. There is a wide discrepancy between these two sets of estimates with the isotope derived estimates being at least one, and sometimes two, orders of magnitude larger than those from ice sheet models.

We shall describe here two different methods to further constrain these events. First, we use an iceberg model that includes sediment to simulate the delivery of sediment to the north Atlantic during a Heinrich Event. Second we use a three dimensional ice sheet model (Glimmer) with realistic topography to determine the volume of ice that leaves Hudson Strait during the thermo-mechanical surging events that the model simulates.

We show that the iceberg model can simulate the pattern of ice raft debris from a Heinrich Event and that we can simulate the sediment layer thickness that would result from the volume of ice released by the different estimates. We show that to best fit the observed Heinrich layer sediment thickness, 60×10^4 km^3 of ice needs to be released during the event. This matches the icesheet derived estimates better than the isotope derived estimates and suggests that Heinrich Events released relatively small volumes of ice. The surges from the 3-D ice sheet produce a larger volume of ice for each Heinrich Event than the iceberg model suggest is needed to form the Heinrich Layers, but the volume is consistent with other ice sheet models and significantly smaller than the volume that the isotopes suggest.

Variation in volatile content: Chichinautzin volcanic field, Mexico.

PHILIPPE ROBIDOUX[1*], JULIE ROBERGE[2], PAOLINA CAROLINA REYES LUNA[3], ARMANDO VÁZQUEZ CAMARGO[3], MARIE-NOËLLE GUILBAUD[1], LUIS ROBERTO JUSTO ESPINOSA[3], ÁNGEL BRISEÑO ARELLANO[3]

[1] Instituto de Geofisica, Universidad Nacional Autonoma de Mexico (UNAM), Av Universidad 3000, Ciudad Universitaria rphil85@hotmail.com (*presenting autor)

[2] Instituto Politécnico Nacional, Av. Ticomán No. 600, Col. San José Ticomán

[3]Facultad de Ingeniería, (UNAM), Av Universidad 3000, Ciudad Universitaria

Project

The Chichinautzin volcanic field (CVF) includes more than 220 volcanoes (cinder cones, shield volcanoes, maars) as well as larger stratovolcanoes (Popocatepetl) which erupted important quantity of volatiles since the Quaternary. It is located in the central portion of the Trans Mexican Volcanic Belt which is largely affected by the subduction of the Cocos plate and by effect of intra-continental rifting in Central Mexico [1]. This work focus on the volatiles content of three cones from the CVF selected based on their location, different range of documented ages and compositions [2]; Xitle (1665 yr B.P.), Pelagatos (< 14 000 yr B.P.), La Cima (<10 410 yr B.P.). Analyses of major gasses (H2O, CO2, Cl, S) trapped inside olivine-hosted melt inclusions were used to establish degassing mechanism. Crystals were selected from the main tephra deposits of these three cinder cones. Preliminary results show an overall dissolved sulphur concentrations varying between below detection limit (~ 50 ppm) and 1450 ppm and chlorine content varying from 56 to1601 ppm. FTIR analysis of doubly intersected olivine-hosted melt inclusions show that the dissolved H2O and CO2 contents vary from 0.1 to 4.31 Wt% and from 51 to 976 ppm respectively. The maximum H2O and CO2 content obtained for each volcano is presented in the table below:

	Xitle	Pelagatos	La Cima
H2O (%)	2.47	4.31	2.66
CO2 (ppm)	630	976	780

Table 1: Maximum H2O and CO2 content for each of the studied volcano.

Conclusion

For Xitle volcano, most melt inclusions have relatively low H2O and. This was previously found by [1] and may indicate that degassing at Xitle started at great depth as it is the case for the neighbour stratovolcano Popocatepetl [3]. Pelagatos volcano has the highest values, La Cima also have significant CO2 contents, but overall lower H2O compare to Pelagatos. The variations in volatile content suggest distinctive degassing mechanisms for each volcano.

This study examines the distribution of the long-lived thorium isotopes ^{232}Th and ^{230}Th in the Atlantic Ocean. ^{232}Th in the ocean is derived from the partial dissolution of lithogenic minerals. ^{230}Th is produced at a predictable rate by the decay of uranium, and its subsequent removal by efficient reversible scavenging onto settling particles provides a method to quantify ^{232}Th fluxes to the ocean, and eventually to the seafloor. As such, combining analysis of these two isotopes in seawater has the potential to improve our ability to calculate present and past detrital fluxes to the ocean. Challenges to using this approach are both analytical, for example ^{232}Th contamination issues encountered by many labs during the international GEOTRACES intercalibration, and the lack of systematically collected sample sets. The GEOTRACES program is helping to overcome these issues, giving deeper insights into the processes controlling the sources, sinks and cycling of thorium isotopes in the ocean.

In this study we analyze ^{232}Th and ^{230}Th in two zonal Atlantic transects, crossing a range of oceanographic settings. The first is the U. S. GEOTRACES North Atlantic Zonal Transect, between 17N and 40N, for which six stations have been analysed thus far. The second consists of three stations from the CoFeMUG cruise across the South Atlantic at about 30S. All profiles are full depth and were analyzed together with GEOTRACES intercalibration standards. The CoFeMUG sites have ^{232}Th concentrations that range from 15 to 60 pg/kg, are similar across the basin, particularly in the upper 1000m and show no surface enrichment. Station 13 in the east has the highest ^{232}Th values at depth, but this small difference between sites is overwhelmed by the difference from the concentrations in the North Atlantic. The GEOTRACES samples in the eastern basin (stations 1 to 12) range from 25 to 191 pg/kg. The highest values both at the surface and at depth are from stations 9 and 10 which are the closest to the African coast. These high values likely reflect the input of Saharan dust. We discuss the controls on the ^{232}Th distributions in the context of local and basin scale processes.

Widespread expansion of intermediate water suboxia at 2 Ma

ABSTRACT

The transition from the warm Pliocene to the cool Pleistocene appears to accompany a decrease in intermediate water oxygenation. The Plio-Pleistocene cooling begins with the onset of major Northern Hemisphere glaciation, around 3.0-2.7 million years ago (Ma). High latitude cooling and extension of the polar ice caps led to cooling of the deep ocean and shoaling of the thermocline. Cooling of the whole surface ocean and establishment of strong zonal and meridional atmospheric circulation occurred around 2.0 Ma. A compilation of high-resolution nitrogen isotope records from the eastern tropical Pacific, North Pacific, and the Arabian Sea and a global multi-site survey, indicates that regional intensification of oxygen minimum zones (OMZs) and expansion of water column denitrification accompanied the surface cooling and circulation changes at ~2.0 Ma. Large-scale open ocean suboxia intensified with the inception of a modern polar frontal system, despite lower temperatures and thus higher initial oxygen contents of the mode waters themselves. This likely reflects the increased importance of aged mode waters as the principle conduit of nutrients and oxygen to the OMZs and stresses the importance of ocean circulation in regulating oxygenation.

Morphologies of fungal Mn oxide biomineralization in southern Appalachian caves

LEIGH ANNE ROBLE[1], SARAH K. CARMICHAEL[1], CARA M. SANTELLI[2], BRYAN ZORN[3], AND SUZANNA BRÄUER[3]

[1]Department of Geology, Appalachian State University, Boone, NC 28608, USA. roblela@email.appstate.edu (*presenting author)
[2]Mineral Sciences, Smithsonian Institution, National Museum of Natural History, Washington, DC, 20560 USA
[3]Department of Biology, Appalachian State University, Boone, NC 28608, USA

A common characteristic of southern Appalachian caves are thin, brown-black manganese (Mn) oxide coatings on the walls, on flowstone associated with springs and seeps, and on pebbles and cobbles in streams and pools. These mineral coatings are often associated with bacterial communities, suggesting that microbial activity plays a role in the precipitation of Mn(III/IV) oxides (through catalyzing the oxidation of Mn(II) compounds). Until recently, a fungal contribution to this Mn biomineralization process in caves has been largely overlooked.

In this study, we sought to examine the role of fungi in Mn biomineralization in Daniel Boone Caverns in southwest Virginia and Carter Salt Peter Cave in east Tennessee, all located in the Ordovician Knox Dolomite. Sample locations were chosen based on the presence of black or brownish-black mineral coatings or biofilms on the cave walls and floors, or growing on materials left in the cave by human and animal visitors (tape, socks, feces). X-ray diffraction analyses indicate that the primary cave substrates supporting the Mn oxide coatings was either nontronite clay, dolomite, or anthropogenic materials. Mn oxidation was confirmed in the field using the leucoberbelin blue (LBB) assay, a colorless chemical compound that turns bright blue in the presence of Mn(III) or Mn(IV) compounds. Oxidation was observed in both pristine and agriculturally-contaminated cave systems.

We isolated several different species of Mn(II)-oxidizing fungi from the variety of cave samples. Fungal isolates were analyzed by scanning and transmission electron microscopy (SEM and TEM). TEM imaging with STEM analysis revealed that in several samples, Mn oxidation occurred along the fungal hyphae cells, particularly where new hyphal branches were forming. In other cultures, Mn oxides formed crumpled sheets surrounding the entire exterior of fungal hyphae. In addition to the hyphae-associated oxidation, Mn oxides were produced at the base of fruiting bodies. Interestingly in one culture, fungal spores appearred to be sequestering Mn^{2+} within the spore, but no Mn oxides were present on the cell exteriors.

The Mn oxides produced by fungal cultures were poorly crystalline and amorphous to laboratory-based X-ray sources. Tentative crystallographic identification of Mn oxides by single crystal micro-X-ray diffraction indicate that buserite and todorokite (layer and tunnel structures, respectively) were the dominant Mn oxides present in samples isolated from biofilms in Carter Salt Peter Cave. In the cave environment, the presence of cations, such as Ca^{2+}, may result in the transformation of poorly-crystalline oxide phases to more crystalline and stable forms, such as birnessite and todorokite.

Dynamics of Uranium Release from the Capillary Fringe of Contaminated Hanford Sediments

Introduction

The fate and transport of radionuclides from contaminated sediments represents a major long-term risk at department of energy (DOE) sites. Waste disposal units at DOE sites have undergone source zone removal, however, a number of persistent subsurface plumes remain. Sediment analysis from these sites suggests the residual contamination has migrated into sediment fractures, pores and pore-throats and is influenced by coupled nanometer scale reactions. These pore scale reactions affect pore-scale contaminant concentrations and control the presence of persistent subsurface plumes. Our objective was to quantify the dynamics of U concentrations in the pore water of micropores compared to large pores.

Methods

We investigated the dynamics of U release to pore water during river stage changes from two contaminated capillary fringe sediments, sampled from 7.0 m and 7.6 m below ground surface (bgs) in the Hanford 300 area. Sediments were packed into columns and saturated with Hanford groundwater for three to 84 days. After specified times, sediment pores > 48 μm radius were drained, followed by draining pores to 15 μm radius.

Results

U release in the first two weeks was similar between sediments and pore sizes with a range of 4.4 to 5.6 μM U in the two-week sample. The 7.0 m bgs sediment U declined steadily in the larger pores to 0.22 μM at day 84, whereas the smaller pores released U to 9.4 μM at day 28 then to 6.7 μM at day 84. The 7.6 m bgs sediment released 6.2 μM U on day 28 and 1.4 μM on day 84, in the large pores. MINTEQ simulations where pH was increased from 8.1 to 8.35 can be used to model the U release and reincorporation into a solid phase. A mineral phase in the sediments was identified as a U-carbonate species, similar to rutherfordine.

[3] Laurentian University, Department of Earth Sciences, Sudbury

The disappearance of mass independent fractionation in sulfur isotopes (S-MIF) around 2.45 billion years ago is associated with an increase in atmospheric oxygen content. However, the large S-MIF that characterizes the Archaean has not yet been identified in Mesoarchaean (3.2 to 2.8 Ga) rocks. This diminished variability has been attributed to atmospheric compositional changes including fluctuations in atmospheric oxygen, variations in volcanic SO_2- H_2S ratios, and high-altitude methane hazes. In order to constrain the geographic and lithologic distribution of the diminished Mesoarchaean S-MIF signal, we obtained S isotope data from a variety of lithologies from previously uninvestigated Mesoarchaean terrains.

Samples were collected from four greenstone belts within the Superior Province in Northwestern Ontario (Finlayson Lake, Lumby Lake, Red Lake, and Woman Lake) that span an age range of 2.99 to 2.87 Ga. Metamorphic grade within the sampled portions of each belt is no higher than greenschist facies. We studied multiple lithologies, including shales, cherts, carbonates, banded iron formation (BIF), volcanic massive sulfide (VMS) showings, pillow basalts as well as greywackes and phyllites of volcanoclastic and siliciclastic origin. Whole rock samples and individual macroscopic sulfide grains were analyzed for their multiple S isotope compositions.

Sulfide $\delta^{34}S$ values range from -4.6‰ to 8.9‰ V-CDT, while the associated $\Delta^{33}S$ values range from -0.93‰ to 2.32‰ V-CDT. Samples with significant $\Delta^{33}S$ values also have $\Delta^{36}S$ values that fall on a slope of approximately -1, which is typical for Archaean S-MIF. The clastic rocks in our sample suite exhibit near-zero $\Delta^{33}S$ values, while the non-clastic rocks preserve significant S-MIF.

Macroscopic pyrites within some samples show resolvable differences in their multiple S isotope compositions. For example, the silica-rich layers in BIF seem to have more positive $\delta^{34}S$ and $\Delta^{33}S$ values compared to the silica-poor layers. Other samples contain different types of sulfides with similar isotopic compositions. Chalcopyrite and pyrite grains within a single VMS sample, for example, show negligible difference in their multiple S isotope compositions.

Compared to literature data for the Mesoarchaean, we observe a slightly larger spread in both $\delta^{34}S$ and $\Delta^{33}S$ values. The overall S-MIF range is still much reduced relative to the rest of the Archaean. The identification of diminished S-MIF range in multiple localities and lithologies (including shales, carbonates, cherts, and BIFs) suggests that this is a primary feature of the Mesoarchaean atmosphere rather than the effect of sampling bias. This interpretation is supported by the lithologic controls on S-MIF preservation that we have identified here.

Despite the reduced S-MIF magnitude, the full Mesoarchaean sulfur isotope distribution shows similar systematics to other parts of the Archaean. For example, the observed $\Delta^{33}S$ and $\delta^{34}S$ variability can be explained by covariation along the Archean reference array and a horizontal spread of $\delta^{34}S$ values all with similar $-\Delta^{33}S$ values. These features suggest that the diminished Mesoarchaen S-MIF record may be best explained through dilution by a S source without S-MIF, either in the atmosphere or in the marine reservoir, rather than by changing the photochemical regime producing S-MIF.

Searching for traces of early life in Earth's oldest sulfate deposit: the ca. 3520 Ma Londozi barite, Swaziland

DESIREE ROERDINK[1*], PAUL MASON[1], FRAUKJE BROUWER[2], MARTIN WHITEHOUSE[3], NOAH NHLEKO[4]

Microbial sulfate reduction may have been one of the earliest metabolisms to emerge on Earth. Paleoarchean pyrite and barite deposits potentially record such metabolic activity through stable sulfur isotope fractionation, but this requires proof that microbial signatures were not obscured by metamorphic processes. Here, we discuss the origin of isotopically depleted pyrite in the oldest known sulfate deposit on Earth: the Londozi barite in western Swaziland, for which we obtained a minimum age of 3521±13 Ma by U-Pb zircon dating of felsic volcanics overlying the barite.

Field evidence indicates that the barite was formed in a low-energy marine environment with dominant mafic volcanism and intense hydrothermal activity. It was subsequently affected by amphibolite facies metamorphism and extensive metasomatism. Dominant mineral assemblages include Ca-rich phases actinolite, diopside and epidote with secondary Ba-rich feldspar (celsian and hyalophane) and witherite.

SIMS multiple sulfur isotope analyses of pyrite in the Londozi deposit identified three distinct populations of sulfide: (1) barite-hosted grains with average $\delta^{34}S$ = -5.2‰ and $\Delta^{33}S$ = -1.0‰ (n = 18), (2) massive chert-hosted grains with average $\delta^{34}S$ = -1.1‰ and $\Delta^{33}S$ = 0.2‰ (n = 7) and (3) grains in a silicified silicate matrix with average $\delta^{34}S$ = -0.2‰ and $\Delta^{33}S$ = -0.6‰ (n = 71). We hypothesize that silicate-hosted pyrite was derived from a sulfide pool generated by microbial reduction of sulfate, showing a shift in $\delta^{34}S$ of 5-8‰ relative to the barite. In contrast, association of the most ^{34}S-depleted pyrite with barite might not reflect microbial processes, but could represent sulfide produced during metasomatic remobilization of the barite by reductive dissolution. This process is in agreement with an average sulfur isotope temperature of 524°C calculated for barite-pyrite mineral pairs, and explains the presence of secondary barium-rich feldspar with increasing Ba content towards the barite.

Our work, therefore, demonstrates that the geological context of isotopically depleted sulfides must be carefully interpreted before arguing for the presence of sulfate reducing prokaryotes in the Paleoarchean.

Si isotope fractionation during silica precipitation in batch-reactor experiments

DESIREE ROERDINK[1], SANDER VAN DEN BOORN[1,3], MANFRED VAN BERGEN[1]*, PIETER VROON[2]

Recent research has demonstrated the versatility of silicon isotopes in reconstructing pathways and processes in (bio)geochemical systems. Interpretations of data from siliceous chemical sediments in the rock record rely on quantitative insight into isotopic fractionation during precipitation from silica-carrying solutions. We performed batch-reactor experiments to explore the isotopic fractionation behavior of precipitating silica in low-temperature environments.

Supersaturated silica solutions were obtained by cooling a 90°C saturated solution to temperatures of 10-35°C in silica-seeded batch reactors. Decreased silica solubility induced by the temperature drop resulted in deposition of monomeric silica on the seeds. Solution samples, taken at regular time intervals, were analyzed for silicon isotopic composition by MC-ICP-MS with a typical precision of 0.12‰ (2σ) [1]. The isotope fractionation followed Rayleigh distillation trends and proceeded in two consecutive stages. Initially (stage I), at high degrees of oversaturation, fractionation factors ($\varepsilon_{ppt\text{-}dis}$) were negative and ranged between -1.1 and -2.0‰. Subsequently (stage II), when saturation levels had decreased, fractionation factors were positive and ranged from +0.4 to +0.7‰. The magnitude of the fractionation factor appeared to increase with decreasing temperature in both stages.

We propose that silicon isotope fractionation is controlled by the degree of oversaturation in the reactor, resulting in dominant precipitation in stage I and partial re-dissolution of precipitated silica in stage II. We hypothesize that fractionation during precipitation occurs due to energetically preferred breaking of ^{28}Si-O bonds in the dissolved silica ($\varepsilon < 0$), before formation of new Si-O-Si bonds at the surface of silica grains. In stage II, the system approaches equilibrium, and decreased oversaturation allows partial re-dissolution of Si from the surface with a relatively high rate for ^{28}Si. Consequently, more ^{28}Si goes back into the solution than precipitates, with the net effect that ^{30}Si is preferentially retained in the solid ($\varepsilon > 0$).

Our results suggest that the ultimate isotopic composition of cherts and non-biogenic silica deposits is a function of the degree of oversaturation, for example in cases where rising hydrothermal fluids with different loads of dissolved silica cool down to the same ambient temperature when venting at the seafloor.

Discordant polymetamorphic zircons: the rule in crystalline nappes of the SW Norwegian Caledonides

C. ROFFEIS[1*], F. CORFU[1]

* cornelia.roffeis@geo.uio.no (presenting author)

5a. What zircons tell us about crustal evolution

Resetting of zircons is commonly due to Pb loss related to metamictisation and subsequent alteration, or to other processes such as strain and recrystallization disturbing the crystal lattice. In general it is possible to identify domains of zircons that have escaped partial resetting. Such domains can then be isolated and analyzed separately. In the crystalline nappes of the SW Norwegian Caledonides, however, zircon populations typically yield data that are variously discordant, defining either discordia lines or, in more complex cases, scattered arrays. The most common pattern is exemplified by zircons in orthogneisses from a klippe on Hardangerjøkulen near Finse, that defines a line with an upper intercept age of 1658 ± 9 Ma, indicating magmatic formation, and a lower intercept age of 968 ± 26 Ma, reflecting the Sveconorwegian metamorphic overprint. The discordia line is defined by seven precise ID-TIMS measurements on clear, inclusion free, optically undisturbed zircon fractions on mainly short prismatic grains subjected to either air or chemical abrasion. The fact that even chemical abrasion did not remove the discordance indicates that the discordance is frozen in by recrystallization. The grains themselves show little indication of metamorphic new growth. Coexisting titanite, however, formed during Sveconorwegian metamorphism. Although the nappe was emplaced during the Caledonian orogeny, the U-Pb data were left nearly completely unaffected by these secondary events. This type of behavior is very common in the gneisses of comparable nappes in the Hardanger-Ryfylke Complex to the south and the Jotun Complex to the north of Hardangerjøkulen, although a Caledonian influence is more evident in some cases and creates more scatter. A very different U-Pb discordant pattern is observed instead in anorthositic-jotunitic gneisses of the northern Lindås Nappe, where the Caledonian amphibolite facies overprint and local deformation strongly affected the zircon populations, causing strong Caledonian resetting and local new growth. In zircons of one of the anorthosite localities the resetting can be linked to strain and plastic deformation, but the other key factors seem to be metamorphic reactions and the release of chemicals that allow to form new zircons.

The stability of iron–nickel carbides in the Earth's mantle

ARNO ROHRBACH[1,2*], MAX W. SCHMIDT[2], SUJOY GHOSH[2], CLAZINA H. WIJBRANS[1] AND STEPHAN KLEMME[1]

[1]Institute for Mineralogy, WWU Münster, 48149 Münster, Germany arno.rohrbach@uni-muenster.de (* presenting author), stephan.klemme@uni-muenster.de, ineke.wijbrans@uni-muenster.de

[2]Institute of Geochemistry and Petrology, ETH, 8092 Zürich, Switzerland, max.schmidt@erdw.ethz.ch, sujoy.ghosh@erdw.ethz.ch

A substantial amount of carbonate entrained in partially altered lithosphere likely survives shallow devolatilisation during subduction [1] and will thus be carried by the downgoing plate deep into Earth's mantle. Such carbonates are liberated as carbonatitic liquids whenever the subducting plate is heated to ambient mantle temperatures [2], e.g. when the lithosphere deflects into the transition zone above the 660 km discontinuity. When such carbonatites infiltrate the mantle they have to face an environment where oxygen fugacity is potentially lower than defined by the iron–wustite equilibrium, i.e. where (Fe,Ni)-metal is likely to be an accessory phase (at depths greater than ~250 km) [3–5]. When carbonatites become reduced by such (Fe,Ni)-metal, graphite or diamond would not form as long as excess metal is present, but instead (Fe,Ni)-carbides should be stable. Such carbides may form along the boundaries of carbonatite infiltration zones, where the mass of pervasively infiltrating carbonatites is insufficient to oxidize all metal. We thus performed experiments in the Fe–Ni–C ternary, to define the stability of the various carbides in this system. The subsolidus ternary was determined at 1050 °C, 10 GPa. Diamond coexists with (Fe,Ni)-metal to an X_{Fe} (molar, =Fe/(Fe+Ni) of ~0.48, and no carbide is stable on the Ni-rich side of the ternary. $(Fe,Ni)_3C$ is only stable in the range of X_{Fe} = 1.00 to ~0.75, opening a 3-phase field (Fe,Ni)-metal – $(Fe,Ni)_3C$ – diamond. The phase $(Fe,Ni)_7C_3$ is stable up to X_{Fe} ~0.89 and defines together with $(Fe,Ni)_3C$ (X_{Fe} ~0.82) and diamond a second 3-phase field. A second series of experiments indicates that Fe–Ni–C melting temperatures appear to be lower than expected; at 10 GPa, melting is observed down to 1150 °C, which is at least 200 °C lower than both an average mantle geotherm and the previously determined eutectic temperature in the Fe–C binary [6]. If confirmed by further experiments, such low eutectic temperatures would imply that any adiabatic mantle containing metallic iron and iron carbide, i.e. any mantle at depths >300 km with an average mantle C-content, must contain a small (0.1–1 wt%) fraction of (Fe,Ni)-C melt. The infiltration of carbonatite melts should then also lead – in an intermittent stage – to such (Fe,Ni)-carbide melts.

Bio-inspired Fe_3S_4 catalyst for CO_2 reduction: DFT study

ALBERTO ROLDAN,* NORA H. DE LEEUW

University College London, Department of Chemistry, United Kingdom.
alberto.martinez@ucl.ac.uk (* presenting author)
n.h.deleeuw@ucl.ac.uk

Introduction

Carbon dioxide capture and utilisation is gaining attention, driven not only by enviromental factors but by the posibility to use it as chemical feedstock. The main challenge in CO_2 reduction is increasing the energy efficiency of the process, which is hindered primarily by its high reduction over-potentials. However, this process takes place under mild conditions in chemoautotrophic bacteria catalysed by FeS cubane clusters [1]. Similar structures are found in the iron thiospinel mineral (Fe_3S_4) which is present in deep sea vents and marine anoxic sediments. We present a theoretical (DFT+U) [2] investigation using Fe_3S_4 as a catalyst to transform CO_2.

Results and Conclusions

In agreement with previous benchmarks, we find that the CO_2 adsorption/activation process is the determinant step. This step consists of an electron transfer form the metallic atom in the surface to the empty antibonding orbital on the molecule leading to $CO_2^{\bullet-}$. The presence of other transition metals, such as Ni, can enhance the electronic rearrangement making the CO_2 activation energetically possible. A thermodynamically more favorable process is the H_2 dissociative adsorption either on pure or doped greigite. Thus, H_2 becomes a source of (H^++e^-) which can be added to the co-adsorbed $CO_2^{\bullet-}$ molecule by a common Langmuir-Hinshelwood mechanism. We also find a downhill pathway for that addition leading to products of interest, such as formic acid (Fig. 1).

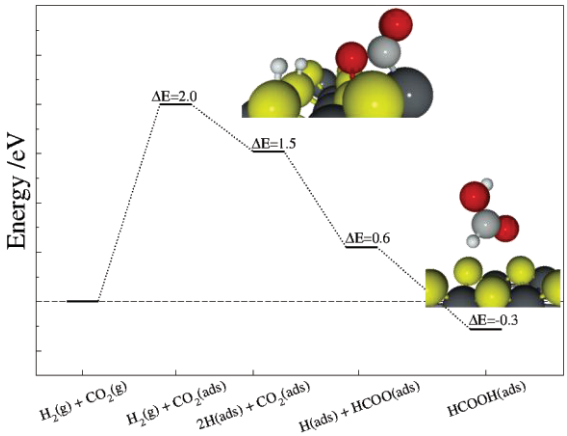

Figure 1: Potential energy diagram for CO_2 transformation to formic acid catalysed be pure greigite.

Experimental and modeling investigation of conservative and reactive transverse mixing in porous media

MASSIMO ROLLE[1,2]*

[1]Center for Applied Geosciences, University of Tübingen, Sigwartstrasse 10, 72706 Tübingen, Germany
[2]Department of Civil and Environmental Engineering, Stanford University, 473 Via Ortega, CA 94305, Stanford, USA (correspondance: mrolle@stanford.edu)

Transverse mixing is of primary importance in many relevant groundwater quality scenarios. For instance, the transport and natural attenuation of organic contaminants is often controlled by the extent of mixing of soluble reactants at the plume's fringe. Conservative and (bio)reactive flow-through experiments have been performed for a detailed investigation of transverse mixing and its coupling with reactive processes. The experiments were carried out at the laboratory bench-scale in quasi two-dimensional flow-through systems, including both homogeneous and heterogeneous saturated porous media. Since the extent of mixing in groundwater systems is typically small, the characteristics of the flow field that result in enhanced mixing are of particular significance. The experiments showed that flow focusing in high-permeability inclusions significantly enhances dilution of conservative tracers as well as transverse mixing of reactants.

Numerical simulations have been performed to extend the experimental results to field-scale scenarios where conservative and reactive transport were evaluated in complex heterogeneous hydraulic conductivity fields. In such systems, measures such as the flux-related dilution index and the flux-related spatial moments have been proposed to quantify mixing [1]. These measures are useful since they allow one to define a mixing-relevant upscaled transverse dispersion coefficient. This parameter accounts not only for the variability of flow in the heterogeneous formation (e.g., flow-focusing in high-permeability inclusions and defocusing in low-conductivity zones) but also for small scale, compound-specific effects. The latter include incomplete dilution in the pore channels, which was investigated in pore-scale simulations and multi-tracer laboratory experiments, and was shown to lead to a non-linear compound-specific parameterization of local transverse dispersion [2]. For reactive transport, the effects of a correct quantification of transverse mixing on the length of reactive solute plumes are illustrated.

Incorporation and early diagenesis of Mo and U isotope records in Bahamian carbonate sediments

STEPHEN J. ROMANIELLO[1*], ACHIM D. HERRMANN[1,2], ARIEL D. ANBAR[1,3]

[1]School of Earth and Space Exploration, Arizona State University, Tempe, AZ, USA, sromanie@asu.edu (* presenting author)
[2] Barrett Honors College, Arizona State University, Tempe, AZ, USA
[3] Department of Chemistry & Biochemistry, Arizona State University, Tempe, AZ, USA

Transition metal concentrations and isotopes are widely used to understand past changes in ocean redox. Most of these proxies were developed for use in black shales. However, black shales are not ubiquitous in the geologic record and so our conception of ocean redox evolution may be biased by the conditions of resistricted marginal basins in which such shales are often deposited. Along with other groups, we are exploring the use of complementary lithologies, such as carbonates, which are abundant in the geologic record and often deposited along open ocean margins [1-3].

Here, we examine the incorporation and early diagenetic evolution of Mo and U isotopes in shallow Bahamian carbonate sediments. The Bahamas is one of the largest and best studied Holocene carbonate platforms, and its location far from continental land masses results in sediments which contain very little siliclastic detritus. Our sample set consists of a wide variety of modern coral, algae, ooids, and mollusk samples ("primary precipitates") as well as 4 short push cores taken from tidal flats, sea grass meadows, and an organic-rich, tidal pond.

We find that Mo and U concentrations are much higher in shallow carbonate sediments than in primary precipitates, increasing from <0.1 ppm Mo to an average of 5.6 ppm Mo, and from an average of 1.5 ppm U to 4.1 ppm U, respectively. In almost all cases, the lowest sediment Mo and U concentrations were as high or higher than the highest concentrations found in primary precipitates, consistent with authigenic accumulation of Mo and U from reducing porewaters. $\delta^{234/238}U$ and $\delta^{238/235}U$ were very close to seawater values in all of the primary precipitates, but $\delta^{238/235}U$ in sediments was 0.2-0.4‰ heavier than in seawater. $\delta^{98/95}Mo$ ranged from ~1.0‰ lighter than seawater in a tidal flat core with low organic matter and low porewater sulfide, to values similar to or even slightly exceeding that of seawater in the most organic- and sulfide-rich cores, a pattern also consistent with control by porewater H_2S concentrations.

These results indicate that authigenic accumulation of Mo and U under sulfidic porewater conditions strongly affects Mo and U concentrations and isotopes in carbonate sediments. The extent of this process appears sensitive to porewater H_2S, and thus indirectly to sediment organic content. In the Bahamas, these parameters can vary over 100s of meters, with potential implications for Mo and U isotopic records in the geologic record. For example, in one case $\delta^{98/95}Mo$ of sediments varied by ~1‰ between a tidal flat region and core in a sea grass meadow ~100m away. To cope with such effects, proxies for porewater redox conditions may be required (e.g. organic content, iron speciation, or trace metal distributions).

Kinetics of Pyrrhotite Oxidation in Seawater: Implications for Mining Seafloor Hotsprings

GINA Y. ROMANO[1], MICHAEL A. MCKIBBEN[1]

[1]University of California, Riverside, USA, groma002@ucr.edu, michael.mckibben@ucr.edu

A rapid increase in the price of transition metals in recent years has piqued interest in deep sea in situ mining of seafloor massive sulfide (SMS) deposits. There are unique incentives to seafloor mining that make it more attractive than traditional land mining of sulfides, but these are accompanied by important unanswered questions about the potential environmental effects, including localized sulfuric acid generation. Currently there is a paucity of data on the oxidation kinetics of sulfide minerals in seawater. Pyrrhotite specifically is of interest because it is a major non-economic component of SMS deposits that will be disposed of on or above the seafloor during mining. Pyrrhotite oxidizes rapidly via an irreversible, acid-producing reaction. Knowledge of sulfide mineral oxidation rates will also provide constraints on metal and sulfur cycling in oceans by quantifying the natural, abiotic weathering rates of SMS deposits.

Laboratory experiments have been performed to evaluate the effects of pH, temperature, oxidant concentration, and mineral surface area on the rate of oxidation of pyrrhotite in seawater. Temperature controlled circulation baths, Teflon reaction vessels, synthetic seawater, and pure, hand sorted natural pyrrhotite crystals are used in experiments. Both batch and flow-though reactor methods are employed. Reaction products are analyzed using ICP-MS. The rate law is expressed as follows:

$$R = -k\,(M_{O2,aq})^{a}(M_{H+})^{b}$$

where R is the specific oxidation rate of pyrrhotite, k is the rate constant (a function of temperature and surface area), and a and b are reaction orders for reactant concentrations (M) that need to be determined experimentally. The initial rate method is used to isolate the reaction order of each reactant.

Current data from batch experiments indicate positive influences of oxidant concentration, surface area, temperature, and $[H^{+}]$ on the initial rate. Pyrrhotite oxidizes significantly faster than chalcopyrite, providing an upper limit to the anthropogenic and natural weathering rates of SMS deposits, but acid production rates do not appear to exceed the buffering capacity of seawater. There will be potential for microbial studies in the future to quantify the effects of bacterial oxidation of pyrrhotite using this study as a baseline.

Evaluation of non-conventional geothermal potential in a Volcanic Island

CARLOS ROSA[1,2*], RITA CALDEIRA[1,3], DIOGO ROSA[1,4] AND LUISA RIBEIRO[1,5]

Madeira, is an intraplate volcanic island, located at the eastern North Atlantic Ocean, with an emerged area of 737 km^2 and maximum altitude of 1861 m. Although there are no historical eruptions, the existence of recent volcanism (6 my) with well preserved volcanic cones and thermal evidences, such as the occurrence of hot water rich in CO2, suggest a heat source at subsurface and the existence of rocks/water with significant temperatures at depths likely to be exploitable for economic generation of electricity.

In a volcanic geothermal system the heat source comes from magma emplacement at relatively shallow levels, thus knowledge of magma chamber(s) depth is one of the keys to geothermal reservoir assessment. In the evaluation of Madeira island geothermal potential, geophysical methods are being applied but, these are most useful for locating chambers beneath active volcanoes. Petrological and geochemical methods supported on whole rock analysis and mineral chemistry can be a helpful tool to constraint the crystallization temperatures and pressures/depths of magmas and to unveil the physical-chemical crystallization history of selected phenocrystals, hence the depth of magma chambers. Volcanic rocks (effusive and explosive) in Madeira are predominantly alkaline basalts. Generally they are holocrystaline presenting porphyritic texture with phenocrystals of olivine and clinopyroxene and, sometimes, calcic plagioclase in a groundmass composed by plagioclase microlites, clinopyroxene, oxides and occasionally interstitial glass. Petrographic and chemical criteria show that phenocrystals had a polibaric crystallization, suggesting that they paused in crustal magma chambers prior to eruption, and that the first minerals to crystallize were olivines and clinopyroxenes. One of the methods to determine the pressure of crystallization is the Ol-Cpx-Plag cotetic method that requires glass composition, or an assumption of it. We applied selected geothemobarometers, based on olivine-liquid and clinopyroxene-liquid equilibrium, to core-mantle analysis of olivine and clinopyroxene phenocrysts to estimate P, which is related to the depth at which magma resides in a chamber, and T of equilibrium crystallization. When required, oxygen fugacity (fO_2) was calculated from oxides and whole rock composition. The first results seem to point out a concentration of core crystallization occurring between 2 to 4 kb/6 to 12 km, which is a good indication of a single and wide magma chamber beneath the island.

Interaction between lamprophiric and riolitic magmas in the Neoproterozoic Sergipano Belt, NE Brazil

MARIA LOURDES SILVA ROSA[1*], VINÍCIUS A. CARVALHO LISBOA[1], HERBET CONCEIÇÃO[1], JOANE ALMEIDA CONCEIÇÃO[1], ANA CAROLINE SOARES OLIVEIRA[1], CLEVERTON CORREIA SILVA[1], DÉBORA CORREIA RIOS[2]

[1]Sergipe Federal University, Núcleo de Geologia, Aracaju, Brazil, lrosa@ufs.br

[2]Bahia Federal University, Instituto de Geociências, Salvador, Brazil, dcrios@ufba.br

The Neoproterozoic Sergipano Belt occurs on the northeastern margin of São Francisco Craton and in south of and Pernambuco-Alagoas Domains. At the north area of Sergipe State a voluminous granitic rocks intrude a turbiditic Neoproterozoic sequence (Macururé Domain), which due to the action of a low to medium grade regional metamorphism, result in garnet-schists, meta-pelitic e meta-graywacke. In the core, these granitic plutons show magmatic foliation and, at some places, also a tectonic foliation, however in the border with metamorphic country rocks the contacts are abrupt, frequently showing dykes and an increasing of the metamorphic regional grade. The plutons are constituted by muscovite-granite on borders which gradually or suddenly become biotite-granites, hornblende-granites, hornblende-granodiorite, and sometimes, to monzonites, suggesting a magmatic zoning. These granites are medium to coarse rocks, with allotriomorphic, and occasionally porfiritic textures. The magmatic flux foliation is give by the hornblende, biotite or feldspar mineral alignment. Mafic-ultramafic rocks occur as micro-granular enclaves, with a variety of sizes, with or without a border of biotite or amphibole, and as well sin-plutonic dykes. The main enclaves mineralogy is composed by hornblende, biotite, opaque minerals, diopside, alkali-feldspar and plagioclase. The accessory minerals comprise apatite, allanite, carbonate and occasionally zircon. These rocks are correlated to lamprophyres and mafic-monzonites. The presence of these enclaves are indicative of felsic-mafic magmas co-existence and mixing. The geochemical data show that the granites have a shoshonitic to high-K calc-alkaline signature, and the enclaves are ultrapotassic. In the Harker's diagrams the alignment from mafic-ultramafic enclaves to granites from different massifs area straight. Yb and Ta contents suggest a volcanic arc signature. The field and geochemical data point out that some of the granitic rocks from Sergipano Belt are products of the interaction between mafic-ultramafic lamprophiric magmas and riolitic magmas of crustal nature. *Acknowledgements: We thanks the financial funds from FAPITEC and CNPq to the development of this project.*

Simulating iron(III) oxyhydroxide precipitation kinetics using a polymer-based modelling approach

ANDREW L. ROSE[1*]

[1]Southern Cross GeoScience, Southern Cross University, Lismore, Australia, andrew.rose@scu.edu.au (* presenting author)

Conceptual Framework

The precipitation/dissolution behaviour of iron(III) oxyhydroxides (FeOx) is relatively well understood empirically at a macromolecular scale, but poorly described at the mechanistic level. Previously we have used a polymer-based kinetic modelling approach to describe these processes at the molecular scale (i.e. via mechanistic steps), and shown through a steady-state analysis of the resulting differential equations that this approach is consistent with the thermodynamic notion of a solubility limit.[1] Here I extend this approach to numerically simulate temporal evolution of FeOx precipitation and ageing, and compare simulation results with experimentally observed trends.

Modelling Approach

FeOx precipitation is described by sequential addition of monomeric Fe species (denoted by Fe') to other Fe' molecules and existing FeOx polymers, with kinetics controlled by the rate of water loss from Fe' molecules. FeOx dissolution is described by the sequential loss of Fe' from FeOx polymers, and FeOx ageing is described by internal reorganisation of the bonding structure in polymers. Model simulations with several thousand reactions of this type were run using Kintecus.[2]

Results and Conclusion

The polymer-based approach enabled simulation of key aspects of FeOx precipitation and ageing behaviour, including decreasing apparent reactivity and increasing particle size over time (Figure 1).

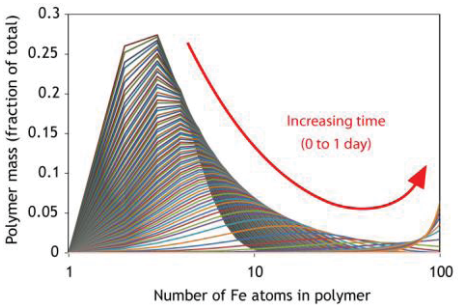

Figure 1: Evolution of FeOx particle size distribution over time at pH 8, as predicted by the polymer-based kinetic modelling approach.

The model was able to simulate the effect of pH on FeOx formation and dissolution kinetics, and successfully reproduced several other experimentally observed phenomena. The polymer-based kinetic modelling approach therefore appears useful to interpret and explain diverse experimental observations in the context of fundamental aquatic chemical reactions.

Trace metals and soil solids: effects of soil heterogeneity on Zn mobility

C.E. ROSENFELD[1*], R.L. CHANEY[2], A. LANZIROTTI[3], C.E. MARTÍNEZ[1]

[1]Pennsylvania State University, Department of Crop and Soil Sciences, University Park, PA, USA, cer196@psu.edu(* presenting author), cem17@psu.edu

[3]Consortium for Advanced Radiation Sources, University of Chicago, Chicago, IL, USA lanzirotti@uchicago.edu

Abstract

Trace metal contamination in soils is a global problem, often causing plant and microbial toxicity and leading to diminished crop production or decreased land cover and subsequent land degradation. In soils, the majority of trace metal contaminants such as Zn are associated with solid phase materials. This can be through cation exchange sites, surface adsorption and/or mineral (co-) precipitation. The specific forms or speciation of metals in soils determines both their bioavailability to plants and microorganisms and their mobility within and out of soils.

In this experiment, we used five contaminated field soils with a variety of sources and Zn:Cd ratios. Bulk soil Zn concentrations ranged from 112 mg/kg up to 26,237 mg/kg with Cd:Zn ratios between 0.05 and 0.003. Each soil was separated using sodium polytungstate, a variable density liquid, into fractions with density less than 1.6 g/mL (light fraction), between 1.6 g/mL and 2.8 g/mL (medium fraction), and greater than 2.8 g/mL (heavy fraction). It is expected that the light fraction contains organic matter, the medium fraction contains aluminosilicate primary and secondary minerals, and the heavy fraction contains high density minerals such as Fe and Mn oxides and their coprecipitates. Each fraction was analysed using μ-XRF, μ-XRD, and μ-XANES to determine the Zn solid phase forms in the natural soils.

The majority of the Zn in four of the five soils resided in the light fraction, though the smelting contaminated soil contained roughly equal light and heavy fraction Zn. A substantial portion of Zn was also present in the medium and heavy fractions of all soils, indicating the transfer of large quantities of Zn between different fractions, regardless of the initial Zn form applied. Based on XANES analysis, the light and heavy fractions from the different soils contain Zn in different chemical environments. Elemental distributions indicated Zn co-location with Fe and/or Mn in heavy fractions, while light fractions often contained Zn co-located with Ca and K as well as Fe and occasionally Mn. μ-XRD data for all soils will also be analysed to confirm differences in mineralogy between fractions and to link with Zn chemical forms.

Soil solids retain substantial portions of toxic trace metals, maintaining the metals within the soil profile and potentially limiting leaching losses to ground and surface waters. Regardless of the initial form, large amounts of the metals are able to transfer between density fractions (e.g. organic matter associated to aluminosilicate associated), indicating that the metals can still be quite mobile among fractions, perhaps impacting their bioavailability as well as their potential for loss via leaching.

Kinetics of Ca-Na ion exchange, induced by CO_2-driven acid dissolution of carbonate minerals

JÖRGEN ROSENQVIST* AND BRUCE W. D. YARDLEY

School of Earth and Environment, University of Leeds, Leeds LS2 9JT, United Kingdom

j.rosenqvist@leeds.ac.uk (* presenting author)

b.w.d.yardley@leeds.ac.uk

During carbon dioxide sequestration in deep geological formations, injected CO_2 will dissolve into the formation water, thus lowering the pH and promoting dissolution of carbonate minerals, e.g. calcite and dolomite. The Ca^{2+} and Mg^{2+} ions from these minerals may stay in solution until eventually reprecipitated as carbonates, but the increased concentrations might also trigger ion-exchange reactions if any clays capable of ion-exchange (e.g. smectites) are present (c.f. [1]). Our knowledge of the kinetics of such ion-exchange reactions is limited, and it is unclear how protons are involved, if at all.

To study the kinetics of the Ca-Na ion-exchange, and the role of protons in the exchange, we have constructed a vessel that allows us to react carbonate minerals and clays in a CO_2-environment at elevated temperature and pressure. pH is continuously monitored, while the concentrations of dissolved ions are determined from fluid samples withdrawn periodically.

The results from two calcite-montmorillonite experiments in different ionic media are presented in Figure 1. In both experiments, calcite dissolution occurred in days, causing rapid increase of calcium in solution. A slow decrease of calcium over the next 2 weeks is attributed to ion exchange, and analysis of the clay fraction at the end of the experiment confirmed a significant increase in Ca. The role of protons is however not clear.

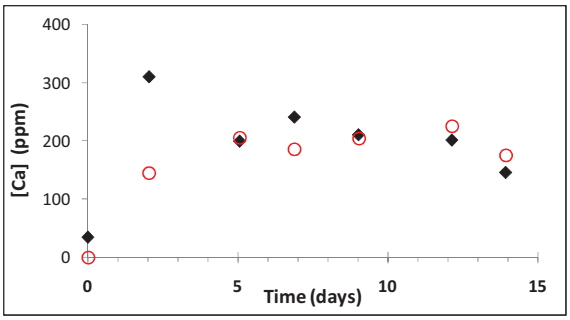

Figure 1: Measured Ca-concentration vs time, in experiments where calcite and Na-montmorillonite were reacted at 70°C and 80 bar CO_2. Filled diamonds: 0.01 M NaCl medium, open circles: 1.0 M NaCl medium.

Our results confirm that the first effect of increased acidity due to CO_2 injection will be dissolution of carbonates in host sediments, but clay minerals are likely to further modify pore water chemistry by ion exchange on the time scale of an injection cycle. This has implications for subsequent precipitation and modification of permeability.

Revisiting the ^{142}Nd deficits in the 1.48 Ga Khariar alkaline rocks, India

ANTOINE ROTH[1*], ERIK SCHERER[2], COLIN MADEN[3], THORSTEN KLEINE[4], AND BERNARD BOURDON[5]

[1*]ETH Zurich, Institute of Geochemistry and Petrology, Switzerland, antoine.roth@erdw.ethz.ch (* presenting author)

[4]Universität Münster, Institut für Planetologie, Germany, thorsten.kleine@uni-muenster.de
[5]ENS Lyon, CNRS, and UCBL UMR 5276, France, bernard.bourdon@ens-lyon.fr

The short-lived ^{146}Sm-^{142}Nd chronometer is a sensitive tracer of early silicate Earth differentiation. Expected variations in the abundance of ^{142}Nd are small (max 10-30 ppm) and their detection requires very clean separation of Nd to lower isobaric interferences to negligible levels and multidynamic acquisition scheme during TIMS measurements to account for drifts in detector and amplifier efficiency. The detection of ^{142}Nd deficits may also be hampered by inappropriate mass bias correction if Nd evaporates from multiple domains that are fractionated to different degrees [1].

Whereas early mantle depletion is well documented by <15 ppm ^{142}Nd excesses in Archean rocks [2], evidence for complementary early-enriched reservoirs remains sparse, e.g., [3]. Deficits in ^{142}Nd of up to about 20 ppm were reported for the 1.48 Ga alkaline rocks from the Khariar nepheline syenite complex in southeastern India [4]. These rocks crystallized long after ^{146}Sm was effectively extinct. It was therefore concluded that the Khariar rocks had inherited the Nd signature of an early-formed, low-Sm/Nd reservoir that was preserved (i.e., escaped mixing back into the convecting mantle) for at least 2.7 billion years.

Here we report the results of replicate analyses (double-blind experiment) performed at ETH Zurich for the four Khariar rocks DU-36, DU-1/2, DU-1/4, and DU-9/2. Each sample was digested once. Nd was isolated by classical ion exchange chromatography and Ce was removed using liquid-liquid extraction. Each Nd cut was then split onto two filaments and measured as Nd^+ with a Thermo Triton (TIMS) in multidynamic mode. Repeated measurements of the JNdi-1 standard yielded an external precision of ±5 ppm 2 SD (n=7). Our replicate analyses for the four Khariar rocks show no resolvable ^{142}Nd anomalies and no evidence of mixing among differently fractionated domains on the filament, e.g., [1]. This is in contradiction with previously reported anomalies for the samples DU-1/4 (-13.6 ppm) and DU-36 (-14.4 ppm) [4].

We are currently investigating the reason for the discrepancy between the two data sets, such as mass fractionation, detector linearity, and duration of measurements.

Helium isotopes and gas compositions in Aira caldera: Comparative study of hydrothermal activity at Sakurajima volcano and Wakamiko submarine crater, Japan

EMILIE ROULLEAU[1*], YUJI SANO[2], NAOTO TAKAHATA[3] AND SHINSUKE KAWAGUCCI[4]

[1] The University of Tokyo, AORI, Kashiwa, Japan eroulleau@aori.u-tokyo.ac.jp (* presenting author)
[2] The University of Tokyo, AORI, Kashiwa, Japan ysano@aori.u-tokyo.ac.jp
[3] The University of Tokyo, AORI, Kashiwa, Japan ntaka@aori.u-tokyo.ac.jp
[4] JAMSTEC, Yokosuka, Japan kawagucci@jamstec.go.jp

Aira caldera, located in Kagoshima bay, southern Kyushu, Japan, is a typical example of submerged caldera; it is composed of an active subaerial volcano, Sakurajima, and an active submarine crater, Wakamiko. Sakurajima is a stratovolcano which had its eruptive activity reinforced in the Showa crater since October 2009. Hydrothermal activity such as hot springs is widely observed in the foot of Sakurajima volcano. Wakamiko crater is a submarine depression where lies a hydrothermal activity such as fumarolic gas emissions on the seafloor. Wakamiko hydrothermal activity is considered to be related to the magmatic activity of Sakurajima volcano, but there have been no comparative studies yet to prove it.

In this study, we report He isotopes and gas compositions of hydrothermal waters for both Sakurajima volcano (hot springs) and Wakamiko crater (seawater) to constrain this relationship. First results of helium isotopes for Sakurajima and Wakamiko indicate very consistent values between the two edifices. The ^{3}He/^{4}He ratios for Sakurajima and Wakamiko range from 0.99 to 5.74Ra and 1.09 to 2.81Ra, respectively. Sakurajima ^{3}He/^{4}He ratios are explained by mixing of mantle-derived (MORB) and atmospheric helium dissolved in water (air-saturated water, ASW). Helium ratios in Wakamiko seawater samples increase with depth below the sea surface. Higher δ^3He in samples from 150 to 200m depth indicate a mixing between a mantle-derived component and ASW, as deduced for Sakurajima volcano. The ^{3}He/^{4}He ratio of injected mantle-derived helium component is 6.0±0.3Ra for Sakurajima volcano and 5.9±0.2Ra for Wakamiko crater. This similarity of He signatures for the magmatic source of Wakamiko seawater and Sakurajima hot springs suggests that (1) Wakamiko and Sakurajima share the same magmatic system and (2) the injected mantle-derived helium into the Wakamiko system comes from Sakurajima volcano itself. First results of $CO_2/^3$He ratios (207 to 611×10^9) in Sakurajima hot springs are higher than the average $CO_2/^3$He ratios observed in gas samples in Japan (10×10^9) [1]. High $CO_2/^3$He ratios in hot springs are commonly explained by physical fractionation processes, related to the difference of solubility between He and CO_2 in ground water [2]. However, the ^{3}He/^{4}He and $CO_2/^3$He ratios for Sakurajima decrease with increasing distance from the vent (Showa crater), suggesting that the source of CO_2 (as it is for He) is related to the volcanic activity. These correlations suggest that high $CO_2/^3$He ratios are also the result of addition of CO_2 by decomposition of carbonates from sediment rocks [3].

Introduction

To reduce radiation exposure rates at the site and prevent atmospheric resuspension of radionuclides (RN) released by the Chernobyl reactor 4 explosion (april 1986), about 800 trenches were dug on site to dispose contaminated material: debris, organic matter and topsoil containing reactor fuel particles. Since 1999, the CPS (Chernobyl Pilot Site) project was set up to study the migration of radionuclides from one of these trenches, the trench T22, through the unsaturated and saturated zone. A plume of ^{90}Sr was identified downstream from the trench [1]. The fate of buried RN and migration processes hence needs to be characterised. The aim of this study is to investigate processes governing non-reactive transport from the trench to the groundwater by studying the behaviour of a conservative tracer: ^{36}Cl.

Results and discussion

Significant ^{36}Cl contamination of the groundwater was demonstrated [2] with ^{36}Cl/Cl ratios approximately 10^2 to 10^4 higher than the theoretical natural ratio. New measurements have been performed to complete the dataset. The main source of ^{36}Cl in groundwater is most likely ^{36}Cl from the trench however other ^{36}Cl sources are probable which origins may be: (i) residual contamination after site clean-up and (ii) contamination from upstream trenches. Mixing processes are shown between these two sources. These observations lead to a conceptual non-reactive transport model in the groundwater, which includes the results of previous studies on recharge and groundwater flow system [3][4].

This conceptual non-reactive transport model will be quantitavely tested using the chemistry-transport Hytec code [5]. In a second stage, this model will be considered as a basis to investigate reactive transport for major elements, U and Sr.

Coupled Fe and S-isotope composition of sedimentary pyrite: Implications for Precambrian ocean chemistry and isotope biosignatures

OLIVIER J. ROUXEL[1] AND ANDREY BEKKER[2]

[1] IFREMER, Centre de Brest, and UEB-IUEM, 29280 Plouzané, France, (orouxel@ifremer.fr)

[2] University of Manitoba, Winnipeg, Canada, (bekker@cc.umanitoba.ca)

The rise of atmospheric oxygen level at ca. 2.3 Ga have led to dramatic shifts in the Fe-C-S oceanic cycles. Past studies of the Fe and S isotope record in sedimentary sulfides over geological time have placed important constraints on the evolution of the Precambrian ocean chemistry. Since the biogeochemical cycles of Fe and S are closely coupled in marine systems, Fe-limitation and S-limitation for pyrite formation in black shales should leave a coupled imprint on the isotopic record of both elements.

Here, we investigated the fine scale variations of Fe and S isotopic compositions of diagenetic pyrite nodules in several Devonian, Paleo-proterozoic and Archean black shales in order to (1) explore potential biosignatures using co-variations of Fe- and S-isotopes at the grain-size scale; (2) assess potential diagenetic effects on Fe-isotope fractionation during sulfide formation; and (3) assess potential mixing between isotopically distinct pools of Fe and S using multiple S isotope data. Results show that Devonian pyrite display a range of 50‰ in δ^{34}S values whereas δ^{56}Fe values vary between –1.0 and +0.1‰ consistent with Fe isotope variations in modern marine sediments. Similarly, pyrite in the 1.88 Ga Gunflint Formation has δ^{34}S values ranging from –32‰ to +10‰ and displays a range of δ^{56}Fe values between 0 to –0.4‰. In contrast, Archean black shales display a smaller range of δ^{34}S values between –5 and +18‰ but a larger range of δ^{56}Fe values from –3.5 to +0.2‰. A transitional period between 2.3 and 1.8 Ga is marked by a larger spread of δ^{34}S values from –34 to +28‰ and a larger range of δ^{56}Fe values from –1.7 to +1.1‰. These results confirm that after the rise of atmospheric oxygen, the Paleoproterozoic ocean became stratified and gradually affected by an increase of sulfate concentration in an Fe-limited system whereas pre-2.3 Ga ocean was S-limited and characterized by extensive Fe-oxide precipitation and redox cycling. This transition was also linked to profound changes of microbial processes, diagenetic conditions, and Fe redox cycling, that are all ultimately linked to the evolution of the global ocean chemistry.

We also investigated the chemolithostratigraphic variations of Fe-isotopes and Fe speciation in order to establish an Fe isotopic mass balance in black shales and its relation to environmental conditions. All together, our results confirm the existence of an isotopically negative, anoxic, Fe-rich seawater pool before 2.3 Ga, which may be in part fueled by dissimilatory Fe reduction as well as hydrothermal input. Regardless of potential Fe sources, light Fe isotope signatures in Archean and Paleo-proterozoic oceans are consistent with partial Fe oxidation in the photic zone, leading to the precipitation of isotopically enriched Fe-oxides and fueling extensive microbial Fe cycling.

Deep Sea Metalliferous Deposits as Modern Analogues for Ancient Marine Environments

OLIVIER J. ROUXEL[1,2*], YOHANN RESNAIS[2], NOLWENN CALLAC[1], AND PIERRE ANSCHUTZ[3]

[1] IFREMER, Centre de Brest, Dept. Ressources physiques et Ecosystèmes de fond de Mer , 29280 Plouzané, France, (orouxel@ifremer.fr)
[2] Université Européene de Bretagne, IUEM, 29280 Plouzané, France
[3] Université de Bordeaux 1, UMR CNRS 5805 EPOC, 33405 Talence, France

Modern seafloor metalliferous deposits provide unique analogues of ancient deposits currently mined on land. Their study is crucial for the establishment of genesis models and their relationships to oceanic and crustal evolution through time. Trace metal concentrations and isotopic compositions of laminated, organic matter-rich sediments (i.e. black shales) and iron formations are now widely used to draw inferences concerning paleoredox conditions as well as metal inventories in ancient oceans. Transition metal isotope geochemistry (e.g. Fe and Mo isotopes) is of special interest due to its potential to provide information about the biogeochemical cycling of bio-reactive metals, which allows both quantitative and qualitative estimates of their sources and sinks in the oceans. However, despite the increasing number of investigations, it is still unclear whether ancient metalliferous deposits and organic matter-rich rocks faithfully record ocean-scale processes, considering the importance of diagenetic and hydrothermal overprinting.

Here, we will focus on "calibrating" and "proving" a range of proxies - in particular Fe-isotopes - by undertaking a comparison between ancient metal deposits and modern seafloor metalliferous deposits. We will present geochemical and Fe-isotope signatures of (1) exhalative metalliferous sulfide and oxide deposits from the Atlantis II Deep, Red Sea which offers a unique modern analogue of laterally extensive metalliferous deposits such as ancient SEDEX deposits and possibly banded iron formation; (2) organic matter-rich sediments from the Guaymas Basin seafloor hydrothermal field as modern analogue of Precambrian black shales that are considered to be affected by hydrothermal metal input and reworking; (3) hydrothermal Fe-oxide deposits and microbial mats from the Loihi Seamount hydrothermal field which provides an ideal system in which to test hypotheses on biotic vs. abiotic origin of iron formation and Fe-isotope biosignatures.

This comparative approach should provide better constraints on the effects and signatures of hydrothermal overprinting on the ancient ocean rock record, ultimately leading to a better understanding of mechanisms of metal redox-cycling and microbiological interactions in ancient oceans.

Individual organic compounds in oil sands process-affected waters: identification and toxicity

STEVEN ROWLAND*, CHARLES WEST, ALAN SCARLETT AND DAVID JONES

Plymouth University, Biogeochemistry Research Centre, srowland@plymouth.ac.uk (* presenting author)

Introduction

The toxicity of oil sands process-affected water (OSPW) has often been at least partially attributed to compounds given the uninformative term 'naphthenic acids' (NA). Until our studies in 2011, no-one knew what any of these NA in OSPWwere, or how toxic they were [1-4]. Even now, many compounds remain to be identified and the concentrations remain to be accurately measured with isotopically-labelled analogues.

The present study therefore describes use of gas chromatography x gas chromatography-mass spectrometry (so-called' 2D GCMS'or GCxGC-MS) with both nominal and accurate mass resolution, 'normal' and 'reversed' phase GC column couplings and synthesised isotopically labelled authentic standard compounds, to identify and measure the individual NA components of OSPW. The distributions of the acids can be used to profile and distinguish different sources of NA in the environment.

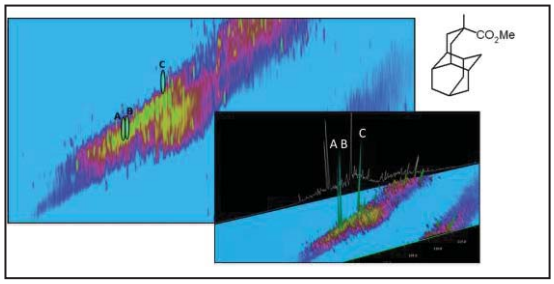

Figure 1: GCxGC-MS mass chromatogram of some of the individual isomers of tetracyclic acids (methyl esters) in OSPW.

Results and Conclusion

Use of trideuterated analogues of diamondoid acids (e.g. esters of adamantane carboxylic acids) and measurement of electron ionisation response factors for the analytes and for the deuterated internal standards, allowed the cocntrations of individual NA in OSPW from different industrial processors of oil sands ore, to be measured for the first time. GCxGC-MS with high accuracy mass resolution and reversed phase GCxGC columns allowed novel acids to be identified with greater certainty. Synthesis of novel acids allowed the toxicity to a number of biological endpoints to be determined. Such studies remove some of the need for speculation about the actual toxicants in OSPW.

A short oceanic residence time for Hf: element/isotope comparison

M. ROY-BARMAN[1*], S. MARCHANDISE[2]

[1]Laboratoire des Sciences du Climat et de l'Environnement, France, Matthieu.Roy-Barman@lsce.ipsl.fr (* presenting author)
[2]Laboratoire des Sciences du Climat et de l'Environnement, France, Sandra.Marchandise@lsce.ipsl.fr)

The oceanic residence time of isotopic tracers is a key parameter for their use in paleo-oceanography. Despite the recent direct determination of the Hf isotopic composition (ε_{Hf}) of seawater and of high resolution GEOTRACES sections, the Hf oceanic residence time remains poorly relatively constrained. River input budget suggest a residence time of 400-1500 y [1,2]. The variability of ε_{Hf} are difficult to use to estimate Hf residence time because the ε_{Hf} of continental inputs to dissolved Hf are not well constrained due to the storage of the Hf of crustal rocks in unsoluble and unradiogenic zircons. It is generaly admitted that the Hf residence time is grossly in the same range as the Nd residence time.

Here litterature data available are reviewed and used to constrain the isotopic residence time of Hf as well as the isotopic variability of the continental inputs:

- Hydrothermal plumes do not seem to affect Hf vertical profiles demonstrating that Hf is primarily of continental origin [2].
- As Hf and Nd inputs are dominated by lithogenic sources, it is likely that Hf inputs to the ocean are dominated by "boundary exchange" like Nd rather than by river inputs.
- A first order estimate of the Hf residence time can be obtained from the fraction of Hf in seawater present in the labile/seawater-derived fraction of particulate matter [3]. Comparison between Hf, Nd and Th suggests a Hf ocean residence time of 100 (compared to 380 y for Nd).
- Simple modeling implies that there is an inverse relationship between the ocean residence time of a radiogenic tracer such as (ε_{Hf}) and the variability of its isotopic composition in the ocean compared to its souce. A residence time as short as short 100 y implies that the variability of ε_{Hf} in the ocean is smaller but close to the variability of ε_{Hf} in continental sources of dissolved Hf. It implies that in a ε_{Hf} - ε_{Nd} diagram, the slope of seawater array matches the slope of the continental inputs and is only 1/3 of the slope of the terrestrial array.
- Inventory of Lu-Hf rich minerals in marine sediments confirms that Hf is mainly contained in zircons even in fine sediments allowing a preferential release of radiogenic Hf. Preferential storage of Lu in xenotime and zircon limits this preferential release [4].

The short residence time of Hf compared to Nd explains the decoupling observed between ε_{Hf} and ε_{Nd} in the present and past ocean.

Synthesis, characterization and stabilities of Mg-Zr(IV)-Al-Cl containing layered double hydroxides (LDHs)

KONSTANTIN ROZOV[1*], HILDE CURTIUS[1], AND DIRK BOSBACH[1]

[1]Forschungszentrum Jülich, Institut für Energie- und Klimaforschung, IEK-6, Jülich, Germany, k.rozov@fz-juelich.de (* presenting author)

Layered double hydroxides (LDHs) are of interest as potential sorbents for anionic radionuclides. In the present study the investigation of Zr-containing LDHs was performed because such substances were identified as specific secondary phases in corrosion products under repository relevant conditions of disposed research reactor fuel elements [1].

LDHs $Mg_3Al_{1-x}Zr_x(OH)_8Cl_{1+x}\cdot nH_2O$ with variable Zr(IV) content and fixed cationic ratio $Mg^{2+}/(Zr^{4+}+Al^{3+}) \approx 3$ were synthesized by co-precipitation method at 25 °C and pH = 10.00±0.05. PXRD measurements confirm the presence of a LDH single LDH phase. Cell parameters as a function of zirconium content (x_{Zr}) follow Vegard's law and corroborate the existence of a continuous solid solution series.

Results of infrared (IR) spectroscopic measurements clearly show strong OH^- (3482 cm^{-1}) and H_2O (1636 cm^{-1}) stretching and bending bands. The presence of small quantities of CO_3^{2-}-groups in the interlayer was detected by observation of the very weak band at 1376 cm^{-1}.

TGA measurements demonstrated the temperatures at which interlayer H_2O, Cl^--anions and OH-groups are lost. Moreover, we established that the increase of Zr(IV)-content in LDH solids does not result in a visible changes of the temperatures of removal of the interlayer H_2O, dehydroxylation of brucite-like layers and lost of Cl^-- anions.

Using the Gibbs free energy minimization software GEMS [2] and based on chemical analyses of the LDH solids and corresponding liquids after syntheses we provided the first estimates of $G°_{298}$ of Zr-containing hydrotalcites.

For the further investigations with Zr(IV)-containing hydrotalcites additional careful designed synthesis and dissolution studies at elevated temperatures will be performed. These studies will provide more data about thermodynamic properties (i.e. standard molar Gibbs free energies, entropies and heat capacities) of such phases in order predict their behaviour and retention properties at conditions of nuclear waste disposal environments.

Generation of moderately to very alkalic young Honolulu Series lavas from Th-U-Os-Pb-Nd-Sr isotopes

K.H. RUBIN[1*], D.G. PYLE[1], C.R. RUSSO[1], D. VONDERHAAR[1], G. RAVIZZA[1], D.A. CLAGUE[2]

[1]Dept. of Geology & Geophysics, Univ. of Hawaii, Honolulu, HI 96822 USA (*correspondence: krubin@hawaii.edu)
[2]MBARI, 7700 Sandholdt Road, Moss Landing, CA 95039 USA

The Honolulu Series volcanics on the Hawaiian Island of Oahu, are a type locality of alkalic ocean island rejuvenation stage magmatism. They have been studied by multiple researchers over the past several decades. Rejuvenation volcanism episodically spanned nearly 1 Myr. Our study focuses on the last two groups of eruptions (at ca 80 Kyr, Rubin et al., unpub.), which are known to represent the compositional extremes of the series. Lavas and pyroclasts of the Koko (subaerial/submarine) and Tantalus (subaerial) rift zones are mildly to highly silica undersaturated and alkalic (45-47 and 37-41wt% SiO2; 3.5-5 and 5.5-7 wt% tot. alkalis, respectively), and thought to be derived by small degrees of melting of one or two oceanic mantle source(s), perhaps containing exotic residual mineralogy (multiple authors, too numerous to cite).

We find highly correlated variations in Th/U and age-corrected ($^{230}Th/^{238}U$) in both lava groups, ranging to extreme disequilibria of >50%. Very small degree melts are likely involved. Both groups span the same U-series range, with no correlation to alkali content or other major element indicators of rock composition (e.g., SiO_2, MgO, TiO_2). Disequilibria are not correlated with trace element indicators of residual garnet (e.g., La/Yb). Relationships to tracers that would be sensitive to a Cretaceous lithosphere influence (e.g., $^{187}Os/^{186}Os$) are weak to non-existent. Sr-Nd-Pb isotopic variations are smaller in our sample set than the extant literature. Ratios are nearly constant in the Tantalus samples; Koko lavas display small but significant Pb and more subtle Nd isotopic variations, indicating variable or mixed source chemistry. Pb and Nd isotopes are correlated with U-series signatures on the Koko rift zone. We use these data to discuss the petrogenenis of these magmas and to evaluate both previously proposed and new models for their generation in the asthenosphere, lithosphere or both. The U-series disequilibria appear to require a magmatic phase that can strongly enrich Th relative to U without a strong effect on most LIL or REE.

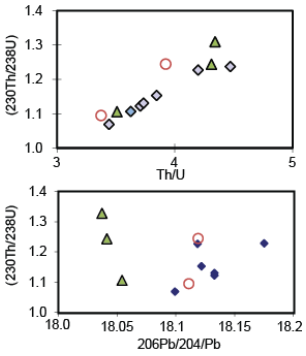

Figure #1: $(^{230}Th/^{238}U)_{meas.}$ verus Th/U and $^{206}Pb/^{204}Pb$ in Koko (diamonds), submarine Koko (circles) and Tantalus (triangles) lavas.

Craton formation

ROBERTA L. RUDNICK*[1]

[1]Geochemistry Laboratory, Department of Geology, University of Maryland, College Park, MD 20742 USA

Archean cratons throughout the world share key features indicating a commonality of processes in their formation and modification. These features include: a) a thick (110 to 220 km) keel of refractory peridotite (typical Fo of 92-93), b) generally increasing fertility of peridotites in the lowermost sections of keels, c) rhenium-depletion model ages of cratonic peridotites that are similar to the age of the overlying crust, d) presence of lithospheric diamonds, as well as diamonds with lower mantle mineral inclusions, now described from most cratons, e) low surface heat flow, averaging 40 mWm^{-2}, f) a ~40 km thick crust composed of granites and greenstone belts at the surface, with increasing seismic velocities with depth, but average intermediate to felsic bulk crustal compositions.

The two classes of competing hypotheses for formation of Archean cratons: plume subcretion vs. stacking and accretion of subducted oceanic lithosphere, do not account for all of the above features, particularly the presence of evolved continental crust overlying refractory mantle peridotite (whose complementary melt must be high Mg-Fe basalt, picrite, or komatiite, -- rare lithologies in cratons). If cratonic peridotite forms via melt extraction at Archean oceanic spreading centers [e.g., 1], and assuming that the density of the Fe-rich basaltic crust is sufficient to cause the lithosphere to founder (subduct?), then cratonic mantle may form from buoyant diapirs of harzburgite mechanically segregated from downgoing lithosphere in the transition zone or deep mantle (where some diamonds grow?) that underplate nacsent cratonic crust formed during partial melting of the downgoing basaltic/picritic crust. Rare eclogites found within cratonic mantle lithosphere may be fragments of the (residual?) oceanic crust that were entrained in the buoyant harzburgite diapirs. Assuming the buyoant tonalitic melts that formed by partial melting of foundering oceanic crust intrude and rise to the top of pre-existing picritic crust, there is still a need to remove picritic material from the deep crust. This could be accomplished by delamination [2] or overturn of lithospheric mantle [3], followed by recycling of eclogitic material. The latter hypothesis has the added attraction of explaining the late granite blooms that occur in most cratons well after their original formation and stabilization. The common occurrence of more fertile peridotite near the base of cratonic keels likely reflects refertilization associated with intrusion of basaltic magmas over the long history of the cratons as they move about the surface of the Earth.

Kinetic and step-specific effects on boron incorporation into calcite during growth

Reconstructions of ancient ocean pH are critical for evaluating past changes in the atmospheric CO_2 concentration and thus to obtain insights into the evolution of Earth's climate. These reconstructions are currently based on analysis of the boron composition of marine carbonates such as foraminifera or corals, e.g. [1,2]. The correlations observed between B concentrations and $\delta^{11}B$ in carbonates and the pH of the precipitating fluid in inorganic experiments [3,4] suggest that $\delta^{11}B$ and, possibly, the boron composition of carbonates, reflect changes in the pH of the solution from which they precipitated.

Nevertheless, there are still several aspects on the use of boron isotopes for the reconstruction of past seawater pH that require further investigation. In particular, questions related to the mechanism of boron coprecipitation with carbonates remain essentially unexplored. Although the increase in B incorporation with increasing pH can be explained largely by the change in boron speciation, it cannot be ruled out that other factors, such as kinetic effects associated with changes in growth rate [3], may also play a role.

As has been shown for many other elements, boron incorporation mechanisms cannot be simply studied by means of macroscopic measurements; molecular-scale studies are essential to obtain truly representative information of the surface processes taking place during B coprecipitation with calcite. In this study, boron incorporation during calcite growth was investigated using Atomic Force Microscopy (AFM), as a function of pH, supersaturation and boron concentration. Our results indicate that, together with pH, changes in the saturation degree of the precipitating solution and, as a consequence, in the calcification rate are a key factor to consider when using boron in marine carbonates as a paleo-pH proxy, as these factors could influence the extent of boron incorporation and, maybe, its isotopic signature. As well, this study shows that the calcite crystallographic form in which boron is incorporated may be also a critical factor controlling the amount of boron incorporated and that a change in the site preference of boron for its incorporation into calcite could occur depending on the species which is incorporated and, consequently, on the pH of the precipitating solution. Finally, our nanoscale observations give indirect evidence of the incorporation of boron in non-lattice sites.

Nucleation and crystal growth in confined nanopores

ANNE RUMINSKI[1] AND JEFFREY URBAN[1]

[1]Lawrence Berkeley National Laboratory, Molecular Foundry, Materials Sciences Division

Storage of carbon dioxide in deep geological formations has emerged as an important option in managing anthropogenic CO_2 [1]. One concern of this storage method is the unknown long-term stability of injected CO_2. Moreover, it will be necessary to seal injection reservoirs to prevent release of gases and fluids. The precipitation of metal carbonate bearing minerals in pore spaces is one possible path for both sealing off reservoirs and securely binding injected CO_2. In general, crystallization from solution occurs at solid-liquid interfaces. The detailed structure of the solid surface plays a critical role in liquid-solid phase transformations [2]. Nucleation and crystallization of these metal carbonates are greatly influenced by the surface shape, roughness, chemical species present, and nanoscopic confinement of the native metal oxides. Current understanding of the thermodynamics and kinetics of nucleation and growth is primilarly based upon analyses of homogenous systems near equilibrium; distinctly different from the supersaturated systems with complex interface structures that would be found at real reservoir sites.

Our aim is to bridge this gap, gaining a better understanding of how the subsurface environment influences the earliest stages of mineralization of sequestered CO_2 at nanoscale dimensions. We will examine the rates of metal carbonate nucleation and growth as a function of material surface structure and chemistry. Thin films of silica containing nanometer sized pores of different shapes and dimensions will be screened for preferential crystal nucleation and growth. In-situ transmission electron microscopy utilizing a fluid cell designed with temperature and electrochemical control will be employed to monitor and drive surface-directed crystal growth in real time.

Glacier sensitivity to climate change: observations and modeling

SUMMER RUPPER[1*], JOERG M. SCHAEFER[2], LANDON BURGENER[1], RYAN SMITH[1]

[1]Geological Sceinces Brigham, Young University, Utah, USA, summer_rupper@byu.edu (*presenting author) landonburgener@gmail.com ryan.glen.smith@gmail.com

[2]Lamont-Doherty Earth Observatory, Columbia University, New York, USA, schaefer@ldeo.columbia.edu

Glacier Sensitivity to Climate

A suite of general circulation model simulations and a glacier equilibrium line altitude model are used to test the sensitivity of Asian glaciers to climate changes at the Last Glacial Maximum (21 ka) and mid-Holocene (6 ka) [1,2]. The model simulations provide a test of glacier sensitivity to changes in climate boundary conditions. The results show that glacier sensitivity is strongly dependent upon the accumulation setting. In particular, the high accumulation regions of the southeastern Himalaya are most sensitive to changes in temperature and least sensitive to changes in precipitation. The reverse is true in the dry, interior plateau.

The intermodal differences for both 21 ka and 6 ka highlight regions where climate model uncertainty is greatest [3]. In particular, the southeastern Himalaya is a region where intermodel variability in temperature is extremely high, yet few paleoclimate proxies and glacier studies are available to help constrain the models. This is a region where paleoclimate and glacier reconstructions can provide crucial information for global and regional climate modelling efforts.

Southeastern Himalaya: Bhutan

Glacier retreat in the Himalayas impacts societies in the most densely populated area on earth by affecting river-discharge, hydro-energy and agricultural production, and glacial lake outburst flood potential. Bhutan sits in the bulls-eye of highest accumulation, where glacier sensitivity to temperature is greatest, and where there is a severe modern and paleo-climate data gap. Bhutan is therefore a region of potential scientific importance. In addition, Bhutan is representative of the potential societal impacts of glacier changes. Here we present quantitative predictions for glacier area and meltwater flux changes in Bhutan. Based on gridded climate data and a simple glacier melt model, our results show that Bhutan's glaciers lag behind the climate forcing considerably. Under the conservative scenario of an additional 1°C warming, about half of Bhutan's glaciers would disappear and the meltwater flux would drop to 20% of today's value. Even with no additional warming, almost 20% of the glaciated area would vanish and the meltwater flux would drop by 50%.

The results of the Bhutan study highlight the need to decrease uncertainty in glacier sensitivity to climate change. Given the transient nature of current climate and glacier systems, quantifying glacier sensitivity will rely heavily on well-documented glacier and climate histories. These longer term records are critical to quantifying the non-stationarity of glacier sensitivity, placing recent glacier and climate changes into context of longer term patterns, and validating both glacier and climate models.

Mantle signals in olivine phenocrysts in arc volcanics

PHILIPP RUPRECHT[1*], TERRY PLANK[1]

[1] Lamont Doherty Earth Observatory of Columbia University, Palisades, NY, USA, ruprecht@ldeo.columbia.edu (* presenting author)

Volcanism is fed by crustal storage reservoirs recharged ultimately with mantle-derived primitive melts. In particular withinin arc magmatic systems the nearly ubiquitous processes of mixing, hybridization, and crystallization combine to obscure the diversity of melts from the mantle. Isotope and trace element ratios of volcanic rocks and melt inclusions may help to reveal mantle inputs, but we explore here an alternative approach that uses trace element zonation in primitive olivines. Such zonation patterns both record the diversity of primary melts and provide a mechanism to constrain the timescales of mantle recharge and magma ascent through the entire crustal column.

Laser ablation-ICPMS and electron microprobe traverses provide extensive datasets of major and trace element zonation profiles in large populations of olivine (n>100). We focus here on Irazú volcano, in Costa Rica, as a typical strato-volcano from a continental arc, but we have extended our approach to other arc volcanic systems (Volcano A and West Mata in Tonga and Los Hornitos in Chile). The hybrid basaltic andesites that erupted from Irazú in 1963-65 bear abundant, primitive olivine crystals (up to 70 % of olivines include zones of >Fo88). Ni zonation varies within individual crystals by more than 500 ppm at nearly constant, high Fo content (>Fo88), recording the mixing of different mantle melts. The overall range of Ni in these magnesian olivines (2000-4000 ppm) is consistent with pyroxenitic and peridotitic mantle sources. Zonation profiles can be modeled by diffusive re-equilibration of Ni following a mixing event that sometimes creates a reversal (increase) in Ni. We calculate mixing time scales for these near-primary olivine phenocrysts that range from seven months to five years, accounting for anisotropic elemental diffusion in olivine (lattice orientation with respect to diffusion direction determined by electron backscattered diffraction). These short timescales are on the order of the duration of the eruption itself, providing new evidence for recharge of melts directly from the mantle, feeding on-going andesite eruptions at large stratovolcanoes. As the mixing of these distinct mantle melts occurs at least below the Moho (~ 35 km beneath Irazú), we can calculate average ascent rates of 10-100 m per day for magma to traverse the entire crustal column. Given that syn-eruptive ascent is likely very fast in the uppermost part of the magmatic column (typically from 5-10 km depth of the shallow magma chamber to the surface) we can infer that even in the lower and middle crust average ascent rates are >10 m per day. These rates are relevant to real-time geophysical observations of volcanic plumbing systems from the mantle to the surface.

Planetary oxidation and the biogeochemistry of exoplanets

ANDREW J. RUSHBY[1*], ANDREW J. WATSON[1], MARK W. CLAIRE[1]

[1]School of Environmental Sciences, University of East Anglia, Norwich, U.K.
*andrew.rushby@uea.ac.uk

Atmospheric oxygen is considered a fundamental prerequisite for the evolution of complex organisms with high metabolic demands. On Earth, this requirement can only be met by aerobic respiration. The main source of oxygen on Earth is biological, originating as a by-product of oxygenic photosynthesis. However, geological and planetary factors are important in controlling the relative abundance of oxygen in the atmosphere.

Over geological timescales, planetary oxidation is controlled by two mechanisms: the burial of organic carbon [1] and hydrogen escape from the upper atmosphere [2]. The relative importance of these processes varies significantly over time; hydrogen escape was an important oxidising mechanism during the early evolution of the planetary atmosphere, but represents only a limited source of oxidising power today when compared to the burial of organic carbon.

However, it seems that the 'default' state of the planetary atmosphere is reducing [3], and the oxidising atmosphere of the Earth is unusual. The homeostasis of atmospheric oxygen is perhaps the most obvious example of biogeochemical coupling on the Earth. Is the co-evolution of oxygen and biosphere likely to be a fundamental characteristic of habitable, life-bearing planets?

Planetary characteristics undoubtedly exhibit a fundamental control over these oxidising processes, but our understanding of these factors remains limited. Planet mass may play a particularly important role in controlling hydrogen escape for example, and an upper and lower mass limit must exist beyond which this mechanism fails or operates too slowly or too rapidly to contribute any lasting geochemical signal. Biology is the primary controlling factor in regards to carbon burial, representing the main pathway for organic carbon fixation. However, geological recycling processes enable the burial of organic carbon, and the rate and duration of these mechanisms are sensitively dependent on a number of planetary variables.

Modern biogeochemical models (eg: COPSE [4]) can resolve the rise of oxygen in acceptable agreement with geochemical proxies, but are difficult to apply to planets other than the Earth. Preliminary results from a simplified version of this model return estimates for 'oxygenation time' that vary over several orders of magnitude when forced by either hydrogen escape or carbon burial alone. It is hoped that this model can begin to reconcile these two fundamental processes over time, but also resolve potential oxygen fluxes operating on extrasolar planets, with extensive application to the search for habitable extrasolar planets as well as the emerging field of astrobiology.

Origin of silicic magmas in the primitive, intra-oceanic Tongan arc

T. RUSHMER[1*], S.TURNER[1], J. CAUFILED[1], M. TURNER[1], S. CRONIN[2] AND I. E. SMITH[3]

[1]Department of Earth and Planetary Sciences, Macquarie University, Sydney 2109, Tracy.Rushmer@mq.edu.au*
[2]Insitute of Natural Resources, Massey University, Palmerston North, New Zealand, S.J.Cronin@massey.ac.nz
[3]Department of Geology, Auckland University, Auckland, PB92019, New Zealand, ie.smith@auckland.ac.nz

The origin of felsic magmas (> 60% SiO_2) in intra-oceanic arc settings is a matter of much current debate. In essence, two very different processes are currently invoked: fractional crystallization of basaltic magma and partial melting of lower crustal amphibolites. Importantly, the physical conditions, such as pressure, melt reactions, rates of melting and fluid dynamics of melt extraction differ markedly between the two mechanisms. Concurrently, a number of sophisticated numerical models of lower crustal amphibolite melting have been developed over the past decade. Such models are becoming widely invoked so there is a need for their applicability to be tested. Fonualei is unusual amongst subaerial volcanos in the Tonga arc because it has erupted dacitic vesicular lavas, tuffs and phreomagmatic deposits for the last 165 years and makes for an excellent natural laboratory. All of the products are crystal-poor and formed from relatively low viscosity magmas inferred to have had temperatures of 1100-1000 ºC, 2-4 wt. % H_2O and oxygen fugacities 1-2 log units above the QFM buffer.

Major and trace element data, along with Sr-Nd-Pb and U-Th-Ra isotope data, are used to assess competing models for the origin of the dacites. Positive correlations between Sc and Zr and Sr rule out evolution by closed-system crystal fractionation and an origin by direct partial melting of amphibolite cannot reproduce the data either. Instead, we develop a model in which the dacites reflect mixing between two dacitic magmas, both products of fractional crystallization of basaltic-andesite magma. Mixing was efficient because the two magmas had similar temperatures around 1000 ºC. This is inferred to have occurred around 6 km depth beneath the volcano and the relative proportion of the fractionation-derived dacite has increased over the 165 year eruption period implying crystal fractionation and mixing may all have occurred on a similar timescale. U-Th-Ra disequilibria in the basaltic-andesite and andesite indicate that the magmas parental to the fractionation produced dacite had fluids added to their mantle source regions less than 8 kyr ago.

Laser Ablation Molecular Isotopic Spectroscopy (LAMIS)

Would the ability to immediately analyze any sample in the field for elemental and isotope content be of value to the geological community? It is possible and this talk will describe a new technology that offers just that capability. The technology has been named LAMIS for Laser Ablation Molecular Isotopic Spectroscopy. By expanding the capabilities of a classical laser plasma technology known as LIBS (Laser Induced Breakdown Spectroscopy) to emphasize the measurement of molecular emission spectra in addition to elemental, LAMIS provide geologist with a tool for measuring all elements and their isotopes, including light elements like Li, Be, C which are impossible with XRF. The basis of LAMIS is to analyze a tiny amount of the sample using the laser beam. No sample preparation or consumables are needed. We have developed LAMIS to date by establishing its ability to measure B, C, H, D, Sr and other isotopes. We have demonstrated down to percent levels for sensitivity and have experimental plans to meet ppm levels. This talk will describe the previous isotope work that has been reported in LIBS plasmas and show how LAMIS expands those capabilities.

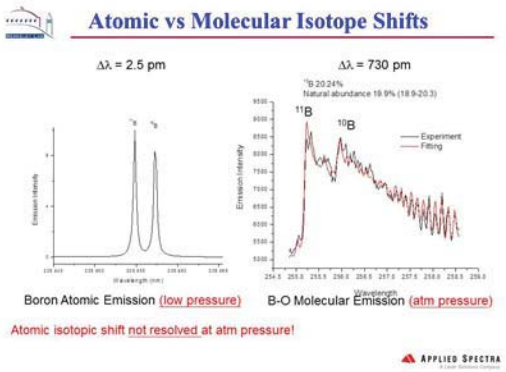

Figure 1: Demonstration of atomic versus molecular isotope emission spectra in laser plasmas

Conclusion

This talk will describe previous isotope work that has been reported in LIBS plasmas and show how LAMIS expands those capabilities.

Changes in $^{231}Pa/^{230}Th$ signatures in the bottom water of the ocean

Michiel Rutgers van der Loeff[1*], Sven Kretschmer[1], Celia Venchiarutti[1]

[1]Alfred-Wegener-Institute for polar and marine research, Bremerhaven, Germany, mloeff@awi.de (* presenting author)

There has recently been much development in the description and modeling of the particulate $^{231}Pa_{xs}/^{230}Th_{xs}$ ratio in the ocean as proxy for the meridional ocean circulation, especially to study the situation in the glacial Atlantic Ocean. Many studies have investigated the effects of ventilation, mass flux and particle composition on $^{231}Pa_{xs}/^{230}Th_{xs}$ ratios. The interpretations as paleoproxy rely usually on the assumption that the isotopic signal stored in the sediment is determined by the composition of suspended or sinking particles when these arrive at the respective water depth. This composition is controlled by exchange with the deep water column [1]. At depths >2500m, Scholten et al. [2] found agreement between $^{231}Pa_{xs}/^{230}Th_{xs}$ ratios in suspended material and surface sediments. Chase et al. [3] observed no difference in activity ratio between surface sediment and a fluff layer present on top of their cores. However, there are several processes that may cause the ratio in surface sediments to differ from the ratio in sinking particles. Bottom currents transport and redistribute the sediment and fractionate grain size [4] and isotopes [5,6]. As a result of this transport and of early diagenetic reactions in the sediment, surface sediments may have a chemical composition and reactivity that is different from sinking particles. We will discuss the possible bias that these processes can give to the signals measured in bottom waters and stored in the sediment.

Whereas Pa/Th ratios have mostly been studied in relation to deep water formation in the North Atlantic, the formation of deep water in the Weddell Sea (Weddell Sea Bottom Water, WSBW) also effects the distribution of ^{230}Th and ^{231}Pa. We will present some new water column data confirming the strong effect of ventilation on the distribution of ^{231}Pa and ^{230}Th in the Atlantic sector of the Southern Ocean. Both nuclides accumulate at intermediate depth in the Weddell Sea while concentrations are appreciably lower in the newly formed Weddell Sea Bottom Water.

Copper isotope fractionation during uptake and translocation in strategy I and strategy II plants

RYAN, B.M.[1*], KIRBY, J.K.[2], MCLAUGHLIN, M.J.[1,2],
DEGRYSE, F.[1], SCHEIDERICH, K.[2], HARRIS, H.[3]

1Soil Sciences, University of Adelaide, Australia,

[2]Land and Water, CSIRO,Adelaide, Australia
[3]Chemistry and Physics, University of Adelaide, Australia

Copper is an essential micronutrient for plant growth, yet is a toxin at above optimal concentrations. It currently remains unclear how plants mobilise, absorb and translocate Cu in soil-plant systems. It has been reported that strategy I plants (dicotyledons or non-graminaceous monocotyledons) can reduce Cu(II) by the secretion of Fe(III) reductases, and that strategy II plants (graminaceous monocotyledons) can complex and absorb Cu(II) using Fe(III) complexing phytosiderophore root exudates [1, 2]. Stable isotopes have the potential to provide in situ information on these mechanisms [3]. This knowledge can assist in developing better agricultural management strategies to enhance uptake in Cu deficient conditions, to limit Cu uptake to allow faster revegetation on contaminated lands, and to trace contamination sources.

A controlled hydroponics experiment that examined the fractionation of Cu isotopes was conducted to assess Cu uptake and translocation mechanisms in higher plants. *Lycopersicum esculentum* (Roma Tomatoes, strategy I), and *Avena sativa* (Oats, strategy II), were grown under nutrient conditions that controlled Cu speciation for 30 days, with an iron deficiency induced on half the plants for the last 6 days of growth.The plants were harvested and separated into roots, stems and leaves for isotopic analysis.

It was expected that if Cu were taken up through Fe acquisition mechanisms, Fe deficiency would increase Cu uptake. Indeed, Cu concentrations were significantly higher in the Fe-deficient plant roots of both species. Furthermore, preliminary Cu isotope data ($\delta^{65/63}$Cu) show Fe-deficient tomato roots being *ca.* 0.5‰ lighter than Fe-sufficient plants, with an average $\Delta^{65}Cu_{(root\text{-}solution)}$ of -2.3‰ in the Fe-deficient tomato plants. The strong negative fractionation suggests reduction of Cu(II) is occuring prior to uptake, possibly at the root surface. Oat roots also showed a light isotopic composition, with a $\Delta^{65}Cu_{(root\text{-}solution)}$ of ca. -1.0‰. However, no significant difference was observed between the control and Fe-deficient oat roots.

Copper isotope data from plant tissues, together with solid-phase Cu speciation from synchotron-based bulk X-ray absorbance spectroscopy, will be used to infer Cu uptake and translocation mechanisms in higher plants.

Black Shales and massive sulfide deposist in the Iberian Pyrite Belt

REINALDO SÁEZ[1](*); CARMEN MORENO[1]; FELIPE GONZÁLEZ[1]; GABRIEL R. ALMODÓVAR[1]

[1]University of Huelva, Huelva, Spain, (*) saez@uhu.es

Introduction

Many massive sulfide deposits at the Iberian Pyrite Belt (IPB) are hosted by black shales. This relationship is well constrained in some of the major deposits at the province, including Neves-Corvo [1], Tharsis[2], Sotiel [3], and Aznalcóllar [4]. Geochemical environment during ore deposition has been atempted only at the Filon Norte deposit, within the Tharsis District [5][6]. New geochemical data from the black shales hosting the MS at Aznalcóllar and Sotiel show significant differences in terms of environmental conditions for ore generation. Considering the differences in metal content of each deposit, this could be noteworthy for exploration.

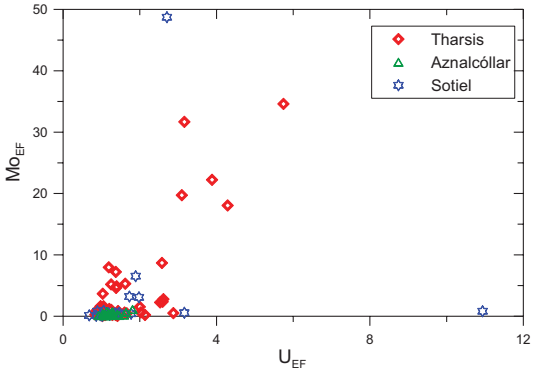

Figure 1: U_{EF} *vs* Mo_{EF} diagram for black shales hosting some IPB ore deposits. Cluster close to x-axis includes the Aznalcóllar and most of the Sotiel samples.

Inorganic geochemical proxies such V/Cr and V/V+Ni suggest general dixosic condition for Tharsis, Aznalcóllar and Sotiel. Recent studies enhance the role of U and Mo as proxies for paleo-environmental reconstructions [7]. Black shales data of these three dstricts on the U_{EF} - Mo_{EF} diagram (Fig. 1) point to disparate environmental conditions. The low absolute values as well as the absence of covariation for the Aznalcollar and Sotiel samples sugest general oxic botom water environents. At Tharsis, the positive correlation together with the dispersion of values sugest changing conditions fron oxic to strongly anoxic, and even euxinic conditions, for the depositional environment.

Chemical U-Th-total Pb ages in recycled metamorphic terranes: the case of the South Carpathian basement units

GAVRIL SĂBĂU[1*] AND ELENA NEGULESCU[1]

[1]Geological Institute of Romania, Bucharest, Romania, g_sabau@yahoo.co.uk ([*] presenting author), elinegu@yahoo.com

Monazite chemical geochronology

Monazite geochronology has emerged as a reliable dating method for metamorphic ages, as monazite, at variance with other widely employed minerals of geochronological relevance, grows coevally with metamorphic assemblages and displays subsequent chemical and isotopic stability; even dating by chemical methods assuming isotopical equilibrium proved to be accurate enough. Yet, few data refer to metamorphic formations with complex history and thorough succesive overprints, for which the basement units of the South Carpathians represent a typical example.

Previous geochronological data and interpretation

The basement units of the South Carpathians are involved in intricate Variscan and Cretaceous thrust and wrench tectonics. Consisting mainly of medium-grade metamorphic rocks, all types of basement were traditionally considered Precambrian in age [1]. Extensive U-Pb zircon dating revealed Gondwanan provenance and protholith ages ranging from Early Proterozoic to Early Paleozoic [2]. Ar-Ar dating aimed to decipher the metamorphic history overwhelmingly indicated Variscan ages [3], sometimes at odds with cover-basement and intrusion – host-rock relationships. Therefore electron microprobe U-Th-Pb chemical chronology was attempted on rock units of the main basement complexes in order to elucidate the building blocks and temporal details of Variscan tectonometamorphic events.

Results and Conclusions

The age values derived from microprobe U-Th-Pb analyses revealed variable responses of monazite to polymetamorphic events, as well as frequent post-climactic records, resulting in age plateaus often joined by quasi-continuous spectra in case of reworked pre-Variscan complexes. Purely Variscan age patterns in rock units, also displaying microstructures and chemical zonation patterns consistent with a monometamorphic history, sandwiched between pre-Variscan terms, indicate frequent imbrication of reworked and juvenile metamorphic units during the Variscan thermotectonic events in the South Carpathian basement. The recorded evolution is consistent with complex interactions of migrating slivers that originate from the northern Gondwanan margin, up to the time of the Variscan collision. Accidental Alpine age values, mostly unrelated to pervasive metamorphic overprints, indicate low-temperature recrystallization domains in monazite, which call for caution in interpreting monazite age data.

Clumped and magnesium isotopes in corals: a comparison with traditional paleothermometers

Corals represent valuable paleoclimatic archieves that may record sub-annual sea surface temperature (SST) over many centuries. Despite strong correlations with SST, the interpretation of traditional proxies (i.e. $\delta^{18}O$, Sr/Ca) is not straightforward because variations in seawater composition and biological vital effects can overprint climatic signals. Evidence for vital effects include 1) proxy-SST calibrations that differ significantly from abiogenic relationships and 2) inter/intra-coral differences in proxy-SST calibrations. Carbonate clumped isotopes (Δ_{47}) and magnesium isotopes ($\delta^{26}Mg$) have emerged as new paleotemperature proxies that may be less prone to seawater variability and vital effects.

Based on the temperature dependent "clumping" of ^{13}C and ^{18}O into a single bond, Δ_{47} temperatures, at equilibrium, do not depend on the composition of the solution from which a carbonate forms. Furthermore, similar Δ_{47}-SST relationships in biogenic carbonates and inorganic precipitates argue against vital effects. However, early sub-annual coral Δ_{47} data deviates from the cannoical Δ_{47}-SST relationship and may reflect a vital effect [1]. We present a survey of Δ_{47} shallow water corals from the Atlantic, Pacific and Red Sea. Sub-annual Δ_{47} in two *Porites* corals shows a temperature sensitivity similar to abiogenic calibrations, but offset toward higher Δ_{47} values that underestimate SST by ~9ºC. This effect cannot be attributed to laboratory artifacts or environmental variables such as salinity, but may result from fast coral calcification. Possible mechanisms for this apparent link to calcification will be discussed.

Like Δ_{47}, temperature dependent magnesium isotope fractionation [2] is unlikely to be affected by solution composition, suggesting it may also be a valuable paleo-thermometer. Sub-annual $\delta^{26}Mg$ variability in two *Porites* corals shows obvious annual cycles that are in phase with $\delta^{18}O$ and Sr/Ca, suggesting a temperature dependence not seen in previous bulk sampling [3]. However, the temperature sensitivity of coral $\delta^{26}Mg$ appears to be larger than abiogenic experiments raising the possibility of a vital effect. Potential sources for this discrepancy will be discussed.

Was Mineral Surface Toxicty an Impetus for Evolution of Bacterial Extra-cellular Polymeric Substances (EPS)?

NITA SAHAI[1*], JIE XU[2], CHUNXIAO ZHU[3], NIANLI ZHANG[4], AND WILLIAM J. HICKEY[3]

[1]University of Akron, Akron, U.S.A., *sahai@uakron.edu

[3]University of Wisconsin, Madison, U.S.A., czhu3@wisc.edu, wjhickey@wisc.edu
[4]University of Michigan, Ann Arbor, U.S.A., nianliz@umich.edu

Bacterial community-living at the mineral-water interface is enabled by an extracellular, polymeric, biofilm matrix. Despite the energetic penalties of EPS production, biofilm formation capability likely evolved on early Earth because of several proposed crucial cell survival functions. The potential toxicity of mineral surfaces towards cells in promoting biofilm formation, however, has not been fully appreciated.

We examined here the effects of nanoparticulate oxides (amorphous SiO_2, anatase β-TiO_2, and γ-Al_2O_3) on EPS- and biofilm-producing wild-type strains and their isogenic knock-out mutants which are defective in EPS-producing ability. In particular, we used the Gram-negative wild-type *Pseudomonas aeruginosa* PAO1 and its EPS knock-out mutant *Δpsl*, and the Gram-positive wild-type *Bacillus subtilis* NCIB3610 and its EPS-knock-out mutant *yhxB*Δ. Results showed that (a) cell viability was lower in the presence of each oxide relative to its oxide-free control, (b) toxicity was mineral-specific, and could be related to surface charge and particle size, (c) toxic minerals could induce EPS production, (d) the amount of EPS generated in the presence of oxides was related to relative toxicity of the minerals, and (e) Gram-positive cells were less susceptible to mineral toxicity than Gram-negative cells. Taken together, these results indicated a previously unrecognized role for microbial extracellular polymeric substances (EPS) in shielding bacterial cells against the toxic effects of mineral surfaces.

The function of EPS proposed here is distinct from the previously proposed roles. It is likely that EPS played multiple functions, including our hypothesized role of protecting against mineral toxicity. Furthermore, not all minerals are toxic or benign, and toxicity depends on surface chemistry and particle size. Our results provide insight to the potential impact of nanoparticulate mineral surfaces in promoting increased complexity of cell surfaces, including EPS and biofilm formation, on early Earth.

Session 18b. Nucleation, Growth, and Dissolution in Aqueous Environments: Elementary Processes and Atomistic Models

Amorphous calcium carbonate (ACC) is a critical transient phase in the inorganic precipitation of $CaCO_3$ and in bio- and biomimetic mineralization. Proteins known to be responsible for the biomineralization of, for instance, bird egg shells, bind to ACC nanoparticles and lower or remove the energy barrier to crystallization. The mechanisms of these processes are related to the structures of hydrous and anhydrous ACCs, but the details are poorly known. To advance fundamental molecular-level understanding of the bulk hydrous and anhydrous ACC, we studied these systems using both classical and quantum mechanical simulation methods. Car-Parrinello molecular dynamics (CPMD) simulations of calcium carbonate solvated in a bath of water molecules have been performed at a temperature of 300K to elucidate the microscopic structure, dynamics, and electronic properties of water molecules in the first two solvation shells of calcium carbonate. The reorientational dynamics of near-neighbor water molecules around Ca^{2+} and CO_3^{2-} ions are investigated through first- and second-order time correlation functions, and are in good agreement with nuclear magnetic resonance experiments. The intramolecular vibrations of CO_3^{2-} ion have also been examined through an analysis of the velocity autocorrelation function of the atoms and are compared with that of isolated $CaCO_3$ and existing vibrational spectra of calcium carbonate. In addition, classical molecular dynamics simulations of pre-nucleated ACC are carried out to understand the role of water molecules in stabilizing these clusters. Starting from a hydrous ACC model with a $CaCO_3/H_2O$ ratio of 1/1, we gradually reduced the water concentration of the system to completely dehydrated ACC. Simulation results using the DL_POLY software on the structure and dynamics of the constituent molecules due to drying will be presented.

Acknowledgements

New U-Pb ages for gabbro sills within the Ramah Group, northern Labrador: implications for Paleoproterozoic extension in Nain craton, and metallogeny

T. SAHIN[1*], M.A. HAMILTON[1], P.J. SYLVESTER[2], AND D.H.C. WILTON[2]

[1]University of Toronto, Geology, Toronto, Canada, tsahin@geology.utoronto.ca (* presenting author); mahamilton@geology.utoronto.ca

[2]Memorial University, Earth Sciences, St John's, Canada, psylvester@mun.ca; dwilton@mun.ca

Archean gneisses of the North Atlantic craton (NAC) in northern Labrador are unconformably overlain by three principal Paleoproterozoic supracrustal remnants – the mostly clastic Snyder/Falls Brook Group, the dominantly volcanic Mugford Group, and, furthest north, the chiefly sedimentary Ramah Group.

Ramah Group is an ~1700m thick cover sequence of lowermost siliciclastic quartz sandstone capped by a distinct supratidal dolomite horizon, together defining a west-facing shallow shelf sequence, overlain by euxinic, pyritic shales and mudstones and pyrite-chert associations (Nullataktok Formation). Upwards, this unit passes through a mixture of carbonate debris flow breccias, and then into voluminous turbiditic sandstones. Sills of diabase or gabbro extensively intrude the upper sedimentary units. The sills typically exhibit chilled margins, and are clearly transgressive to their host sediments. Sills reach up to ~100 m in thickness, though many are only a few meters thick, in many places with preserved primary layering. The entire sequence of sedimentary rocks and sills was deformed and (locally) metamorphosed to amphibolite facies, as part of an east-verging fold-and thrust belt on the east margin of the 1.78 Ga Torngat Orogen. The depositional age of the Ramah Group has only been bracketed only between its late Archean (ca. 2.5 Ga), Nain craton-derived detrital zircons, and Torngat deformation.

We have dated both gabbroic and ultramafic compositional variants of Ramah sills, from samples collected from thick sheets intruding the Nullataktok Formation. ID-TIMS U-Pb baddeleyite analyses yield identical ages of emplacement at 1888 ± 5 and 1887 ± 4 Ma. These represent the first precise U-Pb dates for extension-related mafic magmatism of this age in the NAC in Labrador, and provide a new minimum age for the host Ramah Group sediments. Mafic magmatism of this age is unknown in the Greenland portion of the craton, but is well represented in the Circum-Superior belt, including the ca. 1883 Ma Molson dyke swarm and Fox River sill of Manitoba (Molson Igneous Events), the 1890-1870 Ma Raglan-Expo-Katiniq sills of the Cape Smith belt, Ungava, and the 1884-1874 Ma mafic-ultramafic magmatism of the Labrador Trough.

By analogy with contemporaneous Circum-Superior sediment-sill complexes (Thompson, Birchtree, Raglan-Expo), Ramah Group may have potential for magmatic Ni-Cu-PGE sulfide deposits.

Metazoans first appeared in the fossil record shortly after the termination of the late Cryogenian (Marinoan) glaciation about 635 Myr ago [1]. It has been long hypothesized that an oxygenation event was the driving factor behind the rise and early diversification of metazoans [2], but there is little evidence for a direct link between animal and redox evolution. Here we report new geochemical data from early Ediacaran organic-rich black shales of the basal Doushantuo Formation in South China. These shales were deposited with a strong connection to the open ocean [3] and span the interval of the earliest metazoan fossil [1]. The temporal record of trace metal enrichments (particularly molybdenum) in euxinic shales currently provides one of the clearest signals for a significant redox shift in the Neoproterozoic [4,5]. However, prior to our study the oldest known occurrences of Phanerozoic-like trace metal enrichments are found near the end the Ediacaran (ca. 551 Ma) [4,5], long after the radiation of complex metazoans [1].

In contrast, we found very high, Phanerozoic-like, redox sensitive trace element (molybdenum, vanadium and uranium) abundances in euxinic shales (as identified by sedimentary Fe speciation) that were deposited between 635 and 630 Ma, within five million years of the Marinoan glaciation and coincident with the appearance of the earliest metazoan fossils. Moreover, highly negative pyrite sulphur isotope ($\delta^{34}S_{pyrite}$) values down to –35‰ from basinal samples also point toward an oxidizing ocean-atmosphere system. The isotope fractionation between pyrite and coeval sulphate in the deep basin section is >65‰—equivalent to the maximum fractionations observed in the Phanerozoic rock record [6]. As increase in the fractionation in the Neoproterozoic has been commonly linked to growth of the marine sulphate reservoir and surface oxidation [5], the large sulphur isotope fractionation, therefore, point toward a well oxidized ocean-atmosphere system. Our data provide the first direct evidence for a significant early Ediacaran postglacial oxygenation event. Our results support a casual link between one of the most severe glaciations in Earth's history, the oxygenation of the Earth's surface, and the earliest diversification of complex animals.

Typically, radium is the most significant contributor to dose in mining effluents from legacy uranium mining operations. However, little is known regarding the uptake of Ra^{2+} by iron (oxy)hydroxide minerals under environmental conditions representative of the mining wastes. Here, we assess the behaviour of Ra^{2+} (and Ba^{2+} as a chemical analogue of Ra^{2+}) to provide surface complexation constants that will be used in the prediction of Ra^{2+} speciation, mobility and fate across a range of environmental conditions.

Radium and barium uptake onto ferrihydrite and goethite was studied in the concentration range nM to mM and from pH 5 - 10, conditions commonly found in legacy U-mine wastes. For ferrihydrite, uptake of Ra^{2+} at nM concentrations was strong at pH > 7. At higher concentrations (μM - mM) Ba^{2+} sorption to ferrihydrite was slightly weaker than that of Ra^{2+}. Experiments with goethite showed weaker binding for both metal ions in all systems studied. Ongoing experiments are exploring the reversibility of these systems. In addition, we are exploring the behaviour of Ra^{2+} during transformation of ferrihydrite to goethite, a process of potential importance in the impacted environments.
Surface complexation modelling has successfully simulated Ra^{2+} and Ba^{2+} sorption across the pH and concentration ranges studied. These data will be used in underpinning the safety case for legacy mining sites.

Ectomycorrhizal sclerotia formation and status of organo-mineral complex aluminum in low pH *Fagus* forest

NOBUO SAKAGAMI[1*] AND MAKIKO WATANABE[2]

[1]Ibaraki University, College of Agriculture, sakagami@ams.kuramae.ne.jp (* presenting author)
[2]Tokyo Metropolitan University, Department of Geography, m.wata@tmu.ac.jp

Sclerotia of ectomycorrhizal fungus *Cenococcum geophilum* are preserved in soils with *Cenococcum* mycorrhizae.[1] Ferricrocin is known as an ectomycorrhizal siderophore of *Cenococcum geophilum*.[2, 3] In our previous studies, we reported a characteristic concentration of aluminum in sclerotium and the relationship between aluminum (plus iron) content in sclerotia and active aluminum and iron in soils.[4, 5] Absorption of aluminum and iron may be an evidence of activity of *C. geophilum* associated with its siderophore. This fact harmonizes with microbial dissolution of aluminum and iron from minerals studied on ectomycorrhizal fungus.[6] In this study, we established 10 × 10-m quadrat beneath the *Fagus* forest in northeastern Japan, and then subdivided the plot using a 2 × 2-m grid. Thirty six surface soil samples were collected at each grid node.

The SEM-EDX observation (JSM-6610LV, JEOL) on distribution of elements in a cross section of soil aggregate including a sclerotium showed a slight accumulation of aluminum on soil surrounding sclerotium (Fig.1).

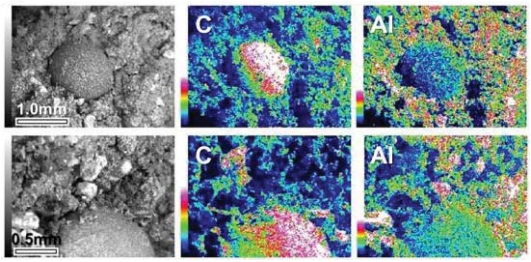

Figure 1: Distribution of C and Al in a cross section of soil aggregate including a sclerotium by SEM-EDX analysis.

According to the analytical results of the sclerotia content, and the status of aluminum in soil (dithionite-citerate, oxalate, pyrophosphate, ammonium acetate, and water extractable aluminum), we discuss the interaction between sclerotia formation and the status of soil aluminum. Furthermore, the interaction between soil and ectmycorrhizal activities in the investigated forest soils are noted regarding with micro topography, *Fagus* stands and floor vegetation.

Spectroscopic studies on sedimentary organic material

FANI SAKELLARIADOU

University of Piraeus, Maritime Studies Dept, Piraeus, Greece, fsakelar@unipi.gr

Introduction

Sediment samples from the Saronicos gulf, belonging to the Aegean Sea, were studied for the characterization of humic substances (HS) and dissolved organic matter (DOM). HS are significant sediment constituents performing in metal and toxic material scavenging and transport. Infrared and fluorescence spectroscopy were applied. DOM corresponds to the most active and mobile form of soil organic matter and the major soluble component of natural aquatic systems, with significant functions in the ecological and environmental system. DOM was studied by fluorescence spectroscopy.

Results and discussion

Spectroscopic methods on HS: The application of IR spectroscopy gives spectra with the characteristic peaks for hydroxyl, methyl, methylene, aromatic bond, carbonyl, carboxyl, phenol, alcohol, polysaccharide and silicate impurities. Conventional fluorescence spectroscopy [1] provides with emission spectra with maximum emission intensity at 415-427nm, excitation spectra with a major excitation peak at 355 to 330nm, and synchronous-scan excitation spectra with a very structured form; suggesting the presence of humic-like material with a marine origin.

Spectroscopic methods on DOM: Mono-dimensional emission spectra reveal one typical broad peak with a maximum between 442 and 439 nm. Excitation spectra show three peaks or shoulders at 330 nm, 351 nm, 377-381 nm, and a shoulder at 440 nm. Synchronous scan excitation spectra show one strongest peak at 340-345nm and another much lower or lower intensity peak or shoulder at 385-387nm. Therefore, it seems that fulvic acids, aquatic humic acids and natural organic matter are present. Higher humification index [2, 3], related to a more condensed nature, corresponds to areas with weaker seawater circulation [4]. Excitation/emission matrix spectra (EEMS) exhibit the peak M [5] corresponding to the marine humic fluorophore, strongly correlated with biological activity

A coupled biomarker-genetic approach to understanding the $U^{k'}_{37}$ SST proxy in estuaries

JEFF SALACUP[1*], TIMOTHY HERBERT[1], WARREN PRELL[1]

[1]Brown University, Providence, RI, USA,
Jeffrey_Salacup@brown.edu (* presenting author)

Towards a mechanistic understanding of $U^{k'}_{37}$

The $U^{k'}_{37}$ SST proxy has been widely and successfully applied in the reconstruction of open ocean temperatures on centennial to orbital timescales and has proved an indispensable tool in our investigations of past climates. However, the utility of the $U^{k'}_{37}$ SST proxy is thought to break down in near shore settings experiencing more dynamic nutrient and salinity fluctuations. Given the importance of coastal systems, , knowledge of past local to regional SST variability is critical to habitat adaptation and restoration strategies. Furthermore, the rapid deposition of both marine and terrestrial organic and inorganic material in estuarine and coastal systems makes them valuable archives of high-resolution paleo-environmental information.

Here, we present the results of a 3-year-long monthly to sub-weekly resolved record of water column $U^{k'}_{37}$ and alkenone concentration (C_{37}total) and associated instrumental SST suggesting that while important and informative seasonal inconsistencies exist, especially during alkenone blooms, the integrated $U^{k'}_{37}$ signal preserved in Narragansett Bay sediments reflects mean annual instrumental SST. A subset of samples were analyzed for haptophyte-specific 18S ribosomal RNA (rRNA) to understand the composition of the alkenone-producing community during times of instrumental-$U^{k'}_{37}$ coherency and incoherency, alike. So far, the only alkenone-producing species detected in Narragansett Bay, *E.huxleyi* and *G.oceanica* - which dominate open-ocean production and form the foundation of the $U^{k'}_{37}$-SST calibration – were detected in the high salinity lower-Bay during the spring bloom of 2010. A second 'brackish' alkenone-producing population is suspected on the basis of high contributions of the $C_{37:4}$ alkenone in the low-salinity upper Bay.

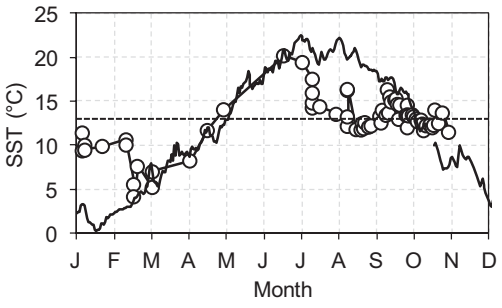

Figure 1. An example of the discrepancy between instrumental SST (solid line) and $U^{k'}_{37}$-inferred SST (open circles) from 2010. C_{37}total-inferred haptophyte blooms peaked in Feb and Aug during periods of maximum instrumental-$U^{k'}_{37}$ SST divergence. Black dashed line is the mean annual instrumental SST for Narragansett Bay for 2009-2011 (~13.4°C).

Fingerprinting uranium-bearing material: development and validation of methods

The nuclear forensics project

Many parameters such as trace elemental impurity patterns [1], uranium or oxygen isotopic compositions [2, 3] and anionic impurities [4] are known to be tracers of geographical origin of uranium-bearing materials. These parameters can allow to go back to a part of the history (industrial treatment or origin) of a seized nuclear material when they are used individually (Figure 1).

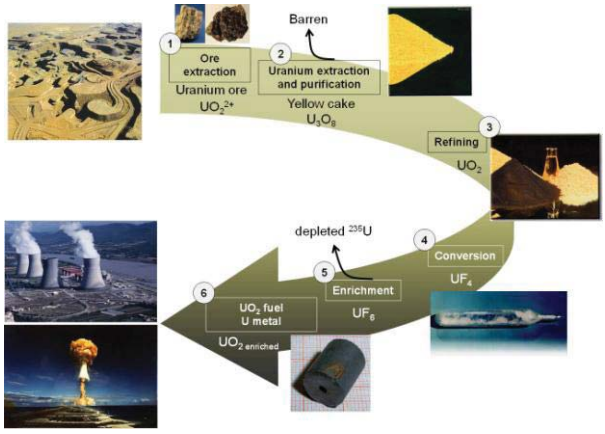

Figure 1: From ore to fuel: a variety of steps for uranium fingerprinting

But in some cases, they are not enough discriminating. We herein document a complete characterization of reference and unknown uranium ore concentrates for which REE, ($^{234}U/^{238}U$) and oxygen isotopic compositions were determined. This original approach which combined all three determinations covers a more global overview of such material.

Methods

A complete analytical procedure has been developed on a single sampling for trace-level determination of lanthanides and U isotopic composition in yellow cakes using ICP-MS, TIMS and PERALS (Photon Electron Rejecting Alpha Liquid Scintillation). The method was validated by the measurement of a reference material and will be applied for the analysis of unknown yellow cakes from various origins. Similarly, oxygen isotopic compositions of reference yellow cakes are currently under measurement by SIMS (Secondary Ion Mass Spectrometry) on particles and by fluorination on bulk samples.

Kinetic modeling of olivine carbonation reaction: study of the rate dependence on temperature and pCO_2 in open and closed systems

GIUSEPPE D. SALDI[1*], DAMIEN DAVAL[1,2] AND KEVIN G. KNAUSS[1],

[1]Lawrence Berkeley National Laboratory, Berkeley, CA, gdsaldi@lbl.gov (* presenting author); ddaval@lbl.gov; kgknauss@lbl.gov

[2] LHyGeS, CNRS UMR 7517, Strasbourg, France

Although both olivine dissolution and magnesite precipitation rates have been studied and modeled over a significant range of temperatures and aqueous chemical compositions, the mechanisms of the process that combines these two reactions have not been adequately described from a kinetic standpoint.

It was shown that the formation of a silica passivating layer at the interface between pristine olivine and aqueous solution can significantly slow down or even stop the dissolution of this mineral, thus hindering the attainment of the conditions necessary to initiate the carbonation reaction [1, 2]. Recent experimental measurements also indicate that magnesite precipitation can be the rate limiting step to forsterite carbonation in some other conditions [3].

To improve the understanding of mineral carbonation processes and provide new data that can contribute to its kinetic description we conducted a series of experiments in pure water from 90 to 180 °C, at a pCO_2 of 100 and 200 bar, using both the well characterized San Carlos olivine and a pure synthetic forsterite sample. Batch experiments were performed in flexible Au bags whereas steady-state carbonation rates were investigated at 150 °C by means of a mixed-flow Ti-reactor. The study of the chemistry of aqueous solution and the analysis of reacted olivine samples by XRD, SEM-EDX and Rockeval 6 allowed us to describe quantitatively the carbonation reaction as a function of pCO_2 and temperature. All experiments were characterized by the ubiquitous presence of a silica-rich layer at the olivine-aqueous solution interface. The nature of this layer changes as a function of temperature, and can lead to increasing rates of carbonation as magnesite precipitation rates increase with increasing temperature.

Comparison between the results obtained from two one-month-long batch and mixed-flow reactor experiments at 150 °C show that the extent of carbonation is limited by the saturation with respect to a silica polymorph, and possibly by the formation of secondary Mg-silicates. In the closed system, olivine to magnesite conversion rates are <1 %, whereas the extent of carbonation are significantly higher in the open system (8-9 % at least) and magnesite precipitation was found to be the rate limiting step of the reaction in this latter case.

The role of Fe in the passivating properties of the silica layer and its incorporation into the carbonate phase under reducing conditions is also being studied and some experimental results will be presented.

High precision 4-isotope Sulfur measurements using the CAMECA IMS 1280-HR

P. PERES, F. FERNANDES, M. SCHUHMACHER, P. SALIOT*

CAMECA, 29 quai des Grésillons, 92622 Gennevilliers Cedex, France, peres@cameca.com

Secondary Ion Mass Spectrometry (SIMS) technique provides direct in situ measurement of elemental and isotopic composition in selected µm-size areas of the sample. The CAMECA IMS 1280-HR is an ultra high sensitivity ion microprobe that delivers unequalled analytical performance for a wide range of SIMS applications: isotope ratio measurements, geochronology applications (U-Pb dating in Zircon), trace element analyses, particle screening measurements,...

Conventional Sulfur isotope studies focus on the two most abundant isotopes ^{32}S and ^{34}S. However, there has been an increasing interest in the minor ^{33}S (~0.7%) and ^{36}S (~0.02%) isotopes since mass independent fractionation effects have been discovered [1-3].

This paper presents 4-isotope Sulfur data obtained on standard and unknown pyrite samples. Measurements have been performed using a small 10µm Cs^+ beam spot, and high mass resolution conditions (~4,500) to resolve the hydride mass interferences. The four S isotopes have been collected simultaneously: ^{32}S, ^{33}S and ^{34}S on Faraday Cup detectors, and the low abundance ^{36}S (intensity ca. $2x10^5$ c/s) on an Electron Multiplier. The EM yield drift has been automatically monitored and corrected using a propriatery algorithm. More than 100 spot analyses have been performed in fully automated mode, with an analysis time of 4 minute/spot.

Data on the standard sample show that a precision < 0.2 permil (1SD) can be achieved for $\delta^{34}S$, $\delta^{33}S$ (and $\Delta^{33}S$). An excellent precision, < 0.3 permil (1SD), is also obtained for $\delta^{36}S$ (**Figure 1**) and $\Delta^{36}S$.

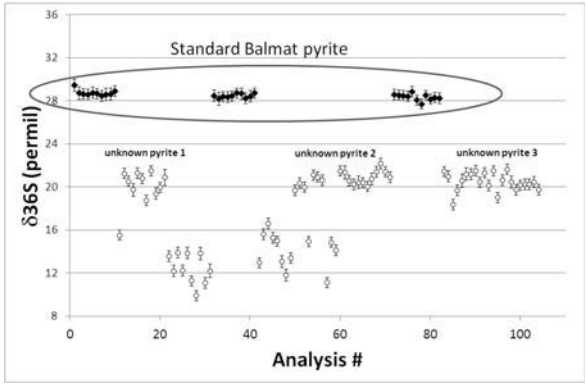

Figure 1: $\delta^{36}S$ data on standard and unknown pyrite samples.

This measurement protocol with multicollection configuration FC-FC-FC-EM allows to work with good spatial resolution (spot size ~10µm) and yields excellent precision for all Sulfur isotopes, including for the lowest abundance ^{36}S.

Ultra depleted mantle at the Gakkel Ridge

VINCENT SALTERS[1*], AFI SACHI KOCHER1, HENRY J.B.DICK[2]

[1]NHMFL and EOAS, Florida State University, Tallahassee, Florida, USA, salters@magnet.fsu.edu (* presenting author) [8pt font size]

[2]MG&G, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts, USA, hdick@whoi.edu

The Gakkel Ridge is one of the slowest spreading ridge segments in the global ridge system and with some of the thinnest oceanic crust. In some locations there is little or no evidence for volcanic activity and oceanic mantle is directly exposed on the ocean floor. This provides an excellent opportunity to investigate the heterogeneity of the oceanic mantle in situ.

We have analyzed a number of peridotites from the western end of the Sparsely Magmatic Zone (3° to 28°E as well as samples further west up to 65°E) and found highly radiogenic Hf and Nd isotopic composition. All but five samples are more radiogenic in either Nd or Hf than MORB. Six samples lie in the extension of the OIB MORB array with ε_{Nd} up to 23.7 and ε_{Hf} up to 54.6. The remainder of the data (14 samples) lie above the OIB-MORB array and its extension with ε_{Nd} values up to 27.4 and ε_{Hf} values up to 291! These values are the most extreme values measured for oceanic mantle. This data confirms the ultra depleted nature of the Gakkel Ridge mantle [1] and its highly heterogeneous nature [2].

Since the Hf and Nd system is expected to behave similar during melting, melt can be added back in the peridotite until the Hf and Nd model age coincide. These calculations show that depleted Gakkel Ridge peridotites have very little melt extracted from them (<1%) and have model ages that ranges from 2.4Ga to future ages with most between 600Ma and 1.2 Ga. The MORB Hf-Nd isotope systematics indicate this depleted component (ReLish) is ubiquitous [3] but under-sampled in basalts due to its depleted character. The presence of ReLish decrease the amount of melt a heterogeneous parcel of mantle can yield during ascent and average melt rate can be much lower requiring depth of melting to start deeper.

Integrated TIMS-TEA/LA-ICPMS constraints on pluton emplacement

K. SAMPERTON[1*], B. SCHOENE[1], J. COTTLE[2] AND J. CROWLEY[3]

[1]Princeton University, Department of Geosciences, Princeton NJ, USA, ksampert@princeton.edu (*presenting author)

[2]University of California–Santa Barbara, Department of Earth Science, Santa Barbara CA, USA, cottle@geol.ucsb.edu

[3]Boise State University, Department of Geosciences, Boise ID, USA, jimcrowley@boisestate.edu

Major conceptual and technical breakthroughs over the past decade have increased temporal and spatial resolutions for both ID-TIMS and LA-ICPMS. An outgrowth of this development is the ability to address whether zircon U-Pb ages can be assumed *a priori* to equate to the timing of pluton emplacement. We employ an integrated analytical regime coupling U-Pb TIMS-TEA with *in situ* LA-ICPMS trace element characterization in order to 1) assess intra-grain trace element zoning at the five micron scale and couple this with "bulk" geochemical and geochronological data, 2) fingerprint crystal populations within a single sample and better interpret age spread in high-precision datasets, and 3) characterize the temporal and geochemical evolution of magmas during ascent, mixing, and pluton assembly.

We apply this methodology to the 32-30 Ma Bergell Intrusion (N Italy), which preserves a spectacular 12-15 km crustal section through a single, continuous magmatic system, in addition to distinct process zones (pluton roof, floor, and feeder zone/tail). Preliminary U-Pb ID-TIMS zircon geochronology of CL-imaged grain fragments documents 400-500 kyr of zircon growth within individual hand samples ranging in composition from megacrystic granodiorite to tonalite. Precision on individual analyses of 10-20 ka (~0.05%) makes this duration easily resolveable. *In situ* trace element transects performed on the exact same minerals prior to ID-TIMS dating exhibit evolving core-to-rim REE and Hf abundances, which are interpreted to represent evolving magma composition and/or temperature. Variability in trace elements across single grains is often small compared to variation across many grains, necessitating high-precision ID-TIMS U-Pb geochronology in conjunction with the trace element data in order to evaluate long term (> tens of ka) trends in magma evolution, even in apparently autocrystic zircon populations. Geochemical transects were used to generate numerically modeled bulk trace element signatures and compared to TIMS-TEA data. The combination of these approaches produces trends strongly suggestive of closed system evolution of zircon chemistry through time for samples from ~15-20 km paleodepth.

While our data support TIMS-TEA as a viable analytical protocol, further work is required to understand the emplacement history of the Bergell. Expansion of our existing geochronologic/trace element dataset to include other dateable accessory phases indentified in Bergell samples, including monazite, allanite, and sphene, will be integrated with field observations and structural data in order to place robust constraints on such geochemical information. Our geochronological approach in the context of detailed geologic mapping will allow us to directly test competing models of Bergell emplacement (e.g., diapiric uprise vs. incremental assembly) by comparing the chronologies of different process zones (e.g., synmagmatically-deformed pluton floor vs. ballooning roof).

The role of fluids in the formation of REE (-Zr, Nb, Ta) deposits associated with alkaline plutons

IAIN M. SAMSON[1] AND ANTHONY E. WILLIAMS-JONES[2]

[1]University of Windsor, Department of Earth and Environmental Sciences, ims@uwindsor.ca
[2]McGill University, Department of Earth and Planetary Sciences

Mineral deposits in which a variety of rare elements, including REE, Zr, Ta, Nb, Be, and Ga, are concentrated are associated with alkaline to peralkaline plutons, typically in rift settings. Although, in general, there are common features among such deposits, the plutons can vary substantially in their internal character and structure, and their degree of Si saturation, from Si-oversaturated (e.g., Strange Lake, Quebec/Labrador) to Si-undersatured (e.g., Thor Lake, NWT, and Illimaussaq, Greenland). The former are characterized by alkaline granites and the latter by nepheline syenites. This variable magma character is reflected in a diverse primary rare element mineralogy. For example, at Strange Lake, Zr was mainly hosted by zircon and elpidite, Nb by pyrochlore and the REE by all three minerals. In contrast, in the Nechalacho deposit at Thor Lake, Zr and REE were hosted by zircon in the upper, miaiskitic, zone and by eudialyte in the lower, agpaitic, zone. Columbite is likely to have been the primary host for Nb. In both settings, the mineralization is characterized by higher HREE/LREE than other systems, such as those associated with carbonates.

The concentration of rare elements through fractional crystallization into pegmatites or by physical crystal accumulation was important in these deposits, however, hydrothermal fluids have played an important role in the subsequent transport and precipitation of rare elements. In particular, water-rock interaction and hydrothermal alteration have significantly modified the mineralogical character of the REE and Zr minerals, and this has increased the mineralogical diversity in such deposits, and resulted in upgrading and ease of beneficiation. The water-rock interaction history can be complex and multi-stage, leading to texturally and mineralogically complex assemblages in which pseudomorphing of early-formed minerals (both rare-element and non-rare element bearing) played a critical role in rare-element mineral precipitation.

The increasing availability of experimental data on the stability of aqueous rare element complexes is making modelling of the processes mentioned above easier, although a lack of data on mineral solubility remains a hindrance. Many models of deposit formation, both in silicic and carbonatitic environments, have employed fluoride complexes to facilitate element transport, with precipitation resulting from their destabilization as a consequence of the addition of Ca from host rocks or by fluid mixing, and the precipitation of fluorite. Although there is ample evidence for Ca metasomatism in the above-mentioned and other deposits, a true evaluation of this model is hindered by a lack of information on ligand concentrations, particularly fluoride. Furthermore, mineralogical and textural observations from these and other systems suggest that other complexation and precipitation models need to be considered.

Zircon, zircon everywhere: What caused the zircon superfertility of Grenville magmas?

SCOTT D. SAMSON[1]*, AARON SATKOSKI[2], DAVID MOECHER[3]

[1]Syracuse University, Earth Sciences, Syracuse, NY, USA, sdsamson@syr.edu (* presenting author)
[2]Syracuse University, Earth Sciences, Syracuse, NY, USA, amsatkos@syr.edu
[3]University of Kentucky, Earth and Environmental Sciences, Lexington, KY, USA, moker@uky.edu

A common assumption in many detrital zircon studies is that the abundance of zircon grains defining a particular age range directly corresponds to the area of exposed continental crust of that age. This is often not the case, however, as much modern alluvium and Paleozoic sandstone have large, sometimes exclusive, 1.3 – 1.0 Ga age peaks, a so-called Grenvillian signature. This is true even for sedimentary rocks very distal to exposed Grenville crust, such as Cambrian sandstone in California and clastic sediment in northwestern Canada. One of the reasons for the extreme abundance of ~ 1 Ga detrital zircon is that magmas associated with Grenville orogenic events contain unusually abundant, and often surprisingly large, zircon crystals. Large and abundant crystals will dominate the zircon budget of alluvium, particularly if sediment has been transported significant distances by major river systems.

A fundamental question about the Grenville Orogeny thus arises: what caused the magmas associated with the tectonic events to be so zirconium rich? One possibility is that the high Zr content, often > 500 ppm, is the result of a high abundance of zircon xenocrysts in the Grenvillian plutons. In this scenario the high Zr whole-rock contents would not be due to actual magmatic compositions but would reflect the total zircon crystal cargo of the intrusion. A second possibility is that the sources of Grenvillian magmas themselves were unusually Zr rich. A recent suggestion has been made that long-lived subduction beneath Laurentia may have significantly chemically enriched the Laurentian mantle lithosphere prior to Grenvillian magmatism. Furthermore, if Zr-enriched parent material was partially melted then the newly formed magma would be even higher in Zr content (assuming Zr distribution coefficients << 1). A third possibility is that unusually hot continental lithospheric conditions existed during the assembly of Rodinia. Very high temperature magmas can become very Zr-rich prior to reaching zircon saturation and thus can crystallize an abundant amount of zircon. These three, not necessarily mutually exclusive, hypotheses have yet to be thoroughly tested, despite their importance to an understanding of what might be one the most Zr-rich magmatic episodes in Earth history. But regardless of the cause, the role of zircon superfertility must be a primary consideration when using detrital zircon as a proxy for studies of continental crustal growth. Estimates of the amount of juvenile crust generated based on isotopic analysis of detrital zircon could be biased if variation in zircon fertility is not taken into consideration.

An experimental and field study on P, Si, As, Cr, V and Se binding to Fe- and Al-hydroxysulfates under oxic and anoxic conditions in acidic pit lakes: chemical *vs.* microbial controls

JAVIER SÁNCHEZ-ESPAÑA[1*], MARTA DIEZ ERCILLA[1], CARMEN FALAGÁN[1], IÑAKI YUSTA[2]

[1]Unidad de Mineralogía e Hidrogeoquímica Ambiental (UMHA). Instituto Geológico y Minero de España, Madrid, Spain, j.sanchez@igme.es (* presenting author)

[2] Unidad de Mineralogía e Hidrogeoquímica Ambiental (UMHA), Universidad del País Vasco (UPV-EHU), Bilbao, Spain, i.yusta@ehu.es

Introduction and scopes

The chemical composition of acidic mine pit lakes usually include trace elements which may form either oxyanions or some other anionic species, depending on pH-Eh conditions and sulfate concentration. Some elements (e.g., P, Si) are biogeochemically important, whereas others (e.g., As, Cr, V, Se) may be highly toxic to aquatic ecosystems. In the pit lakes of the Iberian Pyrite Belt (SW Spain), the fate and transport of most of these trace elements has been shown to be closely associated to the formation and (meta)stability of low-crystallinity solid phases like schwertmannite and hydrobasaluminite [1]. The present work reports recent field and experimental observations on the mobility of these elements through the water column, redoxcline and the sediment/water interfase.

Results and discussion

Schwertmannite is the most abundant mineral product of microbial Fe^{II} oxidation in the studied pit lakes (pH 2.2-3.1) [1]. Field and experimental evidence exists to support that As, Cr and P are temporaly immobilized by sorption on µm- to nm-scale schwertmannite colloids. Experimental data (including titrations under oxic and anoxic conditions) coupled to geochemical modeling, indicate that the most important retention mechanism is that of sorption of arsenate, chromate and phosphate anions to the positively charged, highly reactive schwertmannite surfaces. The process seems to be reversible, and these elements can be again released to the aqueous phase during settling to the underlying, anoxic part by either (i) microbial reductive dissolution, and/or (ii) schwertmannite aging (conversion to jarosite and/or goethite).

The behaviour of Si, V and Se appears to be more closely linked to the precipitation of hydrobasaluminite or an analogous Al phase. An evident discrepancy exists between the sorption behaviour observed under field and experimental conditions. Such discrepancy could be accounted for by recent microscopic (SEM-EDS) findings, which suggest a strong microbial control on Al precipitation and the associated sorption of Si and other elements. The role of acidophilic microbes in the Fe-Al co-precipitation at pH~4.0 represents a geochemically singular aspect which deserves further investigation.

The density of carbonate and silicate melts in the upper mantle

CARMEN SANCHEZ-VALLE[1,*], SUJOY GHOSH[1], WIM J. MALFAIT[1], RITA SEIFERT[1], SYLVAIN PETITGIRARD[2] AND JEAN-PHILIPPE PERRILLAT[3]

[1]Institute for Geochemistry and Petrology, ETH Zurich, Zurich, Switzerland, carmen.sanchez@erdw.ethz.ch (* presenting author)

[2]ESRF, Grenoble, France.

[3]Laboratoire de Sciences de la Terre, UCB Lyon1-ENS Lyon-CNRS, Lyon, France

Although carbonate melts are volumetrically minor phases in the mantle, they may control the mobility of C and its residence time in the mantle, ultimately contributing to the gobal carbon cycle [1]. Carbonate melts are also considered as effective metasomatic agents because of their wetting properties, high migration rate and characteristic trace element enrichment [2]. The density of carbonate liquids is thus an important parameter to model their percolation through the mantle and evaluate their behavior as metasomatic agents and carbon reservoirs, but available data remains scarce at relevant P-T conditions and melt compositions [3,4].

In this contribution we report *in situ* invetigations of the density of carbonate liquids in the Mg-Fe binary and Mg-Fe-Ca ternary systems at upper mantle conditions (2 GPa and 1900 K). Density was determined from the X-ray absorption contrast between the samples and a diamond capsule used to contain the sample at high pressure and temperature conditions. Experiments were perfomed using a panoramic Paris-Edinbugh press at ID27 beamline of the ESRF. Pressure and temperature were determined from the X-ray diffaction patterns of hBN and Pt using the double-isochore method. The measurements provide preliminary constrains on the equation of state of carbonate liquids representative for natural carbonatites, including melt compositions produced by the partial melting of carbonated peridotites [5]. The results are combined with own recent data for the density of silicate melts (rhyolites and phonolites) and literature data for mantle minerals to discuss buoyancy relations in the upper mantle and their evolutions with pressure to better quantify the extraction of C-bearing liquids from residual rocks during partial melting and the ascent of melts through the mantle. Ultimately, we will discuss the role of carbonate-silicate liquids as metasomatic agents and carbon reservoirs.

Permafrost underlies one fourth of the Earth's surface and contains approximately half of the global organic carbon (OC) in soils. Thawing and rapid losses of OC in the form of CO_2 and CH_4, associated with warming of arctic regions, raises serious concerns about the stability of OC in permafrost soils and its influence on the biogeochemical cycling in the surrounding Arctic Ocean. The composition of extractable OC in a soil profile collected from the McGill Arctic Research Station on Axel Heiberg Island in the Canadian high Arctic has been characterized using ultrahigh resolution mass spectrometry and nuclear magnetic resonance spectroscopy. The OC in this polar desert is oxygen-poor and highly enriched in lipids, because algae and detrital carbon from surrounding rocks are the main carbon sources. The OC is poor in lignin and protein in the high Arctic soils when compared to soils of other climates because of the lack of vascular plants. In addition, the OC composition of the whole soils was analyzed by carbon K-edge XANES, which indicated that the OC consisted of mostly aliphatic carbon as well as smaller contributions from unsaturated OC, carboxyls, and proteins. Most striking was the absence of oxygenated OC, which is often present as carbohydrates in polar region soils with more vegetation.

Such a contrasting composition of OC in Arctic soils may result in carbon losses from climate warming that may disagree with the widely-accepted models based upon the biogeochemistry of temperate soils. Heating experiments are currently underway to investigate how and to what extent the OC composition changes as a function of warming, indicative of how these soils may evolve as a result of climate change. Understanding how recalcitrant this highly aliphatic, oxygen-poor terrestrial carbon is will be critical to identifying its impact on the biogeochemical cycling in the surrounding Arctic Ocean.

Geochemistry of mercury and trace elements captured by activated carbons in a Canadian coal-fired power plant

HAMED SANEI[*1], FEIYUE WANG[2], FRANK HUGGINS[3]

[1]Geological Survey of Canada, Calgary, AB, T2L 2A7, Canada, hsanei@nrcan.gc.ca (* presenting author)
[2]Department of Chemistry, University of Manitoba
[3]Department of Chemical and Materials Engineering, University of Kentucky, Lexington, Kentucky, USA

Abstract

The coal-fired power plants in Canada are required to reduce the emission of Hg up to 80% by 2018 and beyond to meet the national and regional regulatory targets. Activated carbon (AC) is considered by industry as an efficient sorbent to capture Hg from the flue gas during the combustion process. A widespread use of AC is anticipated by the coal-fired power plants to reduce the emission of Hg and meet their regulatory obligations.

This study investigates the geochemistry of ESP fly ash and related feed coal samples during an experiment trial by a full-scale coal-fired power plant in Western Canada. Furthermore capturing efficiency and retention ability of 5 different commercial ACs were examined. While the significant amount of Hg is being captured by ACs, the ultimate fate of Hg after capture and possible environmental impacts related to handling and use of Hg-rich fly ash has been a major concern. This study investigates volatilization and leachability of Hg and other elements from the captured fly ash.

The results show that capturing ability varies depending on AC's injection rates, fly ash particle size sorting, and temperature of the flue gas. Thermal release of Hg from fly ash samples appears negligible up to a temperature of 80°C. De-volatilization of Hg begins beyond 80°C, showing a sudden increase after 120°C. The constant heating at 140°C resulted in a steady de-volatilization of Hg during the 8 hour experiment that suggests a slow release of Hg during long exposure to heat. We recommend further investigation of possible Hg de-volatilization at higher temperature with the samples being exposed for a longer period of time.

Mercury is mostly leachable under strong acid digestion suggesting strong chemical retention. However, <10% of the total captured Hg can be released under the more moderate chemical digestion. The retention ability tends to decrease significantly in fine-grained fly ashes. The fly ashes injected with high sulphur AC provided the strongest chemical retention for Hg. We conclude that the possible Hg-S binding associated with ACs not only provides the best Hg capture capacity, but also provides the strongest thermal and chemical retention ability.

[2]Mineral Resources Chemistry Key Laboratory of Sichuan Higher Education Institutions，Chengdu 610059, China

Introduction

Many salt lake brines on the Qinghai - Tibet plateau in China are well known for high concentrations of Li, K and B. Furthermore, a huge amount of underground gasfield brine was also discovered in China,such as Sichuan western basin. Sodium chloride, potassium, boron , bromine and sulfates are the major chemical component of the oilfield brine, which often accompanies Li, Sr and I. The ternary system $Na_2B_4O_7$ - NaBr - H_2O is a subsystem of the underground gasfield brines.

Results

The solid - liquid equilibria for the ternary system $Na_2B_4O_7$ - NaBr - H_2O at 348 K were measured experimentally using the method of isothermal solution saturation. On the basis of experimental data, the phase diagram of the ternary system was constructed. In the phase diagram of the ternary system $Na_2B_4O_7$ - NaBr - H_2O at 348 K(Figure 1), there are one invariant point E and two univariant curves E1E and E2E. The points E1 and E2 represent the solubility of the binary systems of $Na_2B_4O_7$- H_2O and NaBr - H_2O at 348K with mass fraction ($100w_b$) of 19.30 and 54.35, respectively. Curve E1E and E2E are the solubility isotherms of $Na_2B_4O_7 \cdot 5H_2O$ and NaBr, respectively. The invariant point E corresponds to the solution saturated with both NaBr and $Na_2B_4O_7 \cdot 5H_2O$. Phase equilibrium solids were NaBr and $Na_2B_4O_7 \cdot 5H_2O$ in the studied ternary system. The crystallization area of $Na_2B_4O_7 \cdot 5H_2O$ (E1ED field) in the phase diagram is obviously bigger than that of NaBr (E2EA field).

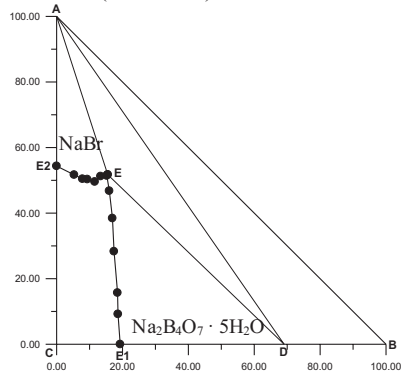

Figure 1 Phase diagram of the ternary system $Na_2B_4O_7$ - NaBr - H_2O at 348 K

Use of two new Na/Li thermometric relationships for geothermal fluids in volcanic environments

BERNARD SANJUAN[1*], RAGNAR ASMUNDSSON[2], ROMAIN MILLOT[3] AND MICHEL BRACH[3]

[1] BRGM, Department of Geothermal Energy, Orléans, France, b.sanjuan@brgm.fr (* presenting author)

[2]Tiger Energy Services, Taupo, New Zealand, ragnar.asmundsson@tigerhd.com

[3]BRGM, Department of Metrology, Monitoring and Analysis, Orléans, France, r.millot@brgm.fr, m.brach@brgm.fr

Thermometers such as Silica, Na/K, Na/K/Ca, Na/K/Ca/Mg or $\delta^{18}O$ (H_2O-SO_4), based on empirical or semi-empirical laws derived from chemical equilibrium reactions between water and minerals in the deep reservoirs, are commonly used in geothermal exploration in order to estimate the reservoir temperatures. Unfortunately, these estimations are not always concordant because of processes which can perturb the chemical composition of the fluids during their ascent up to the surface (water mixing, fluid cooling, etc.). Given these discordances, auxiliary thermometers such as Na/Li, based on statistical relationships, were also developed. As Li is rather lowly reactive, the use of this thermometer can give more reliable temperature estimations. Presently, three different Na/Li relationships ([1], [2]) are mainly available according to the fluid salinity and the geological environment (volcanic/granitic and sedimentary rocks).

This study carried out in the framework of the European HITI project (HIgh Temperature Instruments for supercritical geothermal reservoir characterization and exploitation) with the collaboration of ISOR Iceland Geosurvey proposes two new Na/Li thermometric relationships. The first concerns the fluids derived from high-temperature seawater-basalt interaction processes existing in the oceanic ridges and rises as well as in the emerged rifts such as those of Iceland (Reykjanes, Svartsengi and Seltjarnarnes geothermal fields) and Djibouti (Asal-Ghoubbet and Obock geothermal areas). It can be expressed as follows:

$$\text{Log (Na/Li in mol/l)} = 920/(T°K) + 1.105 \quad (r^2 = 0.994).$$

The second relationship, developed using dilute fluids collected only from Icelandic geothermal wells in the 100-325°C range, surprisingly close to that determined by Fouillac and Michard (1981) for volcanic saline fluids at temperatures ≥ 200°C, is:

$$\text{Log (Na/Li in mol/l)} = 1786/(T°K) - 0.936 \quad (r^2 = 0.976).$$

The uncertainty on temperature estimation is ± 25°C for both relationships. These results confirm that the Na/Li ratios not only depend on temperature but also on other parameters. The nature of the reservoir rocks and fluid seems to be the most influent one. Some literature case studies and thermodynamic considerations suggest that the Na/Li ratios could be controlled by chemical equilibrium reactions involving different mineral assemblages where illite and micas would be, however, always present.

Carbonated basalts at depth: density, compression mechanisms, and potential buoyancy

C. SANLOUP[1*], C. CRÉPISSON[2], G. MORARD[3], H. BUREAU[3], G. PROUTEAU[4] AND S. PETITGIRARD[5]

[5]European Synchrotron Radiation Facility, Grenoble, France

Introduction

The alkali basalt composition was chosen as representative of two potentially relevant contexts : alkali basalts dragged in the Japanese sea have been interpreted as originating from the asthenosphere [1,2], and their high vesicularity suggested high CO_2 content in the pre-eruptive melt. Also, primitive alkali basalts are generated in subduction contexts, as the one used here (Stromboli [3]) and as such, could have contributed to the formation of cratonic roots.

Experiments

In situ density and structural measurements were collected using respectively x-ray absorption and x-ray diffraction techniques. High P-T conditions up to 7 GPa were generated using the Paris-Edinburgh press at the european synchrotron (ESRF, ID27 beamline) and the cell-assembly described in [5]. Recovered quenched samples were analyzed by EPMA and Raman spectroscopy to check for CO_2 content and speciation.

Density measurements as a function of pressure show a higher compressibility than for non-carbonated basalts. Structural data, as expressed by pair distribution function of the melt, show an increased coordination number of Al. Such effect had been proposed based on viscosity measurements at modest P [6,7], and seems emphasized at higher P.

Density of the carbonated alkali basalt is then compared to seismological and petrological values of the density for surrounding rocks to check for potential neutral buoyancy at depth.

Interpretation of helium isotopes in modern hydrothermal systems

Y. SANO[1] AND T. P. FISCHER[2, 3]

[1]Atmosphere and Ocean Research Institute, University of Tokyo, Kashiwanoha, Chiba 277-8564, Japan (*correspondence: ysano@aori.u-tokyo.ac.jp)

[3]Department of Earth and Planetary Sciences, University of New Mexico, Albuquerque, NM87131-1116, USA

Many reviews and textbooks on terrestrial helium isotopes have been published since the discovery of mantle helium in 1969. This work focuses on the interpretation of helium isotopes of fluid samples in modern hydrothermal systems. In hot spot regions such as Hawaii, Yellowstone and Iceland, helium isotopes of fluid samples are generally higher than MORB-type He (8.0+/-1.5) Ra where Ra is the atmospheric ratio of $1.4x10^{-6}$. Seismic tomography data of the three regions show that a continuous low-velocity anomaly is imaged from the surface to at least the surface of the lower mantle [1-3]. The plume-type He may be derived from the lower mantle. In the other hot spot regions such as Afar, Canary and Reunion, the thermal conduit associated with mantle upwelling extends to depths greater than 500 km. There is a weak positive correlation between maximum helium isotopes and the buoyance flux except for Hawaii. Graham [4] compiled 658 MORB glass data and reported that the more than 90% of helium isotopes are lying between 6.5-9.5 Ra. Hydrothermal fluids in MOR shows the helium isotopes varying from 7.2 Ra to 9.2 Ra with the average of (8.09+/-0.49) Ra, identical to that of the global average of MORB. The average ^3He/heat ratios is calculated (8.6+/-3.8) x 10^{-18} mol/J world-wide. When we take into account of a global axial heat flow in MOR [5], the total ^3He flux would become (2.8+/-1.2) atom/cm^2/s, a little smaller than the well-established value of 4 atom/cm^2/s [6]. Helium isotope data of subduction zones were compiled by Hilton et al [7]. Now additional data are available in the Kamchatka, Izu-Bonin, Ryukyu-Taiwan, Sangihe arc in Indonesia and Central American system. The cir-cum Pacific helium data are summarized as follows: (a) helium isotopes vary significantly from 0.01 Ra to 10.1 Ra and the rage is much larger than that of MOR-type He. (b) The highest value of 10.1 Ra observed in the Vanuatu islands suggests the contribution of plume-type He. (c) The second highest values (8.8-8.9) Ra are found in the Colombian Andes and Sunda arc systems, falling within the range of MOR-type He. (d) Relatively lower values (6.5–7.0) Ra are observed in the Ecuadorian, Peruvian and Chilean Andes and the eastern Sunda/Banda arc, slightly lower than that of MOR-type. There is no apparent correlation between the maximum value of arc segments and the magma production rate or the taper angle of the slab.

[4] Space Science and Technology, Canadian Space Agency, Canada, Pablo.Sobron@asc-csa.gc.ca

The study of iron minerals, in particular, sulfates and oxides of evaporitic characteristics, has carried a great interest in the last years, not only for their direct application in the analysis of mine drainage, also in their application to the study of the mineralogy of Mars surface. The jarosite discovery[1], as well as of other hydrated sulfates[2] in the surface of the red planet carried out by MERs represent an important focus of interest for the study of the evolution and the geodynamics of the planet and their possible astrobiological implications.

The use of quick and precise techniques, susceptible of being boarded in missions to other planets, is revealed as an important aspect when carrying out so much analysis of synthetic materials as collected materials from different geologic analogs. In particular, Raman spectroscopy as part of the payload of the mission Exomars[3] and that it will be launched in the 2018 to Mars, shows up like a very powerful technique when analyzing in-situ and in a non destructive way the molecular composition of the analyzed materials, besides giving us a quite precise idea of structural aspects that could be extrapolated in reference to their possible genesis.

In this work we present the results of the application of this technique to materials synthesized in laboratory also to materials extracted in diverse campaigns to different Martian analogs as are Rio Tinto River and El Jaroso Ravine, both in Spain[4]. On one hand, the use of materials of synthetic origin provides us so much patterns for reference use and also an approach to the necessary conditions for the formation of one or another compound, in a controlled way. On the other hand, the materials picked up in the natural localizations give us a real panoramic of how they are distributed and this materials become in the geochemical conditions that surround them. This allows us to compare them among and with the synthetic ones being been able to extract conclusions about the conditions of their origin, their structural characteristics and being able to formulate hypothesis on their formation process and could be extrapolated by methods of the analysis in situ in Mars, of the materials that there are.

Multiple sulphur isotope evidence for an oceanic sulphate concentration decrease in the Marinoan glaciation aftermath

P. SANSJOFRE [1*], P. CARTIGNY[1], M. ADER[1], R. TRINDADE [2] AND A. NOGUEIRA[3]

[1] Equipe de Géochimie des Isotopes Stables, Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Univ Paris Diderot, UMR 7154 CNRS, F-75005 Paris, France, sansjofre@ipgp.fr (* corresponding author)

[2] Departamento de Geofisica IAG, Universidade de São Paulo, Brazil, rtrindad@iag.usp.br

[3] Instituto de Geociências, Universidade Federal do Pará, Bélem, Brazil, anogueira@ufpa.br

In order to better contrain the sulphur cycle in the aftermath of the Marinoan Glaciation, we performed sulphur isotope composition analysis ($\delta^{33}S$ - $\delta^{34}S$ - $\delta^{36}S$) of Ediacarian carbonates, on both Carbonate Associated Sulphate (CAS) and pyrite. Samples come from Carmelo quarry (Mato Grosso, Brazil) where 20m of white dolomicrite (Mirassol d'Oeste Formation) directly cover the glacial sediments related to the Marinoan glaciation (~635Ma). This dolomicrite is overlying by 150m of Guia Formation limestone's which begin with 40 meters of carbonate-rich siliciclastic material evolving to pure carbonate intercalated with thin layers of marls.

Results show an increase in both $\delta^{34}S_{pyr}$ and $\delta^{34}S_{CAS}$ upward along the section. $\delta^{34}S_{pyr}$ and $\delta^{34}S_{CAS}$ vary from -10‰ to +26‰ and from +16 to +51‰ respectively. Our $\delta^{34}S_{CAS}$ data are relatively high compared to present day oceanic sulphate value (+21‰), but they are in agreement with previous data reported for the same time period. $\Delta^{33}S$ data show values close to 0‰ (0.03 ± 0.02‰) at the base of the section and significatively higher values in the upper part, up to +0.16 ± 0.02‰.

For steady-state ocean sulphur concentration, an increase in the isotopic values can be partially explained by an increase in pyrite burial rate together with a higher $\delta^{34}S_{sulphate}$ input. However this model cannot account neither for the extremely high values of $\delta^{34}S_{CAS}$ nor for the $\Delta^{33}S$ signal. We thus developped a non steady state model in which we take into account the effect of Rayleigh distillation on $\delta^{34}S_{CAS}$, $\delta^{34}S_{pyr}$ and $\Delta^{33}S$ values. Results show that the increase in both $\delta^{34}S$ (CAS and pyrite) and $\Delta^{33}S$ are well explained by a decrease of ~50% in the oceanic sulphate concentration. We thus propose that the post-Marinoan ocean experienced a decrease in sulphate concentration which could result from an increase in sulphate consumption by BSR relative to the net riverine sulphate delivery input.

Membrane-dependent microbial inhibition during CO_2 sequestration: Implications for the alteration of subsurface community composition

EUGENIO-FELIPE U. SANTILLAN[1*], CHRISTOPHER R. OMELON[1], TIMOTHY M. SHANAHAN[1], AND PHILIP C. BENNETT[1]

[1]University of Texas Austin, Austin, TX, USA
efu.santillan@utexas.edu (* presenting author)

Background

When CO_2 is stored in deep saline aquifers, many geochemical changes will occur due to CO_2 dissolution [1]. High PCO_2 will also perturb the existing microbial communities that influence the geochemistry of the reservoir through their metabolic activities.

The CO_2 molecule itself is toxic to microorganisms. It is easily permeable through cell membranes changing membrane fluidity, the proton pump, and intracellular pH [2]. Adaptations that slow the diffusion of CO_2 into the cell, like biofilms and thick cell walls, will be selected for in the new environment.

In this study, we assessed the tolerance of several representative organisms to high PCO_2 based on their membrane morphologies: the Gram-negative bacterium *Shewanella oneidensis*, the Gram-positive bacterium *Bacillus subtilis* sp0A mutant, the Gram-positive endospore forming bacterium *Geobacillus stearothermophilus*, and the methanogenic archaeon *Methanothermobacter thermoautitrophicus*.

Results and Conclusions

Results show the Gram-negative organism is the most susceptible to CO_2 toxicity surviving a maximum pressure of 25 atm for 2 hours. However, when grown in the presence of a mineral, survival time increases beyond 8 hours due to biofilm formation. Archaea can withstand 50 atm of CO_2 for 8 hours and Gram-positive endospores can handle 50 atm of CO_2 for at least 24 hours potentially due to thick and rigid cell membrane or wall compositions.

Images taken by transmission electron microscopy show all experimental organisms have a threshhold tolerance to CO_2. We observed clumping of cytoplasmic contents at differing CO_2 pressures suggesting CO_2 plays an effect in altering intracellular activity. Lipid profiles of the bacteria also show a decrease in concentrations of monounsaturated or of short-chained fatty acids during CO_2 exposure indicating CO_2 causes a loss in cell viability.

Our findings suggest that during CO_2 sequestration, biofilms, Gram-positive endospores, and methanogens are organisms that will survive in the new environment. Because each organism varies in their CO_2 tolerance, regions surrounding the CO_2 plume may eventually form where different organisms are most active This in turn can have effects on mineral precipitation catalyzed on cell membranes and the geochemistry of the greater subsurface.

In situ remediation and pedogenesis in bauxite residue ('red mud')

TALITHA SANTINI[1,2*], MARTIN FEY[1], AND ANDREW RATE[1]

[1]University of Western Australia, Perth, Australia,
talitha.santini@uwa.edu.au (* presenting author)
[2]McMaster University, Hamilton, Canada

Introduction

'*In situ*' approaches to tailings management typically address unfavourable properties of the tailings after deposition in storage areas by surface application of treatments. In the case of bauxite residue, *in situ* remediation means selecting treatments that will aid in lowering pH from values of >12 to <9, lowering electrical conductivity from values of >4 dS/m to <1 dS/m, and that will stimulate biological activity in the initially sterile tailings. Treatments including sewage sludge, tillage, green waste, dredge spoil, and topsoil were applied at a bauxite residue ('red mud') storage area in Corpus Christi, Texas.

Results and discussion

Rainfall leaching (for 40 years) prior to amendment removed excess soluble salts, but not all residual sodalite ($Na_8(AlSiO_4)_6Cl_2$) and calcite ($CaCO_3$) which slowly dissolve and continue to buffer pH at values >8. Substantial replacement of Na^+ with Ca^{2+} has occurred on cation exchange sites, particularly in surface residue layers. Calcite dissolution, facilitated by rainfall leaching and organic acids and $CO_{2\,(g)}$ from plant roots, may provide Ca^{2+} for this exchange.

Bauxite residue pore water was high in Al, Ca, Fe, Na, and Si. Formation of gravel in the residue was attributed to precipitation of aluminosilicate coatings on surfaces exposed to the atmosphere during drying and cracking of residue (Figure 1). Some pores in the gravel contained nordstrandite or bayerite (both $Al(OH)_3$). Given that silicate inhibits crystallisation of aluminium hydroxides from solution [1], it appears that the aluminosilicate coatings formed first, lowering Si content of pore water, which then allowed precipitation of nordstrandite/ bayerite inside the gravel pores after further drying.

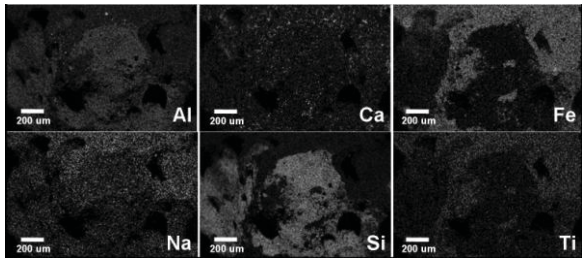

Figure 1: Element maps from gravel with aluminosilicate coating.

Sewage sludge was more effective than dredge spoil or topsoil in lowering bauxite residue pH, and increasing total N and extractable NH_4^+. Sewage sludge outperformed other treatments in terms of generating a suitable soil-like medium for plant cover, and addressing high pH and lack of plant nutrients such as organic C and N, K, Mg, and P in bauxite residue. Applied treatments can influence bauxite residue chemistry and mineralogy, and improve soil formation and *in situ* remediation.

Sr and Nd isotope composition of the Alcáçovas calc-alkaline rocks (Ossa-Morena Zone, Portugal)

JOSÉ F. SANTOS[1]*, PATRÍCIA MOITA[2], JONI MARQUES[1]

[1]Geobiotec / Dep. Geociências, Univ. Aveiro, Portugal, jfsantos@ua.pt*

[2]Centro de Geofísica / Dep. Geociências, Univ. Évora, Portugal

The Alcáçovas area is located in the SW sector of the Ossa-Morena Zone (OMZ), close to a major fault that separates this geotectonic unit from the South Portuguese Zone (SPZ). Along this boundary, in the OMZ, testimonies of low-K tholeiitic and calc-alkaline magmatism are common and have been interpreted as being related to the operation of a subduction zone between OMZ and SPZ during the Variscan cycle [1]. Two main igneous lithologies, both displaying calc-alkaline compositions, can be found in the studied area: gabbro-diorites and dacitic-rhyolitic porphyries [2,3]. Outcrop conditions have not yet allowed to establish unequivocally the sequence of magma emplacement. In previous geochronological studies on the porphyries, whole-rock Rb-Sr dates and K-Ar ages cluster around 320 Ma [4,5,6].

According to field observations, sometimes felsic dykes cut mafic rocks, but there are also gradual transitions from gabbroic to tonalitic compositions, within bodies mapped as gabbro-diorite, revealing that different melts coexisted.

In this study, rock samples of both gabbro-dioritic bodies and porphyries were analysed for Rb-Sr and Sm-Nd isotopes. Considering the whole set of samples, no isochron was obtained, showing that they can not be simply related by crystal fractionation processes.

Rb-Sr data of porphyries from a single quarry (at Lameira, 7 km to the SW of Alcáçovas) give 323±16 Ma (MSWD=1.9; initial $^{87}Sr/^{86}Sr$=0.7097±0.0018). Taking into account that the rocks of the Lameira outcrop show strong hydrothermal alteration, this date must be viewed as a consequence of a very efficient redistribution of mobile elements during aqueous fluid circulation and, as such, it places a minimum limit to the actual magmatic age

The plot of compositions of the gabbro-dioritic bodies, including their transitions to tonalites and the associated felsic dykes, in the ε_{Nd}-$^{87}Sr/^{86}Sr$ diagram, define an almost perfect hyperbole (from εNd_{323} = +3.9 and $^{87}Sr/^{86}Sr_{323}$ = 0.7058 to εNd_{323} = -3.8 and $^{87}Sr/^{86}Sr_{323}$ = 0.7085), as expected in a mixture between mantle-derived melts and crustal materials. In the same diagram, samples from the Lameira quarry show an almost constant εNd_{323}, between -2.4 and -2.9, and $^{87}Sr/^{86}Sr_{323}$ varying from 0.7092 to 0.7106. Therefore, the Lameira porphyries could represent a member of the same mixture, with the Sr signature modified by hydrothermal fluids with a stronger crustal component.

Correlation of magnetic susceptibility with $\delta^{18}O$ data in magnetite- and ilmenite-type granites from Iberian massif

HELENA SANT'OVAIA[1*], HELENA MARTINS[1], JOSÉ CARRILHO LOPES[2], JOANA MACHADO[1] AND FERNANDO NORONHA[1]

[1] DGAOT, Centro de Geologia, F.C. Univ. Porto, Portugal, hsantov@fc.up.pt (* presenting author)

[2] Centro Geologia Univ. Lisboa; Dep. Geoc., E.C.T. Univ. Évora, Portugal (carrilho@uevora.pt)

The relationship between oxygen isotopic values and magnetic susceptibility composition on 11 Variscan Portuguese granites has been investigated. Whole-rock oxygen-isotope ($\delta^{18}O$) values for Vieira do Minho (VM), Vila Pouca de Aguiar (VPA), Chaves, Castelo Branco (CB), Manteigas and Serra da Estrela (SE) granitoids, were compilated from bibliography [1,2,3,4], and $\delta^{18}O$ for Santa Eulalia Plutonic Complex (SEPC) were obtained by laser fluorination at the Stable Isotopic Laboratory of Salamanca. Magnetic susceptibility (Km) values were obtained with a Kappabridge equipment from Toulouse University and Geology Centre, Porto University [2,5,6,7,8]. In this study is shown that there is a significant inverse correlation between Km and $\delta^{18}O$. *Magnetite*-type granites (Manteigas granodiorite and SEPC external facies) have Km>10^{-3} SI and low $\delta^{18}O$ values ranging from 8.9 to 10.3‰ instead those of *ilmenite*-type (all the other granites) have Km≤10^{-4} SI and are $\delta^{18}O$ enriched (9.3 to 13.5‰). The *I*-type granites (VM, VPA, Chaves, Manteigas and SEPC external facies) show lower average $\delta^{18}O$ (10.2‰) and higher Km values (100x10^{-6} SI) than the *S*-type granites (SE and CB) with $\delta^{18}O$ = 12.6‰ and Km = 65x10^{-6} SI.

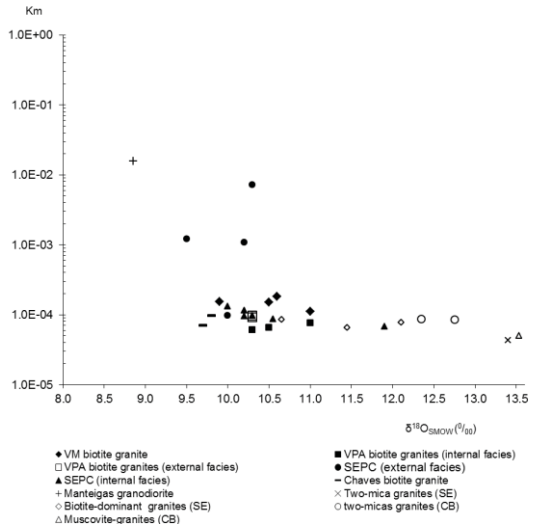

Figure 1: Semi-log plot of Km (in Si units) versus $\delta^{18}O$.

During KEOPS 2 (KErguelen Ocean and Plateau compared Study 2, Oct.-Nov. 2011), the distribution of dissolved Fe was investigated in the upper 1300 m in the vicinity of the Kerguelen Islands. Samples were analysed on board by flow injection analysis and chemiluminescence detection, with a detection limit of 0.02 ± 0.02 nM (n=13). A clear enrichment was observed above the Plateau. Indeed, the highest concentrations (2-4 nM) were observed at the most coastal station, east of the Kerguelen Islands. Then concentrations decreased eastward with the lowest values in an anti-cyclonic structure (0.06 nM at sea-surface and 0.3-0.4 nM at depth). A similar behaviour was observed at our reference station in the HNLC area, west of the Kerguelen Islands. In the polar front region, concentrations increased with values around 0.3-0.4 nM at sea-surface and 0.6-0.7 nM at depth. On-board incubations on natural plankton communities clearly showed a strong iron limitation at our reference station, a moderate one in the anti-cyclonic structure and no limitation above the Plateau.

Sorption of borate on calcined products of natural dolomite

Keiko Sasaki[1*], Yukiho Hosomomi[2], and Xinhong Qiu[3]
[1]Kyushu University, Earth Resources Engineering, Fukuoka, Japan, keikos@mine.kyushu-u.ac.jp (* presenting author)
[2] Kyushu University, Earth Resources Engineering, Fukuoka, Japan, y-hosomomi11@mine.kyushu-u.ac.jp
[3] Kyushu University, Earth Resources Engineering, Fukuoka, Japan, q-q11@mine.kyushu-u.ac.jp

Introduction

Boron is a dynamic trace element that can affect the metabolism or utilization of numerous substances involved in life processes, and also one of the most difficult elements to immobilize in aquatic environments [1]. Natural dolomite was modified to provide as a sorbent for borate. Calcination condition was investigated at 700 °C ~900 °C under air and reducing atmosphere.

Results and Conclusion

Calcite ($CaCO_3$) and magnesian calcite (Ca, Mg)CO_3 were included as impurities as well as dolomite ($CaMg(CO_3)_2$) in the specimen. Increasing with calcination temperature, sequential decarbonation was confirmed by XRD, that is, transformation of dolomite into magnesia and calcite at 700 °C, transformation of magnesian carbonate into magnesia and calcite at 800 °C, and transformation of calcite into lime at 900 °C. Surface molar ratio of Ca/Mg decreased from 1.6 to 0.6 independently of calcination temperatures. Sorption isotherm of borate at 25 °C was compared with calcined products under different conditions. In calcination under air, the greatest sorption density of borate was found with calcined product at 700 °C (Fig. 1). BET type of sorption isothedrm curve suggests that removal of borate is expected to occur through destructive sorption of MgO in calcined products. However, under reducing conditions the greatest sorption density was observed with calcined product at 900 °C.

Removal mechanism of borate is principally co-precipitation with $Mg(OH)_2$ in hydration nof MgO. The above result suggests the surface of magnesia (MgO) was more significantly affected by CO_2 in a process of decarbonation at higher temperature, and that higher crystalinity of MgO is more reactive in hydration.

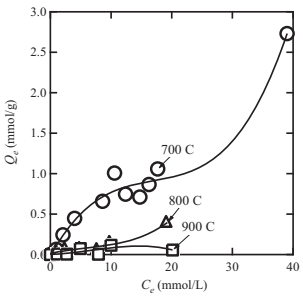

Figure 1: Sorption isotherm of borate at 25 °C on calcined products of natural dolomite at 700 °C ~900 °C under air.

Experimental studies on carbon isotope fractionation in the deep Earth

M. SATISH-KUMAR [1*], TAKASHI YOSHINO[2], SHOGO MIZUTANI[1], HAYATO SO[3], AND MUTSUMI KATO[4]

[1]Department of Geosciences, Shizuoka University, Shizuoka, Japan smsatis@ipc.shizuoka.ac.jp

[4]Graduate School of Sciences, Chiba University, Chiba, Japan

Carbon is the fourth most abundant element in the solar system. It has a key role in the melting phase relations of mantle rocks [1] and metallic core [2]. Carbon further acts as an agent of mass transfer in the form of mobile carbonate-rich melts [1]. An efficient tool to understand the carbon cycle, both in the shallow and deep Earth environments, is by using carbon isotopic composition. However, our understanding of carbon isotopic composition of deep Earth is very limited. Here we present results of experimental determination of partitioning of carbon isotopes at high-pressure high-temperature conditions, in systems analogous core formation environment and carbonate melting in the mantle conditions.

High-pressure experiments were performed using a Kawai type multi-anvil high-pressure apparatus at the ISEI, Okayama University, Misasa, Japan. Two types of starting materials were used. First type is a mixture of Fe + 9.0wt% C with known carbon isotopic composition. Second set of experiments were carried out in the Mg-Si-C-O system, where San Carlos enstatite and olivine was mixed with graphite and magnesite. Experiments were carried out at a pressure of 5 and 10 GPa at temperature conditions between 1200 ºC and 2100 ºC. Carbon isotope measurements were carried out using an IRMS.

The distribution of carbon isotopes between iron carbide melt and graphite/diamond at high-pressure high-temperature conditions shows the presence of large and measurable carbon isotope fractionation in the Fe-C system. These results were also consistent with the carbon isotope distribution between graphite and cohenite (Fe_3C) in iron meteorites. A temperature-dependent fractionation of carbon isotopes between iron carbide melt and graphite/diamond, as reported in [3], is believed to have created a "^{12}C-enriched core" with a significant difference in the distribution of carbon isotopes between the carbon core and bulk silicate Earth during accretion and differentiation of early Earth. In order to further characterize the carbon movement in the mantle, the carbon isotope systematics during melting of carbonated mantle in the presence of graphite/diamond were investigated in the Mg-Si-C-O system. Preliminary results indicate that carbon isotopes show considerable partitioning between graphite/diamond and carbonate melt at temperatures and pressures corresponding to upper mantle conditions. We attempt to discuss the carbon isotope systematics in the mantle and core based on our experimental results.

δ^{26}Mg of brachiopod shells and the composition of past seawater

S. SAULNIER*[1], C. ROLLION-BARD[1], C. LECUYER[2], N. VIGIER[1] AND M. CHAUSSIDON[1]

[1]CRPG-CNRS, BP 20, Vandoeuvre-lès-Nancy, France, saulnier@crpg.cnrs-nancy.fr (* presenting author)
[2]Laboratoire de Géologie de Lyon, CNRS, Université Claude Bernard Lyon 1, Villeurbanne, France.

The Mg isotope composition of marine carbonates can provide information on the dynamics of the Mg cycle through geological times (e.g. [1]). Brachiopods were extensively used for tracking both physicochemical conditions and secular isotopic variations of past oceans (e.g. [2]). Articulated brachiopods shells are made of low-Mg calcite, which is relatively resistant to most diagenetic processes [3]. However, significant intravariability in oxygen and carbon isotope ratios have been shown for several species, mainly due to kinetic and metabolic effects operating during calcite formation (e.g. [4]).

Magnesium, oxygen and carbon isotopes were measured in various fragments of a fossil *Terebratula scillae* (2.1 Ma) in order to test whether brachiopod shells could constitute valuable proxies of the seawater Mg isotope composition. The external parts of the shell, including the primary layer and external contamination were physically removed before analyses. Mg isotope ratios were measured by MC-ICP-MS Neptune *Plus*, with an external 2σ error of 0.15‰. Oxygen and carbon isotope ratios were measured by IRMS, with an 2σ error of 0.04‰.

The ventral and dorsal valves have similar isotope compositions and variability: δ^{26}Mg ranges from -2.95 to -2.02 ‰, δ^{18}O ranges from 2.57 to 3.15‰ and δ^{13}C ranges from 1.12‰ to 2.00‰. No correlation is observed with Mg/Ca ratio. A negative trend can be observed between δ^{26}Mg and δ^{18}O. The lowest δ^{26}Mg values correspond to isotope equilibrium determined for inorganic calcite relative to seawater Mg (Saulnier et al., submitted), and are systematically observed in the fragments located at the outer parts of the shell. This suggests that the outermost parts of brachiopod shells can be used to track the Mg isotope composition of past seawter. This aspect will be tested by studying ancient brachiopods with geological ages spanning from 0 to 54 Ma.

Diffusion chronometry and seismology: insights into eruption precursors

KATE SAUNDERS[1*], JON BLUNDY[1], RALF DOHMEN[2] AND KATHY CASHMAN[1]

Timescales of magmatic processes are key to our understanding of active volcanic systems, yet remain one of the most poorly constrained variables. Today many active volcanoes are monitored through a combination of seismicity, ground deformation, gas emissions and geodetic methods. In some instances these methods can be used to track magma movement in the crust prior to eruption, but not every magma pulse of magma results in an eruption.

Petrological methods can interrogate the products of recent eruptions. Zoned volcanic crystals potentially perserve a record of magmatic processes during the lifetime of a crystal from nucleation to eruption. As the magma evolves, changes in the composition, water content, temperature or pressure will result in renewed growth of a different composition generating zoned crystals. In particular, diffusion chronology (relaxation of elements across compositional interfaces) enables us to calculate a time series, precisely dating the perturbations that occur in the magma chamber prior to eruption. These petrologically determined times series can be correlated with time series generated through geophysical techniques from the same eruption to ascertain links to pre-eruptive processes.

Mount St. Helens produced a series of well studied and characterised eruptions during 1980-86. Orthopyroxene is an ubiqitous crystal phase throughout the eruption sequence. Over 500 orthopyroxene crystals from nine of the eruptions have been investigated through a combination of back-scattered electron imaging and major element chemistry by electron probe microanalyser. This revealed multiple orthopyroxene crystal populations of both unzoned and zoned crystals. Zoned crystals populations were further sub-divided into: (1) normal zoned crystals (Fe-rich rims); (2) reversed zoned crystals (Mg-rich rims); (3) oscillatory zoned crystals. Diffusive chronometry of Mount St. Helens zoned orthopyroxene reveals that the majority of rim growth occurred within two years prior to eruption. Episodes of magma mixing identified in the petrological rocord are temporally correlated with the recorded seismicity indicating both tectonic and degassing driven seismic events occurred.

Molecular- and pore-scale response of uranium to advective geochemical gradients in heterogeneous sediments

KAYE S. SAVAGE[1*], WENYI ZHU[1], MARK O. BARNETT[2], C. TYLER WOMBLE[1] AND JAN E. PATTON[1]

[1]Wofford College Environmental Studies, Spartanburg SC, USA, savageks@wofford.edu (* presenting author), zhuw@wofford.edu, womblect@email.wofford.edu, pattonje@email.wofford.edu

[2]Dept. Civil Engineering, Auburn University, AL, USA, barnem4@auburn.edu

Experimental approach

Column experiments were devised to investigate the role of changing fluid composition on mobility of uranium through a sequence of geologic media. Fluids and media were chosen to be relevant to the ground water plume emanating from the former S-3 ponds at the Oak Ridge Integrated Field Research Challenge (ORIFC) site. Synthetic ground waters were pumped upwards at 0.05 mL/minute for 21 days through layers of quartz sand alternating with layers of uncontaminated soil, quartz sand mixed with illite, quartz sand coated with iron oxides, and another soil layer. Increases in pH or concentration of phosphate, bicarbonate, or acetate were imposed on the influent solutions after each 7 pore volumes while uranium (as uranyl) remained constant at 0.1mM. A control column maintained the original synthetic groundwater composition with 0.1mM U. Pore water solutions were extracted to assess U retention and release in relation to the advective ligand or pH gradients. Following the column experiments, subsamples from each layer were characterized using microbeam X-ray absorption spectroscopy (XANES) in conjunction with X-ray fluorescence mapping and compared to sediment core samples from the ORIFC, at SSRL Beam Line 2-3.

Results

U retention of 55 – 67 mg occurred in phosphate >pH >control >acetate >carbonate columns. The mass of U retained in the first-encountered quartz layer in all columns was highest and increased throughout the experiment. The rate of increase in acetate- and bicarbonate-bearing columns declined after ligand concentrations were raised. U also accumulated in the first soil layer; the pH-varied column retained most, followed by the increasing-bicarbonate column. The mass of U retained in the upper layers was far lower.

Speciation of U, interpreted from microbeam XANES spectra and XRF maps, varied within and among the columns. Evidence of minor reduction to U(IV) was observed in the first-encountered quartz layer in the phosphate, bicarbonate, and pH columns while only U(VI) was observed in the control and acetate columns. In the soil layer, the acetate and bicarbonate columns both indicate minor reduction to U(IV), but U(VI) predominated in all columns. In the ORIFC soils, U was consistently present as U(VI); sorption appears to be the main mechanism of association for U present with Fe and/or Mn, while U occurring with P appears in discrete particles consistent with a U mineral phase. U in soil locations with no other elemental associations shown by XRF are likely uranium oxide phases.

A silicon isotopic record of long term changes in continental weathering

PAUL S. SAVAGE[1,2]*, R. BASTIAN GEORG[3], HELEN M. WILLIAMS[4] & ALEX N. HALLIDAY[1]

[1]Department of Earth Sciences, University of Oxford, Oxford, UK
[2]Department of Earth and Planetary Sciences, Washington University, St. Louis, MO, USA (* presenting author; savage@levee.wustl.edu)
[3]WQC, Trent University, Peterborough, Ontario, Canada
[4]Department of Earth Sciences, Durham University, Durham, UK

High precision MC-ICP-MS analyses of a suite of globally sourced clastic sediments suggest that the Si isotope system behaves more conservatively than other stable isotope tracers (i.e. Li, Mg, O) during continental weathering. This is contrary to expectation, as previous studies have shown that Si isotopes can be significantly fractionated toward lighter compositions during formation of secondary phases [1]. Nevertheless, Si isotopes in shales do not correlate with canonical proxies for weathering. Instead, good negative correlations between δ^{30}Si values and insoluble element concentrations (Nb, Hf, TiO_2) indicate that intensive chemical weathering is required before resolvable negative Si isotopic fractionation occurs in such lithologies.

On this basis, Si isotope variations in the long-term clastic sedimentary record could be used to provide a reliable proxy for investigating long term changes in the degree of reworking of continental crust and/or the intensity of continental weathering. When there is extensive formation and exposure of continental material (the Si in which has not undergone prior weathering), erosion should produce sediment with Si isotopic compositions similar to igneous continental crust [2]. If the availability of new crustal material is reduced, then the sedimentary record will become increasingly dominated by reworking of pre-existing lithologies, which will drive the Si isotope compositions to lighter values over time.

Such a hypothesis has been tested here using the post-Archaean Australian shale (PAAS) suite [3]. These samples are ideal, as they were all sourced from the same continental mass (Australia and, before, Gondwanaland) and have a wide range of depositional ages, from 1500Ma to 200Ma. The data display an enrichment in isotopically light Si with time, which appears to relate to increasing Nd crustal residence age [4]. As such, sediment derived from sources dominated by recycling of older crustal lithologies display the lightest isotopic compositions, as predicted. There is also evidence, however, that incorporation of authigenic marine lithologies can complicate this simple relationship.

Extremely negative Si isotopic compositions in Archaean shales (also sourced from Gondwanaland) cannot be explained by long-term continental weathering, as they were deposited when new continental crust dominated the budget. This could, therefore, reflect more intense weathering, due to more aggressive climatic conditions, early in Earth history.

Improved calibration technique for magnetite analysis by LA-ICP-MS

D. SAVARD[1]*, S.-J. BARNES[1], S. DARE[1], G. BEAUDOIN[2]

[1]Université du Québec à Chicoutimi, Chicoutimi (Qc), Canada, G7H 2B1 *ddsavard@uqac.ca
[2]Université Laval, Québec (Qc), Canada

Oxide minerals such as magnetite and chromite are becoming popular in the field of geochemical exploration because the wide variety of trace elements present could potentially be used in provenance studies [1]. The method of analysis used is commonly LA-ICP-MS because it provides limits of detections down to ng/g levels when the analytical parameters can be optimized. No matrix-matched reference materials (RM) are available at the moment for *in-situ* calibration. Artificial glasses could be used to calibrate but only Fe can be used as an internal standard because of the inhomogeneous distribution of most of the other elements in magnetite. [2] proposed using NIST-610 to calibrate. However, the Fe content in NIST-610 is low at c.a. 0.05% while Fe in magnetite is c.a. 72%, thus limiting the use of NIST-610 to a beam >25µm, with a maximum precision of R^2<0.85 when results are compared to EMPA analysis of natural magnetite. [3] proposed the combination of 5 iron-rich RM to cover the elements of interest. Based on the elements for which EMPA results are available this calibration is satisfactory. However, this technique is time consuming and reduces the space available in the ablation cell.

We have found that USGS glasses GSE-1g and GSD-1g provide an accurate calibration for a beam size down to 4µm. The glasses are produced from natural basaltic material, containing c.a. 10% Fe, doped with a wide variety of trace elements. Figure 1 shows a good correlation between working values and those obtained at LabMaTer (UQAC) using a 193nm Resonetics M-50 laser and Aglilent 7700X ICP-MS. GSE-1g was used to calibrate while GSD-1g was used to monitor the precision and accuracy of the calibration. A natural magnetite from the Bushveld, BC-28 [4], was used as a quality control RM. Based on EMPA data, the calibration technique is also suitable for chromites, ilmenites and other Fe-rich oxides.

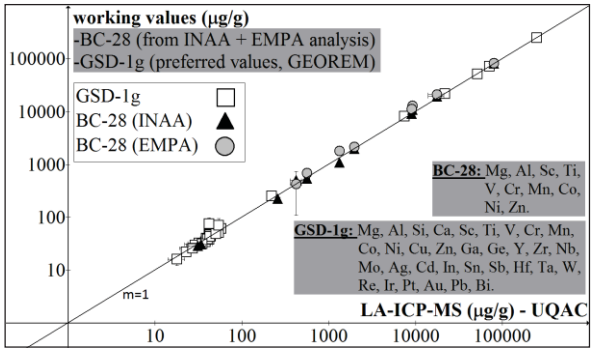

Figure (1): Accurate LA-ICP-MS calibration for magnetite analysis using GSE-1g as calibrant, GSD-1g and BC-28 as quality controls, and ^{57}Fe as internal standard.

How mobile is selenium in claystone? Insights given by radiochemistry and X-ray absorption spectroscopy

S. SAVOYE[1*], M.L. SCHLEGEL[1], B. FRASCA[1,2]

[1] CEA DANS/DPC, L3MR & LISL, Gif sur Yvette, France, sebastien.savoye@cea.fr (* presenting author), michel.schlegel@cea.fr

Introduction

The transport in the Callovo-Oxfordian clay formation of Se under its more oxidised forms, *i.e.* Se(IV) and Se(VI), was studied by means of batch and diffusion experiments [1], carried out at lab in N_2/CO_2 glovebox for mimicking as much as possible the physico-chemical conditions prevailing in-situ. A radiochemical approach using HTO, ^{36}Cl and ^{75}Se, as tracers, was supplemented by a non-radioactive one, for which the solid was investigated by X-Ray Absorption Spectroscopic (XAS) methods.

Results and Discussion

Results showed that Se(VI) diffused almost like ^{36}Cl, with little affinity towards clayey rocks (Rd < 0.02 mL g^{-1}). Conversely, the batch and diffusion-experiments revealed that Se(IV) exhibited a much stronger affinity towards the Callovo-Oxfordian claystone, in inverse correlation to initial Se concentration. Values of Rd were estimated, ranging from 10 to about 200 mL g^{-1} for $[Se(IV)]_{ini}$ decreasing from 10^{-3} to 10^{-6} mol L^{-1}. This behaviour could not be reproduced only with a simple model, especially for the pristine samples (diffusion experiments), since Se showed a secondary maximum ~ 2 mm under the surface, both in the radioactive and stable diffusion cells (Figure 1). The determination of the selenium oxidation state by XAS revealed that the total Se profile was clearly the sum of the contribution of (i) Se(IV), exhibiting a relative regular diffusion profile and of (ii) the more reduced selenium species (Se(red) ~ Se (0), Se(-I) and/or Se(-II)), especially located at about 2 mm from the interface (Figure 1).

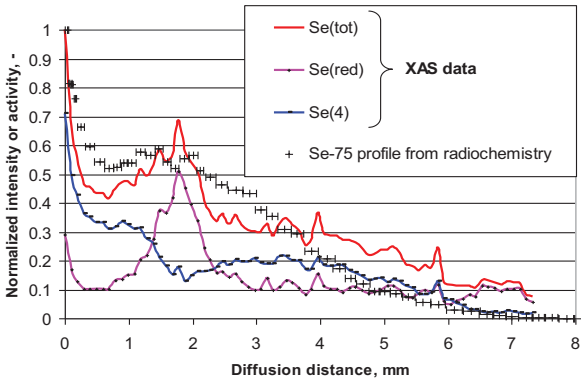

Figure 1: Distribution of the Selenium species along the rock profile obtained by XAS and comparison with radiochemistry data

The origin of the selenium distribution linked to some reduction processes was discussed regarding the mineralogy and the physico-chemical conditions prevailing in the pores.

Retention of melt in granulite terrains

EDWARD SAWYER

Université du Québec à Chicoutimi, Sciences de la terre, ewsawyer@uqac.ca

Introduction

Previous work [1] showed that metagreywacke protoliths in the Ashuanipi Subprovince in northern Quebec produced approximately 600000 km^3 of granitic melt during granulite facies anatexis. Virtually all that melt was extracted from where it formed, leaving behind an Opx + Bt + Pl ± Qz residuum. What became of that melt?

Results

Fieldwork shows that very little of the anatectic melt collected into leucosomes, but a significant proportion remained in the granulite terrain as secondary diatexite migmatite. Melt accumulated in regional-scale dilatant sites. Field, geochemical and microstructural studies indicate that the secondary diatexite plays an important role in the evolution of granitic magma. Their microstructure and whole rock geochemistry indicates that a small proportion have the composition appropriate for the initial, anatectic melt. Most have compositions (supported by field relations) indicative of significant contamination by their melt-depleted wall rocks; contamination by the peritectic phase (Opx) alone is not sufficient. The microstructure (form and composition) of the feldspar-crystal framework in the diatexite reveals a wide range of responses to deformation during solidification. In places, meter-sized patches of leucocratic monzogranite occur in the diatexite and indicate local fractional crystallisation. However, most of the secondary diatexite represents an accumulation of plagioclase from which the fractionated melt has been removed. Kilometre-sized bodies of leucocratic monzogranite in the terrain represent part of the volume of fractionated melt that separated from the secondary plagioclase-rich cumulate diatexite, the balance moved to higher crustal levels.

Conclusions

Granulite terrains are much less depleted in melt than analysis of the residual rocks alone indicates. Large amounts of anatectic melt may be retained and melt from different source rocks can accumulate in the same sites. These sites represent a key reservoir in the deep crust where the composition of granite magma is established. Fractional crystallisation and general contamination exert a greater control on composition than source rock composition, or entrainment of peritectic phases.

Geochemical investigations of the intrabasaltic palaeosols (bole beds) from Deccan Traps, India in deducing the palaeoclimatic conditions

MOHAMMED RAFI SAYYED [1*] AND SAJID HUNDEKARI[2]

[1]Geology Department, Poona College, Camp, Pune, India, mrgsayyed@yahoo.com (* presenting author)

[2] Geology Department, Poona College, Camp, Pune, India, sajid_hundekar@yahoo.com

Geochemical analysis of the intrabasaltic bole beds (palaeosols) occurring in the parts of Deccan Volcanic Province (India) was applied in deducing the palaeoenvironmental conditions prevailed during their formation. The bole beds the study area occur as red or green couloured clayey intercalations between the basaltic lava flows and show distinct environmental conditions during their formation when compared with the modern soils. In general red boles show higher weathering intensity, much leaching of the bases than the green boles while modern soils show moderate weathering but quite high leaching of the bases. The Weathering Potential Index (WPI) however suggests higher weathering in red boles, moderate in green boles and lesser in the modern soils. The Parkers Weathering Index (PWI) and calcination values indicate an enrichment of calcium during the formation of green boles thereby indicating aridity. Red boles were formed under higher rainfall but lesser temperature (more hydrolysis) than the green boles (less hydrolysis) while modern soils were formed under much higher rainfall and comparatively low temperature (strong hydrolysis). Iron species ratio, Product Index and FeO/Mgo values suggest that red boles were formed under strongly oxidizing but lesser acidic conditions while green boles were formed under less oxidizing but higher acidic conditions. The modern soils however indicate not much oxidizing but alkaline conditions. More retention of original mafic components in red boles and felsic components in green boles indicate selective dissolution of mafic components from green boles in more acidic fluids. Less hydrolysis and more calcination in green boles (than red boles) point towards more arid conditions during their formation than the red boles. However modern soils were formed under considerably humid conditions. The values of salinization indicate that the red boles were formed under fairly leached but relatively poorly drained conditions than the green boles while modern soils formed under quite intensely leached but poorly drained conditions. In conclusion the red boles were formed as a result of intense weathering under strongly oxidizing, acidic, more humid (more hydrolysis) environment with fairly leached but relatively poorly drained conditions than the green boles, suggestive of distinct weathering regimes. As a whole the palaeoclimates during the bole bed formation were quite different than the Holocene as the conditions were rather arid, fairly drained more acidic and strongly oxidizing with comparatively lesser rainfall but higher temperature. Although there is lack of age of control it is believed that the modern soil formation from Deccan traps represent much longer geomorphic history than the time lapsed during the formation of individual bole bed. In view of this, much intense weathering under stronger oxidizing conditions and more acidic conditions yet more aridity than the Holocene indicate catastrophic climatic conditions during the bole bed formation which can be related to the perturbations due to Deccan volcanic activity.

Inter-hemispheric patterns of Holocene Glacier and Temperature Change

Glacier and Temperature Change

Glaciers are among the most sensitive recorders of climate change, making them highly valuable as paleo-climate recorders and, at the same time, highly vulnerable to ongoing climate change.

Using independent lines of argument from glaciology, glacial geology and climate science, we make the case that glaciers in temperate climate zones are pre-dominantly driven by temperature change and, in turn, form sensitive thermometers.

Holocene Temperatures from glacier and marine records

Recent progress in the method of cosmogenic nuclide surface exposure dating now affords for precise reconstructions of glacier fluctuations throughout the Holocene and up to present day. In combination with detailed mapping of the paleo-snowline, a measure of past glacier extent, relative to today's snowline, we present comprehensive records of glacier advances in southern and northern mid-latitudes during the Holocene, and deduce regional Holocene temperatures. We compare these terrestrial temperature records with near-by and far field marine temperature estimates to better understand the inter-hemispheric patterns of Holocene temperatures.

We finally discuss implications and potential of these data sets for improving climate models.

Modeling of concentrations in major elements of subsurface and deep waters in the Ringelbach granitic research catchment (Vosges, France)

T. SCHAFFHAUSER[1*], F. CHABAUX[1], B. FRITZ[1], B. AMBROISE[1], A. CLEMENT[1] AND Y. LUCAS[1]

[1]LHYGES, Université de Strasbourg/EOST, CNRS, France (*correspondence: thiebaud.schaffhauser@etu.unistra.fr)

For constraining the nature of water-rock interactions occuring within granitic watersheds and exploring the potential relationships existing between subsurface and deep waters a geochemical study combined with a modeling approach has been undertaken in the small Ringelbach granitic catchment (Vosges, France). Concentrations of major elements were measured in water samples from the main springs emerging within the catchment as well as from two 150-m deep boreholes (deep waters) drilled through the whole weathering profile of the granite bedrock.

The coupled transport/reaction model KIRMAT [1] has been used in this study to discuss and constrain the main spatial and temporal geochemical variations observed in these different waters. It combines geochemical reactions, including clay precipitation [2], and 1D mass transport equations to simulate the reactive transport of a fluid through a rock along a given water pathway.

In the case of the Ringelbach watershed, we have simulated the transfer of rainwaters along different water pathways, from very permeable surficial arenic formation to almost impermeable deep fresh granite. Simulations point out that the initial chemical signature of rainwater is rapidly lost during its transfer through the substratum due to the weathering of rock-forming minerals. Furthermore, simulations indicate that the geochemical characteristics of spring waters and deep waters are mainly controlled by two different water pathways within the substratum: high-rate downslope subsurface flow for the springs, and very low flows through the whole granitic massif for borehole waters. These results suggest therefore that spring waters and deep waters are largely disconnected in the Ringelbach catchment.

The construction of the Alpine Adamello batholith as recorded by zircon

U. SCHALTEGGER[1*], C. BRODERICK[1], A. SKOPELITIS[1], D. FLOESS[2], A. ULIANOV[2], O. MÜNTENER[2], L. BAUMGARTNER[2], P. BRACK[3] AND P. ULMER[3]

[1]Earth and Environmental Sciences, University of Geneva, Switzerland, urs.schaltegger@unige.ch (*presenting author)

[3]Institute of Geochemistry and Petrology, Swiss Federal Institute of Technology ETH, Zürich, Switzerland

Batholiths are formed by incremental melt addition over time scales spanning millions of years. They consist of composite plutons, which are formed through individual melt pulses that cool over a 10 to 100 ka timescale.

Careful laser ablation ICP-MS and CA-ID-TIMS zircon geochronology on the Adamello Batholith in Northern Italy not only reveals these different timescales, but also allows reconstruction of some of the batholith-forming processes: (a) The entire batholith grows from 43 to 33 Ma through melts derived from an increasingly crust-contaminated arc-type source; (b) single mappable plutons are compositionally more or less heterogeneous and consist of a number of melt pulses; (c) each pulse intruded and cooled as a single unit over timescales of several 10 to 100 ka; (d) the Val Fredda pluton in the southernmost Re di Castello unit shows bimodal magmatism with gabbroic melts injecting into tonalite mushes and sharing some 100 ka of crystallization and cooling; (e) the subsequent pulses of diorites and tonalites of the Lago della Vacca pluton are recognized to tap the same source mushes and continuously recycle the crystal cargo [1], while in the case of more evolved tonalites of the Central Adamello unit the pulses consist of fractionated residual melt without inheritance of crystal cargo.

Chemical-abrasion, high-precision ID-TIMS zircon dating also revealed that mapped units show a significant age spread with clear geographic trends interpreted as accretion of pulses that are not discernible in the field. The trace element and Hf isotopic composition of dated zircon is a paramount tool to trace fractionation of major and accessory minerals during zircon crystallization, mixing of melts with different source components or of mixing ante- or xenocrystic crystal cargo into a melt batch [2] In this way, zircon provides a means to trace the thermal and magmatic evolution of deeper crustal reservoirs. Additional titanite U-Pb data may help to quantify the rate of high-temperature cooling down to the solidus or, alternatively, trace prolonged heat advection followed by partial remelting and homogenization of subsequent melt batches, as seen in the Lago della Vacca unit.

Estimating isotope fractionation driven by nuclear size

E. A. SCHAUBLE[1*], S. GHOSH[2], B. A. BERGQUIST[2]

[1]UCLA, Los Angeles, CA, USA schauble@ucla.edu (* presenting author)
[2]U. Toronto, Toronto, ON, Canada

Mass-independent fractionation (MIF), where isotope abundance variations are disproportionate in mass, can have several causes. The nuclear field shift effect, proposed by Jacob Bigeleisen to explain mass independent uranium isotope signatures observed in chemical exchange experiments, stems from slight perturbations in chemical bond strengths caused by variation the volume and shape of nuclei[1]. It is unique in being a thermodynamically driven MIF mechanism that persists at conditions of equilibrium isotope exchange, and is truly independent of isotopic mass. Theoretical calculations have so far been limited to fairly small molecules, atoms and ions, in part because relativity becomes important for electrons interacting closely with nuclei, necessitating an approximate solution of the Dirac equation for electronic structure modeling. Methods for estimating isotopic fractionation factors in more complex materials are needed in order to understand recent detections of nuclear volume signatures in evaporating liquid metals, ores, and sediment, and to guide future studies. In this study we have developed procedures for cross-calibrating calculations made with relativistic electronic structure theory against less computationally intensive models.

Our initial goal was to calculate the equilibrium fractionation between liquid mercury liquid and mercury vapor to compare with experiment[2]. We observed a strong correlation ($R^2 \approx 0.9$) between a) relativistically estimated nuclear volume fractionation and b) the Mulliken population of 6s electrons in Hg-bearing species calculated with methods that incorporate relativistic effects only in the generation of a mercury pseudopotential. This is consistent with the strong correlation between atomic polar tensor charges and fractionation observed previously[3]. Based on the slope of the correlation (~1.5‰ in $^{202}Hg/^{198}Hg$ per 6s electron at 295 K), and estimated ~70-80% occupation of 6s orbitals in liquid mercury[4], we estimate 0.5-0.9‰ nuclear volume fractionation of $^{202}Hg/^{198}Hg$ between liquid and vapor, liquid being enriched in neutron-rich isotopes, and a positive $\Delta^{199}Hg$ signature of 0.1-0.2‰ in vapor. Including mass dependent fractionation effects, a total liquid-vapor $^{202}Hg/^{198}Hg$ fractionation of 0.7-1.3‰ is calculated, in good agreement with experimental results.

Plane-wave density functional theory methods, which can be applied to crystalline solids and liquids (within a periodic boundary condition approximation), appear to similarly show strong correlation with relativistic estimates of nuclear-volume fractionation. This suggests that it may be possible to estimate equilibrium MIF signatures in a wide variety of complex, geochemically interesting materials.

The Rofna Porphyry Complex: Combining LA-ICPMS and CA-TIMS U-Pb ages on zircons.

THOMAS SCHEIBER[1*], BENJAMIN D. HEREDIA[1], JASPER BERNDT[2], AND O. ADRIAN PFIFFNER[1]

[1] Institute of Geological Sciences, University of Bern, Switzerland, scheiber@geo.unibe.ch, benjamin.heredia@geo.unibe.ch, pfiffner@geo.unibe.ch
[2] Institut für Mineralogie, Universität Münster, Germany jberndt@uni-muenster.de

The Rofna Porphyry Complex (RPC) in the northern part of the Suretta nappe of the Penninic zone in eastern Switzerland, is mainly composed of two different lithologies: porphyritic rock types and augengneisses (Fig. 1). The augengneisses are cross-cut by porphyritic rocks and have been traditionally interpreted as Ordovician intrusives [1] without having any radiometric age control. Our field observations indicate that (a) the augengneisses show homogenous penetrative deformation whereas the porphyritic rocks reveal variable degrees of Alpine deformation, and (b) the augengneisses occur structurally above the porphyritic rocks (Fig. 1).

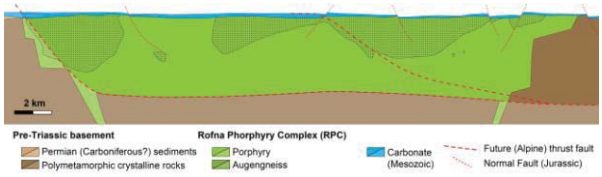

Figure 1: Restored section of the frontal part of the Suretta nappe - a feasible pre-Alpine constellation at the time of Jurassic rifting.

The magmatic event emplacing the porphyry has already been dated by ID-TIMS at 268.3 ± 0.6 Ma, which is a mean $^{206}Pb/^{238}U$ age of two nearly concordant multigrain fractions [2]. In order to constrain the age relationship between the different RPC rock types, we performed U-Pb LA-ICPMS measurements on zircons. In the augengneiss two age populations can be observed: One showing little spread at 311 Ma, and another younger one with a larger spread from 250 to 288 Ma. For the porphyritic rocks there is only one cluster of LA-ICPMS ages yielding an age range from 260 to 278 Ma.

Our new data suggest that the augengneisses are not the result of Ordovician magmatism, but may be related to the Variscian orogeny. The younger population in the augengneisses overlaps with the intrusion age of the porphyry and could either be the result of zircon neoformation or partial resetting of the U-Pb system.We therefore interpret the RPC as a composite late-Variscan and post-Variscan intrusive complex, where the pophyritic rocks followed pre-existing magma conduits, replenishing and disrupting the older augengneiss body at a shallow crustal level. High precision CA-TIMS data will provide further control of the emplacement relationships between these metamorphosed magmatic rocks.

Iron isotopes as a tracer in an acid-sulfate soil system

K. SCHEIDERICH[1*], J. KIRBY[1], P. SHAND[1,2]

[1]CSIRO Land and Water, Urrbrae, Australia, kate.scheiderich@csiro.au (*presenting author)
[2]Flinders University, Adelaide, Australia

Iron isotopes have been extensively studied in many systems and the fractionation factors are at least experimentally well understood for many common processes on earth's surface, including Fe-oxide mineral formation, precipitation reactions, and biological transformations such as microbially-mediated reductive dissolution of hematite. In complex environments, these well-undestood fractionations can be applied to assess the transport and speciation of Fe. However, only a few attempts have been made to understand the fractionations occuring in sulfur-rich systems, and these have been limited to acid mine drainage and hydrothermal vents. Salt marshes, tidal flats, and terrestrial floodplain environments, though well studied from the perspective of nutrients, trace metal cycling, and light stable isotopes (particularly C and S), have received little attention, yet are Fe-rich as a result of Fe monosulfide and pyrite formation.

Here we examine Fe isotope fractionation and Fe speciation in acid sulfate soil profiles and sediments from the Murray River system (South Australia), in order to gain an understanding of processes, pathways and biogeochemical cycling of Fe and associated metals through this environment. Inland acid sulfate soils are present in most fresh and saline wetland systems in the Murray-Darling Basin, largely due to the build-up of sulfide minerals during high pool levels. This situation has existed since the installation of locks in the 1930's. Prolonged recent drought led to oxidation of sulfide minerals and soil acidification with severe impacts on the local soil ecosystem. However, in the floodplain soils, desiccation of pyrite-laded, organic rich sediment allows Fe oxidation, then re-flooding events release acid to the river. Prelimary results from two oxidized soil samples of have a small range of light, near-zero δ^{57}Fe values. However, significant fractionation has been observed between primary sulfide minerals and their oxidation products in other acid sulfate soils in Australia. This is consistent with previously observed isotope fractionation between oxidized Fe minerals precipitated from Fe-rich sulfidic mine drainage [1, 2]. Additional data regarding the exact Fe mineral phases present in the soils, as well as sequential extractions of these phases and isotopic analysis of the extracts may provide additional constraints on Fe translocation in these environments.

Coupled geochemical processes limiting phytosiderophore-promoted iron uptake from soils

W.D.C. SCHENKEVELD[1*], E. OBURGER[2], Y. SCHINDLEGGER[3], A. REGELSBERGER[3], S. HANN[3], M. PUSCHENREITER[2] AND S.M.KRAEMER[1]

[1]Universität Wien. Dept. of Environmental Geosciences, Althanstrasse 14, 1090 Wien, Austria, schenkw6@univie.ac.at (* presenting author)
[2]University of Natural Resources and Life Sciences, Dept. of Forest and Soil Sciences, Tulln, Austria
[3]University of Natural Resources and Life Sciences, Dept. of Chemistry, Wien, Austria

Graminaceous plant species (grasses) exude multidentate complexing agents called phytosiderophores (PS) for the purpose of iron aquisition, in particular under conditions of iron deficiency stress. Upon release from the root surface, the ligands diffuse into soil solution and solubilize iron from iron bearing phases in the soil, forming iron complexes which are taken up at the root surface.

Although the mechanism of action of PS has been intenisively studied, this was mostly done in hydroponics or in soil suspensions with a low soil to solution ration that did not allow to investigate coupled geochemical processes. The aim of the current project is to quantitatively understand the geochemical and geophysical processes limiting PS promoted iron uptake.

In the present work the rate of iron mobilization from various soils by the PS deoxymugineic acid (DMA) was examined in batch experiments, both with and without addition of a sterilant (sodium azide) to prevent biodegradation of the DMA ligand. Both clay and sandy soils, differing in iron availability were included.

Fe mobilization corresponded with 10 to 60% of the added DMA. The extent to which Fe was mobilized positively correlated with Fe availability parameters (e.g. DTPA-extractable Fe) and negatively correlated with the clay content of the soils. Especially in soils of low Fe availability, Fe mobilization was strongly compromised by the mobilization of competing cations like Cu, Zn, Ni and Co.

In absence of sterilant, all metal-DMA complexes were removed from solution within 4 days. Depending on the soil, Fe mobilization reached a maximum after 0.25 to 8 hours.. Except for one soil, maximum Fe mobilization was not dependent on sterilant addition. Also when sterilant was added, FeDMA concentrations eventually decreased, indicating that processes other than biodegradation significantly compromise the FeDMA concentration.

These results strongly indicate that for improving the understanding of plant iron acquisition, the kinetics and thermodynamics of coupled rhizosphere processes need to be studied coherently.

[4]Dept. of Geoscience, University of Wisconsin-Madison, Madison WI 53706

Electron and ion exchange reactions at mineral/water interfaces influence the composition of natural waters, the biogeochemical availability of nutrients, and the environmental fate of heavy metals and contaminants. A new conceptual model is emerging to describe the reaction of aqueous Fe(II) at the mineral/water interface that couples oxidation and reduction reactions between spatially separated surface sites connected through the bulk mineral via either electrical conduction, atom diffusion, both, or some other yet unknown mechanism [1, 2]. We are collaborating to combine ^{57}Fe Mössbauer spectroscopy, Fe isotope tracer experiments, and molecular modeling to investigate Fe electron transfer at mineral surfaces and the rates and mechanism of Fe atom exchange.

We are exploring these processes in commonly occurring Fe oxides and Fe-containing clay minerals over a range of environmentally relevant conditions. Here we provide a summary of what we have learned so far, as well as present new findings investigating whether cation substitution influences the rate of atom exchange, and whether similar reactions will occur in clay minerals, as well as between aqueous Fe(III) and Fe(II) containing minerals.

Effect of Ce(III) oxidation by Mn(IV) on its use as a paleo-redox proxy

JOHAN SCHIJF[1*] AND KATHLEEN S. MARSHALL[2]

[1]University of Maryland Center for Environmental Science, Chesapeake Biological Laboratory, Solomons, MD, USA, schijf@cbl.umces.edu (* presenting author)
[2]University of Maryland Center for Environmental Science, Chesapeake Biological Laboratory, Solomons, MD, USA, marshall@cbl.umces.edu

Research outline

Marine sedimentary cerium (Ce) anomalies are due to enhanced Ce sorption with respect to the strictly trivalent REEs as it is oxidized from Ce(III) to more reactive Ce(IV). They are often interpreted as indicative of oxidizing conditions, specifically the presence of free oxygen, in the bottom water of ancient ocean basins at the time of sediment deposition. Such an interpretation could be complicated if Ce(III) were oxidized in the absence of free oxygen, as has been shown to occur on the surface of manganese oxides. We performed sorption experiments under anaerobic conditions with yttrium and the REEs in 0.5 M NaCl on pure synthetic Fe(III) and Mn(IV) oxides, plus three synthetic ferromanganese oxides containing 25, 50, and 90 mol% Mn. All precipitates were found to be X-ray amorphous and to contain Mn(IV) only.

REE sorption on the pure Fe and Mn oxides is well described with a non-electrostatic surface complexation model (SCM) that accounts for the higher acidity of hydroxyl groups on the Mn oxide, for monodentate and bidentate binding of the REEs by these groups, and for the binding of REE–hydroxide complexes at elevated pH [1,2]. REE sorption on ferromanganese oxides is moreover adequately described with a linear combination of the pure Fe and Mn oxide SCMs that reflects the proportion of each phase in the mixture. A clear presence, respectively absence, of Ce anomalies indicates that Ce(III) is oxidized on Mn oxide at all experimental pH values (4–8), but never on Fe oxide. The extent of oxidation on ferromanganese oxides is similar to that on pure Mn oxide, even at the lowest Mn content.

Below pH ~ 5.5 the Ce anomaly in pure Mn oxides is independent of pH, suggesting that the oxidation reaction involves direct transfer of an electron from Ce(III) to Mn(IV). Above pH ~ 5.5 the Ce anomaly has a linear pH dependence and the oxidation reaction may involve the species $CeOH^{2+}$, or otherwise require the presence of H_2O or OH^-.

Conclusions

Laboratory experiments of REE sorption on pure Fe and Mn oxides and on ferromanganese oxides with a wide range of Mn contents, in 0.5 M NaCl at T = 25°C, demonstrate that Ce(III) is oxidized under anaerobic conditions at the Mn oxide surface and thus probably by Mn in ferromanganese oxides, not by Fe. Hence, marine sedimentary Ce anomalies are not a reliable proxy of the presence of free oxygen in the deep paleo-ocean wherever Mn oxides abound in the watercolumn or on the seafloor. At the very least, such records should be interpreted with appropriate caution.

Microbially-mediated isotopic fractionation of selenium : Relevance for biogeochemical processes in the geological record

KATHRIN SCHILLING[1*], THOMAS M. JOHNSON[2], ROBERT SANFORD[2] AND PAUL R. D. MASON[1]

[1]Utrecht University, Utrecht, The Netherlands, k.schilling@uu.nl (* presenting author)

[2]University of Illinois at Urbana-Champaign, Urbana, IL, USA

The terrestrial and marine evolution and preservation of life are sensitive to changes in redox conditions. Selenium as an redox-sensitive element can provide information about the oxyengenation history of the ocean and atmosphere. Microbial reduction of Se-oxyanions causes isotopic fractionation, and stable Se isotope ratios can be used as a novel tool to detect biological Se cyling in the geological record. In addition, Se isotope ratios, in the geological record as well as in modern environments, may fingerprint specific metabolisms. However, our knowledge about microbially-mediated Se isotopic fractionation is limited due to lack of experimental studies under environmentally relevant Se and electron-donor concentrations. Here we determine new pure culture Se isotopic fractionation factors and investigate their dependence on experimental conditions including selenium and electron-donor concentrations. Results are given as magnitudes of isotopic fractionation, ε (ε=1000*(α-1)[‰]; α = $(^{82}Se/^{76}Se)_{Reactant}/(^{82}Se/^{76}Se)_{Product}$. We aim to investigate metabolically diverse microorganisms, including *Desulfitobacterium* st. Viet1, *Geobacter sulfurreducens* PCA, *Pseudomonas stutzeri* KC, *Aneromyxobacter dehalogenans* FRCW, and *A. dehalogenans* FRC-R5.

The pure cultre of *Desulfitobacterium* Viet1 coupled the reduction of 44µM Se(VI) with oxidation of lactate under strictly anaerobic conditions. This reduction yielded an ε Se(VI)→Se(0) = 9.4±0.3‰ (n=2) . This ε is higher than those previously reported for *Bacillus selenitireducens*, *Bacillus arsenicoselenatis* and *Sulfurospririllum barnesii* [1] and could be useful in explaining very high $\delta^{82/76}$Se values (up to −12.77‰) observed in high-selenium carbonaceous shales from Yutangba deposit, China [2]. Further experiments will determine the ε's for microbial Se reduction under electron-donor rich and electron-donor poor conditions. The results of this study will be useful in interpreting the measured Se isotope ratios in the rock record and may reflect the distribution of microorganisms in modern and ancient Earth.

Geochemistry and thermobarometry of postglacial Llaima tephras

JULIE C. SCHINDLBECK[1] (*), ARMIN FREUNDT[1], STEFFEN KUTTEROLF[1], KAREN STREHLOW[1]

1 GEOMAR, Kiel, Germany, jschindlbeck@geomar.de(*)

Llaima is a large active stratovolcano in the Southern Volcanic Zone in Chile. Field work in 2011 revised the postglacial stratigraphy after Naranjo&Moreno (1991) and led to the subdivision into units I to V. Postglacial activity started 13.500 years ago with caldera-forming eruption of two mafic ignimbrites (unit I). These are overlain by a sequence of three basaltic-andesitic to two dacitic lapilli fallout deposits and reworked tuffaceous sediments (unit II). At ~8600 cal BC a large Plinian eruption emplaced a compositionally zoned dacitic to andesitic fallout tephra (unit III) that became capped by subsequent andesitic surge deposits (unit IV) when the eruption became unstable. The following unit V represents a time interval of ~7000 years during which at least 30 basaltic to andesitic ash and lapilli fallout deposits with intercalated tuffaceous sediments and paleosols were emplaced.

Bulk-rock, mineral and glass chemical analyses constrain the vertical compositional changes of Llaima tephras. Tephra compositions switch between a calc-alkaline differentiation trend (unit I) and a more tholeiitic trend (units II-IV), with samples of unit V varying between both trends, indicating a strong control of $f(O_2)$ (and $P(H_2O)$) on the relative timing of Fe-Ti oxide fractionation. Moreover, iron rich fayalites that are in equilibrium with the glass composition occur in units II and III with calculated T-$f(O_2)$ close to the FMQ suggesting that late-stage fayalite precipitation involved crossing of the FMQ boundary. The younger unit V tephras and historical compositions define a second differentiation trend relatively enriched in K_2O, Rb, Ba and Zr; this is not the results of changing source conditions but can be explained by a stronger early olivine fractionation in the respective magmas.

Thermobarometric calculations based on amph, cpx-liq, plag-liq, ol-liq and Fe-Ti-oxide compositions constrain changing magma chamber positions over time. Storage depths were 14 - 19 km for unit I andesite and and varied between 10 to 17 km for unit II andesites and dacites. The compositionally zoned eruption of units III and IV withdrew dacite magma from ~10 km depth but andesite from a deeper level of 13-15 km. Storage depths of unit V andesitic magmas ranged from 6 to 15 km. Based on temporally changing storage depths and differentiation paths, a 4-stage evolution of the postglacial magmatic system of the Llaima volcanic complex is proposed.

Characterization of U-bearing phases at a U-tailings facility in Sask. Canada

MICHAEL SCHINDLER*[1], JENNIFER DUROCHER[1] AND TOM KOTZER[2]

[1] Laurentian University, Department of Earth Sciences mschindler@laurentian.ca (*presenting author) ; jl_durocher@laurentian.ca

[2] Cameco Corporation, Senior Environmental Geochemist tom_kotzer@cameco.com

Uranium mobility around radioactive waste products such as mine tailings is a growing environmental concern. The characterization of particular U-bearing solid phases in the surface and subsurface around U-mine tailings facilities is essential in understanding and controlling the mobility of uranium [1]. The Key Lake milling facility located in Saskatchewan, Canada, has the world's largest annual U production capacity (25 million pounds U_3O_8) where it processes various grades of U-ore (maximum grade 18%, average grade 4%) from local operations [2]. In general, the ore is crushed; U is dissolved and leached using sulfuric acid and finally extracted and purified using ammonium sulfate and ammonia gas treatments [3]. Mining and milling waste products including tailings (1983-1996) and a portion of the acidic leachates and raffinates are stored in the engineered on-site Above Ground Tailings Management Facility (AGTMF) [4]. The occurrence, paragenesis and chemical composition of U-bearing phases at the AGTMF were examined, in both unconsolidated as well as epoxy impregnated samples to a maximum depth of 10 cm, using Scanning Electron Microscopy, X-ray Diffraction, Raman Spectroscopy, Laser Ablation ICP-MS, X-ray Photoelectron Spectroscopy and synchrotron-based micro-X-ray Fluorescence Spectroscopy. Uranium-bearing phases were observed as micro-sized coatings and included phases belonging to the zippeite group as well as the autunite group. Detailed mineralogical and chemical characterization of the tailings also indicated the presence of β-U_3O_8 (Fig. 1a) and U-bearing gypsum (Fig. 1b).

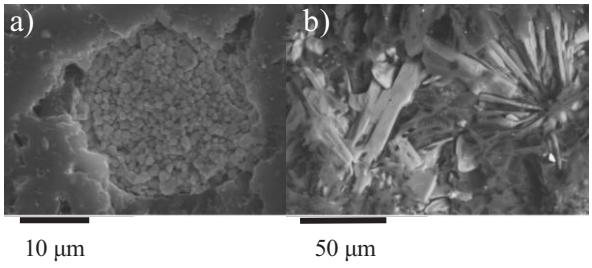

Figure 1: Backskatter electron images of (a) a cluster of β-U_3O_8 and (b) uranium-bearing gypsum.

Pb-isotope measurements and Raman spectra suggest that β-U_3O_8 is an alteration product of uraninite ore rather than a product of the milling process or bacterial reduction. LA-ICP-MS analyses of the gypsum crystals showed surprisingly high U-concentrations which were attributed to nanometre-scale intergrowths and coatings.

The Last Stages of Terrestrial Planet Formation: Dynamical Friction and the Late Veneer

H. E. SCHLICHTING[1,*], P. H. WARREN[1], Q.-Z. YIN[2]

[1]Dept. of Earth & Space Sciences, UCLA 595 Charles E. Young Drive East, Los Angeles, CA 90095 (hilke@ucla.edu) (* presenting author)

[2]Department of Geology, University of California Davis, One Shields Avenue, Davis, CA 95616 (qyin@ucdavis.edu)

The final stage of terrestrial planet formation consists of the cleanup of residual planetesimals after the giant impact phase. Dynamically, a residual planetesimal population is needed to damp the high eccentricities and inclinations of the terrestrial planets to circular and coplanar orbits after the giant impacts stage. Geochemically, highly siderophile element (HSE) abundance patterns inferred for the terrestrial planets and the Moon suggest that a total of about 0.01 $M_\oplus$ of chondritic material was delivered as 'late veneer' by planetesimals to the terrestrial planets after the end of giant impacts. Here we combine these two independent lines of evidence for a leftover population of planetesimals and show that: 1) A residual population of small planetesimals containing 0.01 $M_\oplus$ is able to damp the high eccentricities and inclinations of the terrestrial planets after giant impacts to their observed values. 2) At the same time, this planetesimal population can account for the observed relative amounts of late veneer added to the Earth, Moon and Mars provided that the majority of the accreted late veneer was delivered by small planetesimals with radii ≤10 m. These small planetesimal sizes are required to ensure efficient damping of the planetesimal's velocity dispersion by mutual collisions, which in turn ensures sufficiently low relative velocities between the terrestrial planets and the planetesimals such that the planets' accretion cross sections are significantly enhanced by gravitational focusing above their geometric values. Specifically we find, in the limit that the relative velocity between the terrestrial planets and the planetesimals is significantly less than the terrestrial planets' escape velocities, that gravitational focusing yields a mass accretion ratio Earth/Mars ~ $(\rho_\oplus/\rho_{mars})(R_\oplus/Rmars)^4$ ~17, which agrees well with the mass accretion ratio inferred from HSEs of 12-23. For the Earth-Moon system, we find a mass accretion ratio of ~ 200, which, as we show, is consistent with the mass accretion ratio inferred from HSE abundances of 150-700. We conclude that small residual planetesimals containing about ~ 1% of the mass of the Earth could provide the dynamical friction needed to relax the terrestrial planets' eccentricities and inclinations after giant impacts, and also may have been the dominant sources for the relative and absolute amounts of late veneer added to Earth, Moon and Mars. We argue that the terrestrial planets volatile elements were also delivered by the late veneer in order to account for the ~4.4Ga old terrestrial hydosphere and early felsic crust of granitoids reflected in Hadean zircons [1]. Nanoscale microstructure and texture patterns of bivalve nacre

W. W. Schmahl[1], E. Griesshaber[1], H. S. Ubhi[2]

[1]Department of Earth and Environmental Sciences, LMU München, Germany, wolfgang.schmahl@lrz.uni-muenchen.de

[2]Oxford Instruments, Halifax Road, High Wycombe, UK, Singh.Ubhi@oxinst.com

Biological hard tissues are hierarchical composites. EBSD is one of the best methods available for structural characterization of biological tissues, since it provides microstructure imaging and crystal orientation determination on several hierarchical levels. While the conventionally used 20 kV acceleration voltage yields EBSD with a spatial resolution in the micrometer range, high resolution, low kV (8 to 15) EBSD renders a 100-400 nm step resolution. This enables the investigation of nanostructures such as orientation patterns in the nacreous parts of biological skeletons.

We could map orientation patterns of calcite with high resolution, low kV (8 to 15) EBSD. This rendered measurements with 100-400 nm step resolution and enabled for the first time the investigation of biological nanostructures, especially orientation patterns in nacre and the nacreous parts of biological skeletons. The investigated specimens are the nacreous portions of the oyster *Crassostrea gigas* and of the bivalve *Mytilus edulis.* Further, we investigated the shells of *Elliptio crassidens*, *Cristaria plicatus* (composed entirely of nacreous aragonite) and the pearl of the freshwater mollusk *Hyriopsis cumingii*. The aragonite nanoplatelets are untwined single crystals that assemble to platelets. Stacks of almost equally oriented platelets form clusters with distinct orientations. Within a cluster the orientation goes across the platelets, while neighbouring platelets that belong to different clusters often form twin related orientations (rotation by 60 degrees around the c-axis). The normal to the platelets is the c-axis (setting: a=4.96 Å, b=7.97 Å, c=5.75 Å). The size of the correlated clusters and the abundance of twin relationships between adjacent platelets varies significantly between the investigated mollusk species.

For *Crassostrea gigas*, *Cristaria plicatus* and the pearl of *Hyriopsis cumingii* one crystal orientation dominates, such that the overall texture pattern has a 3D single crystal like appearance. For *Mytilus edulis* and *Elliptio elliptio* the three twin orientations are of similar abundance.

3D STXM tomography of Fe(II)-oxidizing bacteria

Gregor Schmid[1*], Likai Hao[1], Andreas Kappler[1], Martin Obst[1]

[1]University of Tuebingen, Germany, Center for Applied Geoscience, gregor.schmid@uni-tuebingen.de (* presenting author) likai.hao@uni-tuebingen.de, andreas.kappler@uni-tuebingen.de, martin.obst@uni-tuebingen.de

In pH-neutral environments ferrous iron can be oxidized under anoxic or microoxic conditions by Fe(II)-oxidizing bacteria. Different microbial metabolisms of Fe(II) oxidation and biomineralization of these bacteria have been identified and characterized so far. Initial Fe(III) mineral precipitation in the periplasm and subsequently cell encrustation was observed with the mixotrophic, nitrate-reducing, Fe(II)-oxidizing *Acidovorax* sp. strain BoFeN1 isolated from anoxic littoral sediments from Lake Constance, Germany [1]. Iron mineral precipitation in vicinity to the cell was shown for the phototrophic, anaerobic Fe(II)-oxidizing *Rhodobacter* sp. strain SW2 [2]. Also, under microaerophilic conditions iron minerals can be deposited within extracellular polymeric structures such as twisted stalks or sheats which are extruded by microaerophilic *Gallionella* strains [3].

To further our understanding of the different mineralization patterns and mechanisms of Fe-biomineralization, we investigated BoFeN1, SW2 and an environmental biofilm containing twisted stalks (similar to those observed for *Gallionella* strains) from an abondoned silver mine in Germany. We conducted conventional soft X-ray scanning transmission microscopy (STXM) in combination with angle-scan tomography measurements allowing for a 3D reconstruction. The advantage of STXM is the combination of high spatial resolution (≈10 nm) with the possibility of identifying and quantifying cell components such as proteins and lipids, extracellular polymeric substances (EPS) and iron minerals. Therefore, we acquired image sequences across the C1s, O1s and Fe2p absorption edges for BoFeN1, SW2 and an environmental biofilm containing twisted stalks. Compositions maps of the macromoleculars components were obtained by linear combination fits of reference spectra of proteins, lipids, polysaccharides and iron minerals. The association of the Fe-phases with the organic components of the cell-mineral aggregates was then analyzed quantitatively in 3D by correlation analysis.

Our results confirmed that iron is precipitated within the periplasm of BoFeN1, in contrast to SW2 and the environmental biofilm where the iron precipiates are closely asscociated with organic expolymers.

Interpretation of Lu-Hf garnet geochronology by investigation of HREE zoning profiles

ALEXANDER SCHMIDT [1a*], MATTHIAS KONRAD-SCHMOLKE [1b]

1 Institute of Earth- & Environmental Science, University of Potsdam, Germany
[a] alexander.schmidt@geo.uni-potsdam.de (* presenting author)
[b] mkonrad@geo.uni-potsdam.de

Garnets are well suited for Lu-Hf and Sm-Nd geochronology, and a growing number of studies now focus on the Lu-Hf system for evaluating the evolution of different types of metamorphic rocks, because of the difference in the ages obtained by the two isotope systems (Lu-Hf dating early, Sm-Nd dating late growth). However, the interpretation of ages obtained for garnets by the Lu-Hf system is not always straightforward due to the ambiguity in the explanation of observed sharp Lu-peaks in garnet cores. Garnet strongly controls the Lu (and other HREE) budget of many metamorphic rocks, and also more often than not inherit information obtained during pro- and retrograde growth through enrichment of Lu & HREE in early formed cores. The mere occurrence of sharp Lu peaks in garnet cores in rocks of (ultra)high-pressure and high-temperature conditions indicates a resistance to metamorphic resetting, therefore attesting to the suitability of Lu-Hf garnet geochronology for complex metamorphic rocks.

In this study we concentrated on the Lu & HREE distribution in garnets from different metamorphic rocks to evaluate the modes of incorporation during growth and also processes of resetting of these growth profiles. We also investigated the impact of these growth profiles on the Lu and Hf isotopic composition of different garnet zones, trying to determine growth rates of garnets, and how this will affect the Lu-Hf ages obtained for bulk-garnet separates. This includes both a model approach to assess the influence of several garnet growth events on bulk garnet ages, as well as the "in-situ" (small portions of a garnet zone cut-out/drilled-out) measurement of the isotopic composition in suitable garnet grains.

As more garnets from different types of rocks are being analysed for their potential Lu growth profiles our understanding of how to interpret the obtained ages is improving, especially when we compare Lu-Hf ages with geochronology of other minerals based on other isotope systems. Hence a larger database will shed light on the discussion of e.g. which mineral best yields an age estimate for prograde, peak and retrograde conditions in a metamorphic rock.

Experimental study on the pseudobinary H_2O+$NaAlSi_3O_8$ at 600–800 °C and to 2.5 GPa

CHRISTIAN SCHMIDT[1*], ANKE WATENPHUL[2], ANKE WOHLERS[1], AND KATHARINA MARQUARDT[1]

[1] GFZ German Research Centre for Geosciences, Potsdam, Germany, christian.schmidt@gfz-potsdam.de (* presenting author), anke.wohlers@gfz-potsdam.de, katharina.marquardt@gfz-potsdam.de
[2]Hamburger Synchrotronstrahlungslabor HASYLAB at Deutsches Elektronen-Synchrotron DESY, Hamburg, Germany, anke.watenphul@desy.de

There are still uncertainties in phase relations in the high-temperature portion of P-T diagrams for H_2O+$NaAlSi_3O_8$ (e.g., [1]). Dissolution of albite in H_2O is usually considered to be congruent or nearly congruent [2], although many experiments showed formation of the aluminous solids paragonite (e.g., at 500–650 °C, 0.5–0.9 GPa [2], at 500 °C, 0.2–0.7 GPa and 600 °C, 0.4–0.8 GPa [3], and at 700°C, 1–1.5 GPa [4]) and corundum (e.g., at 800 °C, 0.7–2 GPa [4]). However, some of these P-T conditions intersect that of the critical curve [5] along which no solid phase can be present. For information to resolve this conflict, we conducted experiments on several pseudobinary mixtures between 39 and 54 wt% $NaAlSi_3O_8$, i.e., near the critical composition [5]. The system was studied by optical observation and Raman spectroscopy using a hydrothermal diamond-anvil cell [6]. Synthetic zircon was used as Raman spectroscopic pressure sensor [7].

At the start of each run, the assemblage silicate glass and aqueous fluid was heated to 600 °C. Then, the resulting melt and aqueous fluid were held at this temperature until a solid had formed. Jadeite grew rapidly at $P \geq 2$ GPa. In experiments at pressures to 1.06 GPa, albite nucleated within a minute to a few hours. Paragonite formed at 1.64 GPa in an experiment with 54 wt% $NaAlSi_3O_8$ and at 1.09 GPa at 39 wt% $NaAlSi_3O_8$. Upon heating, paragonite was still present at and above the temperature of homogenization of silicate melt and aqueous fluid to a single fluid phase, whereas albite always showed the expected melting at temperatures less than that of melt and aqueous fluid homogenization.

Our data indicate that the high-pressure portion of the critical curve [5] is a metastable extension at $T < 760$ °C, at which paragonite is stable. Furthermore, the formation of a substantial fraction of paragonite at intermediate bulk $NaAlSi_3O_8$ concentrations implies that the aqueous fluid must have a peralkaline composition, which in turn enhances the solubility of high field strength elements. The obtained data for the P-T location of the critical curve based on the determined isochores are close to or at slightly higher pressure than those reported in ref. [5].

The arc delaminate: a geochemical reservoir twice the size of the continental crust

MAX W. SCHMIDT[1*]. OLIVER JAGOUTZ[2]

[1]Dep. Earth Sciences, ETH Zurich, Switzerland, max.schmidt@erdw.ethz.ch (* presenting author)
[2]Dep. Earth Atmos. Planet. Sciences, MIT, Cambrige, USA, jagoutz@mit.edu

Most primitive melts in arcs are basaltic in composition but the continental crust or arc average is andesitic. To evolve from a primitive basalt to an andesitic composition, cumulates have to be fractionated and, if gravitationally unstable, can be delaminated. Such lower crustal cumulates are exposed in the Kohistan arc (N Pakistan) in a 10 km section through dunites, wehrlites, websterites, cpx-bearing garnetites and hornblendites, and garnet gabbros. We have compiled primitive melts for nine island arcs from the literature and fitted these with the bulk Kohistan arc [1] or average bulk continental crust [2] and the Kohistan cumulates. By average, ~15 wt% wehrlite + ~20% garnet hornblendite + ~35% garnet gabbro complement ~30% arc or continental crust and explain very well (r^2~2) the evolution from a tholeiitic/calc-alkaline primitive high-Mg basalt to the continental crust. The bulk delaminate has 44-48 wt% SiO_2, total alkalis of 1.1-1.4 wt% and an X_{Mg} of 0.67-0.69. Mass fractions derived from major elements were employed to compare trace elements: cumulates+crust deviate on average only by 25-30% from primitive melts, with the biggest deviations on the subduction-added traces. Relative to the continental or arc crust, the delaminate mass results to 1.8-2.5 times that of the continental crust.

The delaminates have ρ=3.2-3.5 g/cm^3 and V_P=7.9-8.2. At the base of the crust, they are thus difficult to distinguish seismically. Once reaching a critical thickness, they may sink into the deeper mantle where they form a geochemical reservoir twice the size of the continental crust. With respect to primitive mantle, the delaminate is enriched in Ba, K, Sr, and P and REE with LREE<HREE. The delaminate reservoir would develop highly unradiogenic Pb over time and would counterbalance the radiogenic MORB and OIB reservoirs. Delamination of twice as much material as remains in the arc crust increases the flux of primitive melt in arcs threefold. This places the magma production rate at arcs (per km arc length) slightly above that at mid-ocean ridges indicating that global fluxes and magmatic heat loss need to be revised.

Structural changes on dehydration of amorphous calcium carbonate

MILLICENT P. SCHMIDT[1*], BRIAN L. PHILLIPS[1], ANDREW J. ILOTT[2], AND RICHARD J. REEDER[1]

[1]Stony Brook Unviersity, Geosciences, Stony Brook, NY USA millicentpschmidt@gmail.com (* presenting author), brian.phillips@sunysb.edu, rjreeder@stonybrook.edu
[2]Stony Brook Unviersity, Chemistry, Stony Brook, NY USA andyilott@gmail.com

Introduction and Methods

Amorphous calcium carbonate (ACC) is a common transient precursor to biogenic calcium carbonate, but the transformation and stabilization mechanisms remain unknown. Studies have shown that the calcium carbonate biomineralization pathway for two different biogenic ACC samples follows the progression of hydrated ACC ➔ anhydrous ACC ➔ calcite, aragonite and/or vaterite.[1][2] In this study, we present a structural analysis and comparison of hydrated and partially-dehydrated, synthetic ACC applying novel synthesis techniques to examine the under-studied first transformation step in the biomineralization pathway.

ACC was synthesized using three different methods and then partially-dehydrated by heating to temperatures below the crystallization temperature (ca. 185 °C or 330 °C depending on the synthesis method).[3][4] Hydrated and partially-dehydrated ACC samples were analyzed by X-ray absorption fine structure (XAFS) spectroscopy, pair distribution function (PDF) analysis from X-ray total scattering, FT-IR spectroscopy, thermal analysis, and nuclear magnetic resonance (NMR) spectroscopy.

Results and Conclusions

Thermal analysis showed total mass losses averaging 10% (46% loss of total water) with dehydration to 115 °C (16% and 75%, respectively for heating to 150 °C). XAFS and total scattering results showed no evidence of significant structural changes with heating, suggesting that the effects of dehydration relate primarily to the water component in ways that are largely insensitive to the X-ray based techniques. FT-IR spectra show a loss of structural water as evidenced by decreases in the intensity of the O-H bending and stretching bands at 1630 and 3300 cm^{-1}, respectively. The ^{1}H NMR spectra of hydrous ACC, obtained indirectly via ^{13}C-detection, contain signals from three principal hydrogen environments: a broad spinning sideband envelope from rigid structural water, a narrow peak near +5 ppm from restrictedly mobile water, and a small narrow peak at +0.2 ppm due to hydroxyl. Dehydration of ACC leads to a reduction in signal intensity from both rigid and mobile water that increases with increased dehydration temperature but with little change in their relative proportions. No significant change in the intensity of the hydroxyl peak was observed in samples heated up to 200 °C. The retention of some restrictedly mobile water and lack of change in the PDFs from X-ray total scattering in dehydrated ACC suggest that thermal dehydration does not significantly disrupt the calcium-rich framework of the ACC [5].

Actinide sorption and reactivity at the muscovite-aqueous interface

M. SCHMIDT[1, 2,*], S. S. LEE[1], R. E. WILSON[1], K. E. KNOPE[1], P. FENTER[1], L. SODERHOLM[1]

[1]Chemical Sciences and Engineering Division, Argonne National Laboratory, Argonne, IL, USA

[2]Current Address: Institute for Nuclear Waste Disposal, Karlsruhe Institute for Technology, Karlsruhe, Germany, moritz.schmidt@kit.edu (* presenting author)

Introduction

We present recent findings regarding the interaction of tri- and tetravalent actinides (Th, Pu) with the charged (001) basal plane of muscovite. *In situ* crystal truncation rod measurements and resonant-anomalous x-ray reflectivity were applied to investigate structures in the near-interface region under varying solution conditions (ionic strength, actinide concentration, chemical speciation of the actinide, background electrolyte).

Results

The results show a broad variety of potential forms of interaction, that strongly depends on the actinides' aqueous chemistry. The strongly hydrated cations do not shed their hydration layers upon sorption, but remain as extended outer sphere complexes [1]. In this sorption state the cations are highly concentrated in the near-interface region, and also highly mobile which allows for subsequent reactions (e.g. polymerization) between sorbed species to occur. In the case of plutonium this interfacial reactivity has been found to dominate the sorption behavior.

The results are expected to provide valuable input to the ongoing discussion about potential nuclear waste repository strategies as well as enrich the molecular level understandifng of the actinides' environmental geochemistry in general.

Natural organic matter (NOM) occurs in soils, freshwater, marine and hydrothermal environments, in the atmosphere and represents an exceedingly complex mixture of organic compounds that collectively exhibits a nearly continuous range of properties (size-reactivity continuum). The fate NOM in the bio- and geosphere is governed according to the rather fundamental restraints of thermodynamics and kinetics. In these intricate materials, the "classical" signatures of the (geogenic or ultimately biogenic) precursor molecules, like lipids, glycans, proteins and natural products have been attenuated, often beyond recognition, during a succession of biotic and abiotic (e.g. photo- and redox chemistry) reactions. NOM incorporates the hugely disparate characteristics of abiotic and biotic complexity.

Numerous descriptions of organic molecules present in organic chondrites (COM) have improved our understanding of the early interstellar chemistry that operated at or just before the birth of our solar system. However, all molecular analyses were so far targeted toward selected classes of compounds with a particular emphasis on biologically active components in the context of prebiotic chemistry. Here we demonstrate that a non-targeted molecular analysis of the solvent-accessible organic fraction of Murchison extracted under mild conditions allows one to extend its indigenous chemical diversity to tens of thousands of different molecular compositions and likely millions of diverse structures. This molecular complexity, which provides hints on heteroatoms chronological assembly, suggests that the extraterrestrial chemodiversity is high compared to terrestrial relevant biological and biogeochemical-driven chemical space.

(ultra)High resolution analytical approaches will be presented in their application to unravel the chemical nature and organic signatures in biosystems [1], geosystems [2-4] with a focus on extreme environments such as hydrothermal and meteoritic origins [5] with a special focus on sulphur organic compounds.

Multi-scale geochemical time series constraints on Archean lithosphere formation

BLAIR SCHOENE[1]* AND C. BRENHIN KELLER[1]

[1]Princeton University, Princeton, NJ, 08544 USA, bschoene@princeton.edu*, cbkeller@princeton.edu

Robsust comparisons of lithosphere formation processes in the Archean, Proterozoic and Phanerozoic require: 1) geochronology of adequate resolution to sequence magmatic and stuctural processes with precision relevant to tectonic processes (~1 Ma), which has been difficult in older terranes; 2) an unbiased and continuous assessment of secular change in, for example, petrologic processes through Earth history.

Recent advances in chemical abrasion ID-TIMS U-Pb geochronology permit sub-million year precision on $^{207}Pb/^{206}Pb$ dates of single closed system Archean zircons. Applied to the pristine ca. 3.2 Ga Usutu magmatic system in the eastern Kaapvaal craton, such high-precision geochronology permits evaluation of geochemical evolution during piecewise batholith construction over <20 Ma. Combined with structural data and placed into the context of the adjacent Barberton greenstone belt, these constraints are used to construct a model where regional subhorizontal contraction occurred synchronous with emplacement of an evolving magmatc system. The temporal resolution provided by this work is unprecedented in Archean systems, and allows direct comparison with Phanerozoic arc- and plume-related magmatic systems.

In order to reconstruct billion-year records of secular variation in the continental rock record, we have compiled a database of over 70,000 igneous samples from various sources, each with age, spatial coordinates, and major and trace element data. Monte Carlo simulations with weighted bootstrap resampling significantly reduces sample collection and temporal biases, and allows precise estimation of mean global igneous geochemistry for 3.8 Ga. Both low SiO_2 (basalts) and evolved high SiO_2 rocks show statistically significant trends through time, the former being consistent with decreasing mantle melt fraction in the present and the latter showing increased importance of deep crustal fractionation/partial melting and TTG production in the Archean. Mean values of many geochemical proxies from both SiO_2 ranges show step functions near 2.5 Ga. These data support a model linking high degree mantle melting and lower crustal delamination and TTG production as being more important in the Archean; this process is largely independent of driving plate tectonic models but can be used to inform them.

Our geochemical dataset can be directly linked with geophysical models estimating crustal and lithospheric thickness, heat flow, and seismic velocities. Doing so reveals correlations between, for example, mean crustal thickness and mean geochemistry of continental igneous rocks, that change through time. This secular variation can provide a connection between the formation of continental lithosphere and magma production and evolution, and be used to inform tectonic models for specific terranes. Conversely, inferences from long term average records must be consistent with detailed structural, geochronological, and geochemical studies of preserved crust.

Was more continental crust destroyed than created during Phanerozoic time?

DAVID W. SCHOLL[1*] and ROBERT J. STERN[2]

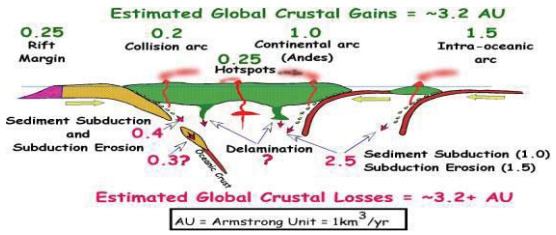
[1]University of Alaska Fairbanks, USA, dscholl@usgs.gov
[2]University of Texas, Dallas

Introduction

It is easy to study what exists but not what has disappeared, so it is generally assumed that the volume of continental crust has increased with time. Field observations can be used to estimate how much new, (juvenile) mantle-derived continental and island arc (CIA) crust is generated and how much CIA material is lost (recycled) to the mantle. Greatest additions (via arc magmatism) and losses (via sediment subduction and subduction erosion) occur at ocean-margin and crust-suturing (collisional) subduction zones (SZs). Lesser volumes are added to plate interiors at rifted margins and hotspots and removed by lower crust delamination.

Estimated Phanerozoic Gains and Losses

The best estimates for additions and losses come from geophysical, geological, and drilling studies of modern SZs and, less reliably, from fossil Cenozoic and older ones. We have estimated that long-term average gains and losses for the Phanerozoic are similar at ~3.2 km^3/yr (i.e. 3.2 AU--Armstrong Units) [1]. These estimates, which do not include a term for



crustal foundering, are comparable to, but distinctly lower than, those of Clift et al. [2] (additions <5 AU, losses ~4.9 AU) or losses (5.25 AU) assessed by C. R. Stern [3]. The range of these estimates usefully captures our present understanding and uncertainty. Losses are least constrained for deeply subducted continental crust, for example Africa, Arabia, India, and northern Australia today, and at older collisional SZs, and by crustal delamination.

Plausible Net Phanerozoic Crustal Loss

It seems likely that at crust-suturing SZs estimated losses of deeply subducted CIA crust (based chiefly on two examples, the Paleoproterozoic Wopmay orogen of NW Canada and the Cenozoic Melanesian orogen of New Guinea), could easily be higher than our [1] estimate of 0.3 AU, and certainly a loss must be considered for our un-estimated volume of lower crust delamination. In consideration of these concerns, the uncorrected-for component of remelted older crust in continental (Andean) arc magma, and the higher volumes of recycled crust estimated by Cliff et al. [2] and C. R. Stern [3], it is plausible that during at least the Phanerozoic the net product of gains and losses has been to reduce Earth's inventory of CIA crust.

Iron (Fe) is a key element in the global ocean's biogeochemical framework because of its essential role in numerous biological processes. A poorly studied link in the oceanic Fe cycle is the reductive release of Fe from sediments in oxygen depleted ocean regions - the oxygen minimum zones (OMZs). Changing rates of Fe release from OMZ sediments may have the potential to modulate ocean fertility which has far-reaching implications considering the high amplitude oxygen fluctuations throughout earth history as well as the ongoing ocean deoxygenation projected for the near future. In order to explore spatial and temporal trends of Fe cycling in OMZs, we present here Fe isotope and speciation data for surface sediments from a transect across the Peruvian upwelling area, one of the most pronounced OMZs of the modern ocean.

Because of continuous dissimilatory Fe reduction and diffusive loss across the benthic boundary, sediments within the OMZ are strongly depleted in reactive Fe components, and the little reactive Fe left behind has a heavy isotope composition. In contrast, surface sediments below the OMZ are enriched in reactive Fe, with the majority being present as Fe oxides with comparably light isotope composition. This lateral pattern of Fe depletion and enrichment indicates that Fe released from sediments within the OMZ is reoxidized and precipitated at the oxycline. First-order calculations suggest that the amount of Fe mobilized within the OMZ and that accumulated at the boundaries are largely balanced. Therefore, benthic Fe fluxes in OMZs should be carefully evaluated prior to incorporation into global models, as much of the initially released Fe may be reprecipitated prior to vertical or offshore transport.

First XRF core scanning results for partly laminated piston cores from the OMZ boundaries reveal downcore oscillations in the content of reactive Fe and redox-sensitive trace metals that are attributed to past changes in OMZ extension. Ongoing work on these cores will focus on their dating and the downcore investigation of Fe and trace metal records in order to better understand past Fe cycling within the Peruvian OMZ and potential interactions with climate variability.

Lung Fluid-Mineral Interaction: Experimental Challenges and Outcomes

MARTIN A. SCHOONEN[1*], ANDREA HARRINGTON[1]

[1]Stony Brook University, Department of Geosciences martin.schoonen@stonybrook.edu (*presenting author) Andrea.Harrington@stonybrook.edu

Introduction

The inhalation of mineral dust can potentially lead to lung disease. Perhaps the best-known examples are exposure to asbestos, quartz, and coal, which can lead to mesothelioma, silicosis, and coal workers' pneumoconiosis, respectively. Despite clear causal evidence, the mechanisms by which mineral particles induce these diseases remain, in part, unknown. Geochemists are in a position to contribute to a better understanding of the mechanisms by which particles induce disease by conducting experimental studies to determine mineral biodurability and their ability to generate reactive oxygen species (ROS). Biodurability is an important factor as it expresses how long a particle is expected to remain in the lung after inhalation on the basis of its solubility in lung fluid. ROS are intermediate species in the reduction of molecular oxygen. Hydrogen peroxide and hydroxyl radical are the two most important ROS. Recent work shows that minerals, such as pyrite and olivine, produce hydrogen peroxide and hydroxyl radical when dispersed in water. Hydroxyl radical is particularly detrimental to human health.

While there is a wealth of data on the dissolution of minerals in water and some data is available on ROS formation in mineral slurries, few experiments have been conducted in a lung fluid proxy. A promising avenue of research is to conduct mineral dissolution experiments in Simulated Lung Fluid (SLF). There is, however, no single, standard recipe for SLF. One approach is to create a "simple" SLF solution that contains a phosphate buffer and several inorganic salts and organic acids. This formulation captures the essentials in terms of pH and ionic strength, but lacks complexity due to the absence of proteins, lipids and other macromolecules.

A comparison of pyrite dissolution rate in water and a simple SLF showed a drastic decrease in rate of dissolution in SLF. Addition of Survanta™, a bovine pulmonary surfactant, showed little or no change in rate, suggesting that the addition of the natural mixture of lipids, proteins and other biomolecules had no effect on dissolution rate. On the other hand, the addition of Survanta™ did lead to a rapid decrease of hydrogen peroxide in the slurry.

Conclusion

It is possible for Geochemists to contribute to a better understanding of lung diseases triggered by inhalation of mineral dust by conducting experiments with well-characterized minerals in SLF. While the addition of complex biomacromolecules is likely to affect the stability of hydrogen peroxide and possibly hydroxyl radical, dissolution rate data obtained in simple SLF are probably good biodurability indicators. The speciation of ROS is affected by the presence of complex biomolecules. It is possible that their presence promotes reactions that consume hydrogen peroxide and/or hydroxyl radicals.

Towards a consistent quantitative description of mineral precipitation and dissolution rates

J. SCHOTT[1*], E. H. OELKERS[1], P. BÉNÉZETH[1], Q. GAUTIER[1], O.S. POKROVSKY[1], G. JORDAN[2], AND G.D. SALDI[3]

[1]Université de Toulouse & CNRS, GET, Toulouse, France, jacques.schott@get.obs-mip.fr (*presenting author)
[2]Ludwig-Maximilians-Universität München, Germany
[3]Lawrence Berkeley Laboratory, Earth Science Div., Berkeley, USA.

Knowledge of the mechanisms and rates of mineral dissolution and precipitation, especially at close to equilibrium conditions, is essential for describing the temporal and spatial evolution of natural and industrial processes including weathering, diagenesis, hydrothermal deposit formation, CO_2 sequestration, and radioactive waste disposal. The Surface Complexation approach (SC) combined with Transition State Theory (TST) provides an efficient framework for describing mineral dissolution over wide ranges of solution composition, chemical affinity, and temperature. There has been a large debate for several years, however, about the comparative merits of SC/TS versus classical growth theories for describing mineral dissolution and precipitation at near to equilibrium conditions. The paucity of combined microscopic and macroscopic rate measurements on identical samples has prevented reconciliation of the surface coordination chemistry and crystal growth approaches.

This study considers recent results obtained in our laboratory on quartz, brucite, gibbsite, boehmite, kaolinite, magnesite, dolomite, and hydromagnesite dissolution and precipitation at near to equilibrium conditions via the combination of complementary techniques including batch and mixed flow reactors, hydrogen-electrode concentration cell (HECC), potentiometric titration cell, and hydrothermal atomic force microscopy (HAFM). Results show that the dissolution and precipitation of hydroxides, kaolinite and hydromagnesite powders of relatively high surface area closely follow SC/TST rate laws with a linear dependence of both dissolution and precipitation rates on fluid saturation state even at close to equilibrium ($\Delta G < 500$ J/mol) conditions. This occurs because sufficient reactive sites are available for dissolution and growth (kink, steps, edges) allowing reactions to proceed via the direct and reversible detachment/attachment of reactants at the surface. In contrast, for quartz and magnesite crystals, whose surfaces contain much fewer active sites, crystal growth (and dissolution) rates at near equilibrium conditions exhibit either a parabolic (defect assisted nucleation, spiral growth) or linear (attachment/detachment at reactive sites) dependence on saturation state depending on the treatment of the crystals before the reaction. For example, after extended dissolution (a process that creates active sites) both quartz and magnesite crystals exhibit transient linear growth rates. SC/TST rate laws can thus be applied only to those minerals that have abundant reactive sites density. It follows that determination of the active site density and origin (screw dislocations, preexisting steps…) on mineral surfaces is critical to identifying the mechanism and thus the rate equations that can describe quantitatively mineral dissolution and precipitation rates as a function of fluid composition in natural and industrial processes.

Intact polar tetraether lipids in the Arabian Sea water column and sediments: Implications for TEX_{86} paleothermometry

STEFAN SCHOUTEN[1,*], SABINE LENGGER[1], ANGELA PITCHER[1], ELLEN C. HOPMANS[1], LAURA VILLANUEVA[1] AND JAAP S. SINNINGHE DAMSTÉ[1]

[1]Royal Netherlands Institute for Sea Research, PO Box 59, Den Burg, Texel, The Netherlands. stefan.schouten@nioz.nl (* presenting author)

The TEX_{86} is an increasingly used paleotemperature proxy and relies on the fact that temperature affects the number of cyclopentane moieties in thaumarchaeal membrane lipids (glycerol dibiphytanyl glycerol tetraether lipids, GDGTs). In living Archaea, these lipids are present as intact polar lipids (IPL) with sugar- and/or phosphate-containing head groups attached to the core lipids (CL). Most studies on TEX_{86}, however, have up to now examined (fossil) CL GDGTs rather than IPL GDGTs, derived from living Archaea.

In this study, we examined the distribution and TEX_{86}-values of CL and IPL GDGTs in both the water column and sediment cores of the Arabian Sea, which contains a pronounced oxygen minimum zone. The depth profiles of crenarchaeol core lipid with a phosphohexose or dihexose head group match profiles of (expressed) genes specific for ammonia-oxidizing Thaumarchaeota. However, crenarchaeol with a hexose head group did not match the genetic depth profiles, suggesting that this IPL is partially of fossil origin. Furthermore, the concentration profiles of core lipid crenarchaeol and IPL-derived crenarchaeol showed a second peak in their abundance within the core of the OMZ which was not found in the archaeal gene concentration profiles. This representing additional evidence for a fossil contribution to the IPL pool, specifically for the glycosidic GDGTs. TEX_{86} values of both fossil core lipid and IPL-derived GDGTs increased from surface waters to the core of the OMZ, below which they decreased again, and did not correlate with *in situ* temperature. TEX_{86} values of IPL-derived GDGTs did correlate well with the relative amount of glycosidic GDGTs and were consistently higher than that those of CL GDGTs.

We subsequently isolated IPL GDGTs from Arabian Sea sediments to determine cyclopentane distributions and TEX_{86} of the individual IPL GDGTs. We observed strong differences in GDGT-composition amongst head groups: GDGT-2 and -3 (numbers indicate the number of cyclopentane moieties) are predominantly present as glycolipids, while GDGT-1 is predominantly present as phosphoglycolipid. A similar observation is made for IPL GDGTs of enriched Thaumarchaeota, i.e. GDGT-0, -1 and crenarchaeol predominantly occurring as CL of phosphoglycolipids, and GDGT-2, -3 and -4 as CLs of dihexose GDGTs [1]. As a consequence, in enrichment cultures, the TEX_{86} shows a relation with the relative amount of dihexose GDGTs, i.e. increasing TEX_{86} with increasing amount of dihexose GDGTs.

Our results thus suggests that head group composition of IPL GDGTs in Thaumarchaeota and selective preservation of glycosidic GDGTs during diagenesis may strongly impact TEX_{86} values of produced GDGTs in deep marine waters.

Arsenic in soils from poultry litter application

MADELINE E. SCHREIBER[1]*

[1]Department of Geosciences, Virginia Tech, Blacksburg, VA 24061 USA (*presenting author, mschreib@vt.edu)

Introduction

The use of organoarsenicals in poultry feed additives has raised a concern about air, water and soil quality in regions of poultry production. This study examined the impact of poultry litter application on the distribution of As and other trace elements in soils. Soils from fields with varying litter applications in the Shenandoah Valley, Virginia, a region of intense poultry production, were collected, digested and analyzed for trace elements of interest. Data were statistically analyzed to examine relationships between litter application rates and trace element concentrations.

Methods

Sixteen cores were collected from the Frederick series, a well-drained silt loam. Sites were selected to represent soils with different histories of litter use: no litter use (control), and low, moderate and high litter use. The three litter amended sites had the following estimated litter application rates: 1.5 tons/acre/year (low), 3 tons/acre/year (moderate) and 6 tons/acre/year (high). At each site, four locations were chosen randomly for soil core collection. Soils in 15 cm increments were collected the surface to 120 cm depth. A total of 128 soil samples were collected for analysis. Soil samples were dried and ground, measured for particle size, organic matter and pH. Subsamples were digested for both Mehlich-extractable elements and acid-extractable elements (As, P, K, Ca, Mg, Zn, Cu, Fe). Statistical analysis was conducted on the dataset using several techniques, including correlation analysis, 1-way ANOVA comparison of means, and principal component analysis using JMP.

Results and Conclusions

Statistical analysis revealed that As does not concentrate in litter-amended soils, in contrast to litter-derived species P, Cu and Zn. While P, Cu, and Zn concentrations decrease with depth in the soil profile, As concentrations increase with depth in all soils and are correlated with iron and clay content, suggesting that As is adsorbed to iron oxides and clays, even in control soils that have not received litter application. At the highest litter application rate (20,000 kg/hectare/year; equivalent to 6 tons/acre/year), an As litter concentration of 40 mg/kg, a soil density of 1.6 m^3/kg, and a 30 year period of litter application, As concentrations in the top 20 cm of litter-amended soil are predicted to be only 4.5 mg/kg above background concentrations, assuming conservative behavior. This low level of As may be difficult to detect, especially in heterogeneous soils. Transport of As in due to competitive desorption by phosphate and DOC, complexation, or adsorption onto mobile particles may also contribute to the lack of observed accumulation of As in soils.

Growth of *Streptomyces mirabilis* P16B1 in heavy metal contaminated soil and impact to Soil Organic Matter formation

EILEEN SCHÜTZE(*)[1], MICHAEL KLOSE[1],DIRK MERTEN[2], SANDOR NIETZSCHE[3], MATTHIAS KÄSTNER[4], ERIKA KOTHE[1]

1 Institute for Microbiology - Microbial Phytopathology, Friedrich-Schiller-University, Neugasse 25, D-07745 Jena, Germany, (Email: eileen-schuetze@web.de)
2 Institute of Geosciences, Friedrich-Schiller-University, Burgweg 11, D-07749 Jena, Germany
3 Centre of Electron Microscopy, Friedrich-Schiller-University Jena, Ziegelmühlenweg 1, D-07740 Germany
4 Helmholtz Centre for Environmental Research - UFZ, Department of Bioremediation, Permoserstraße 15 , D-04318 Leipzig, Germany

It has been shown that streptomycetes are a dominant group of bacteria in heavy metal contaminated soil and that growth of soil bacteria had positive effects on bioremediation, on bioavailability of metals in soil and on biogeochemical cycles.

The former uranium mining site Wismut in Eastern Thuringia, Germany, shows extreme environmental conditions such as scant nutrients, intense salt load and low pH, followed by high metal content. Such habitats only can be colonized by microbes which are adequately adapted. Actinobacteria isolated from this hostile environment show high resistances against a range of heavy metals like nickel, cobalt, cadmium or zinc. Growth of *Streptomyces mirabilis* P16B1 was investigated in mesocosms of contaminated soil from the especially nickel and zinc contaminated sample sites K7 (WISMUT area Ronneburg, Germany). As control uncontaminated soil PaO (paradise parc Jena, Germany) was used. Heavy metal sensitive *S. lividans* TK24 was used as control in both types of soil as well as dead biomass from both used strains. This experiment gave insight in growth and contribution to soil organic matter (SOM) formation of the strain, as well as its impact to heavy metal availability. Scanning electron microscopy and XRD analysis were used to detect the mycelium, spore production, as well as dead bacterial biomass and its attachment to soil particles as patchy fragments. The metal content of soil from the samples was determined by SE methods and MS. Superoxide-dismutase (SOD)-production of *S. mirabilis* P16B1 under natural conditions was detected via native PAGE and qualitative SOD-staining as well as quantitative Assay with extracted protein. Auxine production and siderophore production were measure via MS.

It could be shown that inoculation with the strain has an effect of SOM formation in soil, as well as heavy metal availability in mobile and specifically adsorbed fraction. Due to Fenton reaction and elevated concentration of heavy metals SOD expression could be seen as an important resistance factor of strains. Auxine and siderophore production by streptomycetes could be shown directly in soil. Thereby application of extremely heavy metal resistant strains from WISMUT area for microbial enhanced phytoremediation could be recommended.

Marine terrace soils along the west coast of North America: a weathering archive?

MARJORIE SCHULZ[1*], COREY LAWRENCE[1], DAVE STONESTROM[1], TOM BULLEN[1], JENNIFER HARDEN[1], ART WHITE[1], JOHN FITZPATRICK[1] AND CARRIE MASIELLO[2]

[1]US Geological Survey, Menlo Park, California, USA, mschulz@usgs.gov (* presenting author), clawrence@usgs.gov, dastones@usgs.gov, tdbullen@usgs.gov, jharden@usgs.gov, afwhite@usgs.gov, jfitzpat@usgs.gov

[2]Rice University, Houston, Texas, USA, masiello@rice.edu

Soil chronosequences provide a framework for understanding the influence of time on soil and ecosystem properties. To simultaneously examine how landscapes of different ages will respond to future climate shifts, we can compare landscapes across age and climate. North America's west coast has a significant precipitation gradient (wet in the north, dry in the south), supporting a gradation of ecosystems from northern temperate rainforests, through mixed forests, semi-arid Mediterranean chaparral and southern desert ecosystems. Marine terraces occur up and down the west coast of North America; each flight of stair-like terraces is a chronosequence. The soils of coastal marine terraces in the west provide a "climosequence of chronosequences" ideally suited to examine the interactions of landscape age and climate on soil and ecosystem resistance and resilience to climate change.

Building on work at the Santa Cruz (CA) marine terraces, we are developing a network of terrace chronosequences along the west coast. Past work at the Santa Cruz terraces examined soil development and elemental cycling in detail. Ongoing work on these terraces includes field, laboratory, and modeling efforts to understand carbon cycling. Our future work will extend the methods we have refined at Santa Cruz to other well-established North American marine terrace chronosequences.

We hypothesize that soil properties, processes, and rates on west coast terraces might be meaningfully assigned to climate zones as well as age of soil formation. Comparison of results from different marine terrace chronosequences will require addressing several important questions linking the paleohistory of soil formation with contemporary soil properties: The central question is what memories of past climate do soils possess, and how can we measure them? This problem requires multidisciplinary discussions, inspiration, and work. Soil properties that turn out to be indicative of distinctive climate-ecosystem combinations are potentially useful as references for judging the timing and extent of change in other soils. For example, data from the Santa Cruz chronosequence suggests that the isotopic fractionation of Fe may indicate past chaparral or forested ecosystems in soils currently occupied by coastal prairies. We hope to establish which soil properties change most with climate, and by utilizing multiple time sequences of soils, to bracket the timing of the changes. In this way the potential of naturally occurring archives recorded in marine terraces along North America's west coast can be used to address questions about future effects from climate change.

The case of p-Process ^{180}W heterogeneities in Iron Meteorites

T. SCHULZ[1,3*], C. MÜNKER[1,2], S. PETERS[1,2]

[1] Institut für Geologie und Mineralogie, Universität Köln, Germany

[2] Steinmann Institut, Universität Bonn, Germany

[3] Department für Lithosphärenforschung, Universität Wien, Austria toni.schulz@univie.ac.at (* presenting author)

Introduction

For most elements, in particular for r- and s-process isotopes, the abundances of non-radiogenic isotopes appear to be fairly homogeneous in the early solar system. This is likely to reflect efficient homogenisation of materials in the protoplanetary disk. However, a notably small number of elements are reported to display distinct anomalies, interpreted as being nucleosynthetic. Due to their low abundances, only few studies so far have measured heavy p-process isotopes [e.g. 1]. The low abundances of these neutron deficient nuclides reflect their particular formation conditions [e.g. 2]. Our recently presented ^{180}W measurements in iron meteorites reported clearly resolvable anomalies of up to ~+700ppm [3], interpreted to be of nucleosynthetic origin. However, recent studies [4] argued that such non-radiogenic stable W isotope anomalies may reflect analytical artifacts, resulting from molecular interferences. We therefore conducted replicate measurements of the Cape York IIIAB iron meteorite using modified analytical protocols.

Methods

Tungsten measurements were conducted using the Neptune multicollector ICP-MS at the University Bonn that is equipped with high sensitivity 10^{12} Ohm amplifiers for measuring ^{180}W and the ^{178}Hf interference monitor. Measurements were run in low- and high resolution and by using different sampler cones, including so-called "Jet Cones" with wider aperture. About 6g of Cape York metal was dissolved and loaded onto conventional anion exchange columns. Following modified elution procedures, W was purified from the 6 g sample, and AMES standard solutions were processed as well. For multiple measurements of AMES W standard solutions we obtained external reproducibilities of ±80 ppm (2σ r.s.d). ^{178}Hf intensities were typically an order of magnitude lower than required for accurate ^{180}Hf interference corrections.

Results and Discussion

Our preliminary results confirm a clearly resolvable ^{180}W anomaly for Cape York. Using standard and Jet-cone setups we obtained ^{180}W values of about ~+350ppm and typical ^{182}W and ^{184}W signatures in low- and medium resolution. In high resolution we could reproduce the ^{180}W excess using standard cones, but an offset of as much as 4500ppm using Jet-cones, which can be attributed to anomalous mass bias behaviour potentially reflecting matrix effects. Terrestrial W isotope compositions obtained with standard cones for all AMES W solutions which were processed during column chemistries and for terrestrial metals from reduced basalts provide further support for a nucleosynthetic origin of the measured anomalies.

Conclusions

Evidence for ^{180}W heterogeneities in iron meteorites is provided from (1) systematic excesses in ^{180}W between different iron meteorite groups [3], (2) offsets from the respective group averages for long exposed meteorites due to cosmogenic burn-out of ^{180}W [3]) and (3) analytical evidences presented here. Our results call for further studies evaluating mass bias behaviour in modified ("Jet Cone") interface devices in MC-ICPMS systems.

[3]USGS, Boulder, USA, ddeberl@usgs.gov

[4]FEMR (McGill), Montreal, Canada, hojatollah.vali@mcgill.ca

Introduction and Results

In carbonaceous chondrites there is a strong correlation between the occurrence of clay minerals and the presence of polar organic molecules (*e.g.* oxalic acid) [1][2]. Oxalic acid in the aqueous alteration phase of these meteorites could have enhanced the alteration of olivine and orthopyroxene to form Mg- and Fe-rich phyllosilicates [2]. It has also been proposed that clay minerals might have caused an enrichment of chiral "left"-handed amino acids like isovaline in these meteorites [3]. It is therefore important from the point of view of prebiotic chemistry whether oxalic acid might have catalyzed the formation clay minerals.

In this study we tested whether oxalate catalyses the crystallization of saponite from a silica gel powder at 60ºC and ambient pressure. For comparison in a second experiment NaOH solution was used instead of oxalate. Low magnification TEM images showed clusters of well developed globular aggregates consisting of packets of saponite crystals in the oxalate experiment and poorly crystallized saponite from the NaOH solution. High-resolution TEM lattice-fringe images of the ultrathin sections of the saponite globules treated with octadecylammonium (n_C=18) cations revealed the presence of 2:1 layer structures having variable interlayer charges: (1) short sequences of low-charge 2:1 silicate layers with an interlayer spacing of 13 to 14 Å and (2) sequences of higher charge 2:1 silicate layers having highly expanded interlayers of 25 to 33 Å. The difference in interlayer expansion results from the variation in the substitution of Al^{3+} for Si^{4+} within the tetrahedral sheets of the saponite crystallites. The Si/Al ratio seems to be passed on from layer to layer by heritage which is demonstrated by the regular interlayer expansion within the packets.

Conclusions

This study (i) showed the strong catalytic effect of oxalate on the nucleation and growth of saponite at low temperatures and pressure in contrast to NaOH, (ii) established the composition and structure of the 2:1 silicate layers of the saponite, and (iii) evaluated the replicating capability of the saponite. This study does not only offer an explanation for the formation of clay minerals in carbonaceous chondrites but may also explain the origin of clay minerals in other systems that contain oxalic acid associated with endolithic and epilithic (*e.g.* lichen) communities.

Transformations of mercury, arsenic and selenium in river sediments contaminated with coal ash: Field and laboratory studies

G. SCHWARTZ[1*], A. DEONARINE[1], L. RUHL[2], A. VENGOSH[2], G. BARTOV[3], T. JOHNSON[3], H. HSU-KIM[1]

[1]Duke University, Department of Civil and Environmental Engineering, Durham, NC, USA, grace.schwartz@duke.edu *

[3]University of Illinois at Urbana-Champaign, Department of Geology, Urbana, IL, USA

Coal combustion products, including coal ash, represent the largest industrial waste stream in the United States and contain elevated levels of toxic elements such as mercury (Hg), arsenic (As), and selenium (Se). Much of this waste is stored in unlined holding ponds and landfills that are not always monitored for their discharge to adjacent waters. Moreover, these holding ponds are susceptible to failures such as the disaster at the Tennessee Valley Authority (TVA) Kingston Fossil Plant in 2008 that caused more than 1 billion gallons of coal ash slurry to spill into the adjacent Emory River. In such cases, the fate of toxic elements associated with coal ash is greatly influenced by environmental conditions such as redox potential and microbial activities that induce transformations and leaching of contaminants. Here, we investigated the mobilization of coal ash contaminants in sediments through a field study of the river system surrounding the TVA coal ash spill site and also through laboratory sediment slurry experiments to understand how river conditions could facilitate mobilization of trace elements and production of methylmercury (MeHg). In the field survey, we sampled the sediments and surface water at the spill site during a two year period after the spill event. The results indicated elevated levels of MeHg in the river sediments near the spill site. The mercury originating from the coal ash demonstrated a stable Hg isotope signature that was different from the mercury originating from historical sources to this ecosystem. Thus, the isotope data suggested that the coal ash was stimulating MeHg production in the river sediments near the TVA site (either by providing Hg or other substrates for methylating bacteria). In the laboratory experiments, we cultured anaerobic sediment slurries to determine how the addition of coal ash could influence porewater chemistry and Hg speciation. The microcosms were prepared using sediment and surface water from a location several miles upstream of TVA spill site and cultured in an anaerobic chamber. A selection of the slurries was amended with coal ash obtained from the TVA Kingston Plant. Preliminary results of the sediment slurry incubations showed that the coal ash increased the amount of dissolved As and Se in the slurries at the initial time point. Over 4 days of incubation, dissolved As continued to increase while dissolved Se decreased in the slurries. These results suggested that arsenic was converting from As(V) to more soluble As(III) species in the slurries while selenium was converting from oxidized forms (e.g. selenate or selenite) to less soluble, reduced forms (e.g. elemental Se, selenide). The concentration of dissolved sulfate also decreased during the experiment, consistent with low redox potential in the slurries. While MeHg was observed in all slurry samples, the effect of coal ash on Hg speciation was mixed, with the coal ash providing a stimulating effect for MeHg production in some slurries and no effect in others. Further work will include sediment-coal ash slurries with more active microbial growth conditions. Overall, our field and laboratory studies highlight the need to consider environmental conditions in assessing the potential hazards of contaminants associated with coal ash.

[3]American Museum of Natural History, New York, NY, USA, mathez@amnh.org

Determining the precise age of the Bushveld Complex, the world's largest layered intrusion located in the northern Kaapvaal craton of South Africa, has been a longstanding problem. The age and duration of magmatism associated with the complex is critical for establishing the genetic relations among its different rock units (Rustenburg Layered Suite, overlying Rooiberg Group felsic volcanic rocks, intrusive Rashoop Granophyres) and timing of formation of its world-class ore deposits (Cr-PGE-V). We report chemical abrasion ID-TIMS U-Pb zircon results (all ages reported as weighted $^{207}Pb/^{206}Pb$ averages) for 8 samples from the layered mafic rocks of the complex and the roof. These results demonstrate that the Bushveld Complex spans an ~7 million year interval from 2061 to 2054 Ma with major magma emplacement at ca. 2060 and 2055 Ma. In the mafic rocks of the Rustenburg Layered Suite, the ages overlap within analytical uncertainty at ca. 2055-2056 Ma for a diorite from the top of the Upper Zone ~50 m below the roof (2056.52 ± 0.81 Ma) and for two samples, ~300 km apart in the Western and Eastern limbs, from the PGE-rich Merensky Reef at the top of the Upper Critical Zone (2055.30 ± 0.61 Ma; 2056.13 ± 0.70 Ma, revised from [1]). These results are consistent with rapid filling, crystallization, and cooling of the upper 2/3 of the intrusion [2]. Ages for felsic rocks in the roof above the level of the Upper Zone diorite in the Eastern Limb range from 2054-2056 Ma, including a granodiorite mixed with hornfels or "leptite" (2054.83 ± 0.86 Ma), a granophyre from the Rashoop Granophyre Suite (Stavoren: 2055.70 ± 1.0 Ma), and a granite from the Nebo/Lebowa granites (2054.23 ± 0.79 Ma). These ages indicate that mafic and felsic rocks of the Bushveld Complex are broadly coeval and support the proposal that some of the original magma volume in the intrusion was expelled to form the Upper Rooiberg Group lavas or Rashoop granophyres [3]. Below the Merensky Reef, there is a shift to older ages at ca. 2060 Ma. Results for two samples at different locations of footwall pyroxenite immediately below the UG-2 chromitite (Eastern Limb), ~380 m below the Merensky Reef, are 2060.5 ± 1.4 Ma and 2059.8 ± 1.2 Ma. It has long been recognized that initial Sr isotope ratios in both plagioclase and whole rocks increase sharply at the Merensky Reef over a few metres due to the emplacement of a compositionally distinctive magma batch [4]. The U-Pb geochronological results of this study indicate an age gap of perhaps as much as 5 million years between the uppermost Upper Critical Zone (UG-2 chromitite) and the Merensky Reef and overlying Main and Upper zones. The lowermost mafic-ultramafic rocks of the Bushveld Complex (Lower Zone and Critical Zone) appear to result from an earlier phase of magmatism at ca. 2060 Ma, coeval with the nearby 2060 Ma Phalaborwa carbonatite [5]. After a hiatus, now marked by the level of the Merensky Reef, the major volume of the Bushveld Complex was emplaced at ca. 2055 Ma.

Paleoproterozoic collapse in seawater sulfate and subsequent shallowing of the methane cycle in marine sediments

C. T. SCOTT[1*], B. WING[1], A. BEKKER[2], N. PLANAVSKY[3], P. MEDVEDEV[4], S. M. BATES[3], M. YUN[2], T. W. LYONS[3]

The initial accumulation of atmospheric oxygen, referred to as the Great Oxidation Event or GOE, is fairly well-constrained to between 2,450 and 2,320 Ma. However, the magnitude and duration of that rise in oxygen is subject to debate. It is also not clear how the dynamic oxidation of the early Paleoproterozoic transitioned into the environmental stasis of the Boring Billion. In order to examine the history of Paleoproterozoic surface oxidation, we used a combination of pyrite multiple-sulfur (^{32}S, ^{33}S and ^{34}S) and organic carbon isotopes from marine black shales. We analyzed the (1) 2,320 Ma Rooihoogte and Timeball Hill Formations, from which the GOE is dated; (2) the 2,200 to 2,100 Ma Sengoma Argillite Formation, deposited during the peak of the Lomagundi carbon isotope excursion in an open-marine setting on the Kaapvaal craton; and (3) the Upper Zaonega Formation of the Ludikovian Series, Russian Karelia, deposited in a marine basin between 2,100 and 2,000 Ma, in the immediate aftermath of the Lomagundi carbon isotope excursion.

Pyrite S isotopes display large ^{34}S-^{32}S fractionations (>30‰) relative to seawater sulfate, indicating that a large marine sulfate reservoir (2-20 mM) developed as an immediate result of the GOE and persisted for nearly 250 Ma. In the aftermath of the Lomagundi carbon isotope excursion, pyrite sulfur isotope fractionations drop to <15‰, suggesting a rapid collapse of the marine sulfate reservoir to <200 μM. These low-sulfate conditions persisted for at least 600 Ma. Thus, it appears that the high oxidation state of the atmosphere-ocean system that developed as the immediate result of the GOE was largely lost by 2,000 Ma and did not return until the Ediacaran period. Accordingly, the Boring Billion is best described as a long-lived redox regime that was intermediate between those of the Archean and the early Paleoproterozoic, rather than between the early Paleoproterozoic and the Phanerozoic.

Organic carbon isotopes record a secular shift to more negative values at ca. 2,050 Ma, which is tightly coupled to the positive excursion in pyrite S isotopes. We interpret this carbon isotope excursion as an enhancement in the biological methane cycle in marine sediments as a result of the crash in seawater sulfate. As seawater sulfate concentrations dropped, methanogenesis operated closer to the sediment-water interface, setting up conditions suitable for subsequent methanotrophy and incorporation of ^{13}C-depleted biomass into the marine sedimentary organic carbon pool.

Formation and evolution of cores in asteroids: clues from iron meteorites

EDWARD R. D. SCOTT

University of Hawai'i, Honolulu, HI 96821, USA, escott@hawaii.edu

In 12 out of 14 groups of iron meteorites, chemical variations are consistent with fractional crystallization of single pools of molten Fe-Ni-S (e.g., Ir is inversely correlated with Ni and varies by factors of 10^{1-4}) [1]. These irons have W isotopic compositions indicating they were isolated from Hf-bearing rock <1 Myr after CAI formation [2]. By contrast, irons in groups IAB and IIE do not show fractional crystallization trends (e.g. Ir is uniform), they contain abundant silicate inclusions including chondritic fragments, and their W isotopic compositions indicate more recent metal-silicate exchange. This suggests that most irons come from cores of asteroids that accreted <1 Myr after CAIs when ^{26}Al was abundant enough to form molten cores. Irons in groups IAB and IIE probably come from bodies that accreted later when there was insufficient ^{26}Al to allow metallic pools to form cores.

Irons from cores of differentiated asteroids should have cooled more slowly than irons from metallic pools. However, fractionally crystallized irons show fast cooling rates, e.g., 60-300 °C/Myr for IIIAB irons, 100-6600 °C/Myr for IVA irons, and 500-5000 °C/Myr for IVB irons [3-5]. These cooling rates are incompatible with cooling in cores of asteroids that were melted by ^{26}Al for two reasons. 1) Each group has a wide range of cooling rates whereas metallic cores should have cooled almost isothermally as metal conducts heat much more rapidly than silicate. 2) Bodies that were small enough to have cooled at these rates would have had radii of <10 km and could not have been melted by ^{26}Al. In addition, the 4565 Myr Pb-Pb age of a IVA iron [6] is incompatible with conventional models for fully differentiated asteroids which require cooling over tens to hundreds of Myr. The metallic cores supplying most iron meteorites must have cooled rapidly with little or no insulating mantle.

Impacts between asteroids at current impact velocities of ~5 km/s cannot efficiently remove silicate mantles from cores. However, impacts at lower speeds during accretion can disrupt projectiles impacting at grazing angles and speeds comparable to mutual escape velocities [7]. Repeated collisions under these conditions may have allowed core material to cool with little or no silicate insulation. Low-velocity collisions during accretion may also explain the presence of rock fragments in the IAB and IIE iron meteeorites.

The diversity of melted and unmelted asteroids and meteorites may result from formation of iron meteorites and achondrites from planetesimals that accreted near the terrestrial planets whereas chondrites accreted later in the asteroid belt [8]. Grazing impacts eviscerated differentiated asteroids so that fragments were lofted into the asteroid belt. Planetary accretion may have been a very inefficient process so that the differentiated asteroids represent the construction debris [7].

Microscopy based detection and analysis of carbon nanocomposites in commercially available baseball bats

KEANA SCOTT[1*], CHRISTOPHER MARVEL[2], STEPHAN STRANICK[1] AND JOHN HENRY SCOTT[1]

[1]National Institute of Standards and Technology, Gaithersburg, MD, USA, keana.scott@nist.gov (* presenting author), stephan.stranick@nist.gov, johnhenry.scott@nist.gov

The number of consumer products incorporating polymer nanocomposites has rapidly increased in recent years [1]. Especially in sport equipment, the enhanced material properties such as high strength, high toughness and low density of these nanocomposites are effectively translated into a lighter equipment with improved performance characteristics. Although much work has been done in developing and characterizing these nanocomposite materials and nanofillers (nano-tubes, -particles, -fibers, etc.), characterization and lifecycle studies of nanocomposites in their product condition have been lacking. However, several recent studies have examined nanocomposite degradation and disposal products and explored their environmental impacts. Nguyen et al. have shown that surface exposure of carbon nanotube (CNT) network can result from the photodegradation of polymer matrix under UV exposure of CNT-polymer nanocomposites [2]. Wohlleben et al. have evaluated nanocomposite fragments for the nanofiller release and their in-vivo toxicity [3].

In this study, we examined two different types of commercially available baseball bats that incorporate CNT-polymer nanocomposites into their structures. Several different microscopy techniques were used to identify and analyze the CNTs in the bat and in the release fragments from two different use scenarios (normal and recycle/disposal). The normal use scenario included abrasion of the bat surface with different grades of polishing cloth and sand paper, simulating normal wear and tear. The recycle/disposal scenario included sawing and ripping the bat pieces. The cross-sectional samples of the bats were used to identify the locations of CNT nanocomposites and confirm the presence of CNTs in these materials. The bat surfaces and the release fragments from the two use scenarios are examined for the particle size distribution, release particle morphology and presence of loose or exposed CNTs. The preliminary results from the normal use scenario showed no loose or exposed CNTs in the wear particles or the abraded bat surfaces. The bulk of the release fragments from the sawing and ripping operation were mm to μm sized fragments. However, albeit in very low level, several types of nano-sized particles and fibers, including some that showed morphology consistent with polymer coated CNTs, were also detected in the release fragments. Additional work is in progress to characterize and quantify the nano-sized debris from the disposal scenario.

Constraining the composition of basinal brines in the Athabasca basin from individual fluid inclusion analysis in quartz overgrowths

RYAN SCOTT[1*], GUOXIANG CHI[2]

[1]University of Regina, Regina, Canada, ryan.dj.scott@gmail.com (* presenting author)
[2]University of Regina, Regina, Canada, guoxiang.chi@uregina.ca

Constraining the geochemical composition of basinal brines in the Athabasca basin is crucial in understanding the role of diagenetic fluids during the formation of high-grade unconformity-type uranium deposits. In order to characterize the diagenetic fluids before they were involved in mineralization, samples must be collected distally from mineralization or alteration zones. The Rumpel Lake drill core, which is located far away from known mineralization, is an excellent target for this type of analysis.

Isolated and clustered fluid inclusions in quartz overgrowths in the Athabasca Group sandstones (Fig. 1) were selected for analysis. Unlike minerals in veins, quartz overgrowths cannot be separated for bulk fluid inclusion analysis, therefore individual inclusions were analyzed with the heating-freezing, decrepitation SEM-EDS and cryogenic Raman spectroscopic methods [1, 2]. Ice-melting temperatures range from -37.5 to -11.0°C, suggesting that $CaCl_2$ may be present in addition to NaCl. Raman spectra obtained from frozen fluid inclusions show peaks that are comparable to published data for mixed NaCl-$CaCl_2$ systems (Fig. 1) [1]. SEM-EDS analysis shows that the decrepitates of the inclusions are composed of NaCl+KCl+$CaCl_2$±$MgCl_2$. These results are generally consistent with the proposals that the Athabasca basinal brines were derived from seawater evaporation [3], and indicate that some calcium in the basinal fluids found in uranium deposits may have been derived from fluid-rock interactions within the basin, rather than solely from the basement.

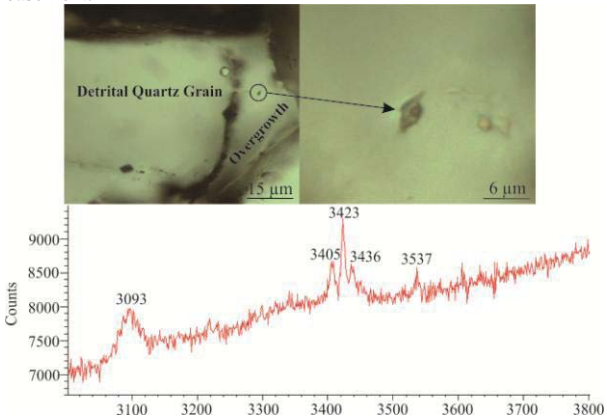

Figure 1: Upper: Isolated fluid inclusion located in the quartz overgrowth. Lower: Raman spectra of the depicted fluid inclusion homogeneously frozen to -185°C.

Vegetation collapse on Flores 69,000 years ago: A consequence of the Toba super-eruption, or a volcanic disaster closer to home?

A large ~8‰ positive $\partial^{13}C$ excursion has been identified at 69,000 years BP in the speleothem archive from Liang Luar cave, Flores, Eastern Indonesia. The excursion, by far the largest in 92,000 years of record, begins abruptly, lasts for over 500 years, and only fully recovers to background $\partial^{13}C$ after 800 years. At its peak the excursion approaches bedrock values and we therefore interpret this event as massive vegetation destruction in western Flores followed by progressive recovery.

The excursion is coeval with the largest spike in concentration of elemental sulphur in the speleothem across this interval, measured using in situ, 30µm scale Sensitive High Resolution Ion Microprobe (SHRIMP) analysis. Atmospheric volcanic sulphate is introduced to the cave system through dissolution in rain and then groundwater. The concentration of sulphate in speleothems serves as a relatively new proxy for volcanic activity.

Taken together, the $d^{13}C$ and sulphur records indicate that this outstanding century-scale event represents massive vegetation loss in western Flores in the aftermath of a major volcanic eruption. Could the Toba super-eruption be the cause of this major event in the history of Flores? We will present $\partial^{18}O$, $\partial^{13}C$ and sulphur concentration records from Flores and nearby Sulawesi detailing the relative timings of the isotopic and concentration changes in order to separate the effects of local eruptions on Flores from the remote volcanic impact of the Toba super-eruption.

Proxy Recognition of Volcanic Ash and Eolian Dust: Implications for Climate Records, Tectonics, and Nutrient Cycling

RACHEL P. SCUDDER[1](*), RICHARD W. MURRAY[1], STEFFEN KUTTEROLF[2], JULIE C.SCHINDLBECK[2]

[1]Department of Earth Sciences, Boston University, Boston, MA, USA, rscudder@bu.edu (* presenting author), rickm@bu.edu
[2]GEOMAR, Kiel, Germany, skutterolf@geomar.de, jschindlbeck@geomar.de

Delivery of aluminosilicate material to the oceans in the form of eolian dust and volcanic ash is controlled by a number of geologic and climate mechanisms. This material can provide a record of physical processes (e.g., tectonics, climate, volcanology) and is also an important part of biogeochemical cycling (e.g., nutrient delivery). In the NW Pacific Ocean, large inputs of volcanic ash from convergent arc systems (e.g., Izu-Bonin, Marianas, Kamchatka) and eolian dust from China are related to the tectonic evolution of volcanic arcs and Cenozoic climate.

Differentiating eolian dust from altered and unaltered volcanic ash, and distinguishing both from primary authigenic phases, is difficult [1]. This is further complicated due to the presence of a large, relatively unrecognized component of volcanic ash that is mixed into the bulk sediment ("dispersed" ash). This dispersed ash is quantitatively significant and is an under-utilized source of critical geochemical and tectonic information [2]. For example, volcanic ash may provide as much bioavailable nutrients (e.g., Fe) to the surface water as does the eolian sources [3]. Because all these phases are aluminosilicates with a small compositional range, distinguishing between them to a precise degree is best achieved by a combination of chemical and quantitative multivariate statistical treatments [2].

We here extend our earlier study of ODP Site 1149 by presenting an enhanced data set that allows higher resolution study of volcanic input to the Izu-Bonin system. Our new expanded study confirms the presence of a significant dispersed ash component at Site 1149 [2]. The aluminosilicates are likely composed of four end members, i.e., loess and three other ash components. Geochemical signatures (e.g., K_2O, Fe_2O_3) of the dispersed ash can be exploited to provide insight into the clay mineralogy (i.e., smectite), which is involved in the hydrologic budget of subducting sediments. We will also present results from discrete ash layers as compared to the dispersed ash.

Hydrochemical analyses to evaluate groundwater system in Horonobe Area, Hokkaido, Japan

M. SEGUCHI [1*], M. OHOKA[1], M. NAKAMURA[1], Y. ICHIKAWA[1], R. SAKAI [2], M. MUNAKATA[2], J.-I. ISHIBASHI[3]

[1]OYO Corporation, 2-2-19 Daitakubo, Minami, Saitama, Japan (seguchi-mariko@oyonet.oyo.co.jp)
[2]Nuclear Safety Reserch Center , Japan Atomic Energy Agency, Tokai-mura, Naka-gun, Ibaraki-ken, Japan (sakai.ryutaro@jaea.go.jp)
[3] Faculty of Science, Kyushu University, Fukuoka 812-8581, Japan (ishi@geo.kyushu-u.ac.jp)

For the safety assessment of a geological disposal of radioactive waste, it is important to establish validation method for estimating regional groundwater flow system.

In this study, first we collected more than 200 data of saline waters which were analyzed by JAEA and other organizations. And in order to indicate the mixing ratio of saline waters from different origins, the multivariate analyses were carried out based on the M3 (Multivariate, Mixing and Mass-balance) model developed by SKB (Laaksoharju et al., 1999) . We analyzed on these data in three cases where chemical components combinations are different. These combinations are as follows: 1.Cl^-, δ D, δ ^{18}O (the components which are not involved in water-rock reaction) 2. Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^- (the components involved in water-rock reaction) 3. Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, δ D, δ ^{18}O (all components) .

We tried to construct a hydrochemical model in the region where Neogene to Quaternary marine sedimentary rocks are deposited. The Wakkanai formation and the overlying Koetoi formation which consist of siliceous and diatomaceous mud-stones are the main targets of our study.

As the result of the multivariate analyses, four types of endmembers were extracted. They are: 1. surface water , 2. Cl-poor water (HDB-5) , 3. Cl-rich saline water (HDB-7), 4. Ca-rich saline water((HOKUSHIN R-1). Spatial plotting of these endmembers shows that high concentration part of HDB-5 water is distributed in deeper region where abnormal formation pressures were measured, and HDB-7 water is more rich in western site. This result suggests that in this area, there are some types of deep groundwaters which flow in different directions.

This study is regulatory support research funded by the Nuclear and Industrial safety Agency, Ministry of Economy, Trade and Industry, Japan.

Interactions of U(VI) with archaea: what is different than with bacteria?

SONJA SELENSKA-POBELL[1*], THOMAS REITZ[1], AND MOHAMED MERROUN[2]

[1]Institute of Resource Ecology, HZDR, Dresden, Germany, s.selenska-pobell@hzdr.de (* presenting author)
[2]University of Granada, Granada, Spain, merroun@ugr.es

Archaea, in contrast to the diverse and dense bacterial populations, occur in uranium mining wastes in low numbers and belong mostly to particular crenarchaeal groups, some of them not yet cultured [1,2]. On the example of the termoacidophilic crenarchaeon *Sulfolobus acidocaldarius*, indigenous for many uranium contaminated wastes [3,4], we demonstrate that archaea tolerate substantially lower concentrations of U(VI) than bacteria and that they interact with this radionuclide in a significantly different way. One of the reasons for this behaviour is the unusual cell wall structure of the representatives of *Crenarchaeota* which is restricted to a single proteinaceous surface layer (S-layer), that is in contrary to the complex, rather thick, and rich on metal-binding ligands cell wall structure of bacteria. Due to the extreme acidic and mechanic stability of the *S. acidocaldarius* S-layer, it was possible to produce empty cells (ghosts) consisting only of the outermost S-layer membrane and to study their interactions with U(VI) at highly acidic (pH 1.5 and 3.0) and at moderate acidic (pH 4.5 and 6.0) conditions. Applying a set of modern spectroscopic techniques such as Time-Resolved Laser-induced Fluorescence (TRLF), X-ray Absorption, and Fourier-Transformed Infrared (FT-IR) we were able to demonstrate that at highly acidic conditions the *S. acidocaldarius* S-layer does not play any protective role against the toxic U(VI). At these conditions low amounts of uranium are bound mainly by the phosphate groups of the cytoplasma membrane [5]. This finding is in distinction to the results obtained with S-layers of the bacterial isolates recovered from uranium mining wastes. The S-layers of the latter bind significant amounts of U(VI) and strongly contribute to the remarkable uranium resistance of their hosts [6]. The high capability of the mentioned bacterial S-layers to bind U(VI) was atributed to the fact that they are phosphorylated [6]. This feature is unusual for both bacterial and archaeal S-layers and is not the case for the S-layer of *S. acidocaldarius* [6, 7]. At moderate acidic conditions (pH 4.5), typical for most uranium mining wastes, the studied archaeal S-layer ghosts, again in contrast to the bacterial ones, bind insufficient amounts of U(VI) exclusively via the carboxylic groups of their carboxylated amino acid residues [7]. At pH 6.0, which is substantially above the growth optimum of *S. acidocaldarius*, the permeability of its cells is increased due to the pH stress and possibly also to the presence of U(VI). As a result uncontrolled uptake of U(VI) as well as release of phosphorylated biomolecules and also of orthophosphate occurs. These processes result initially in formation and precipitation of mixed uranyl phosphate phases. With time most part of U(VI) is biomineralized in inorganic mineral phases. The efficacy of the biomineralization processes is, however, much lower then those published for bacteria, possibly due to the lower amount of polyphosphatic bodies in the studied archaeon [8]. We suggest that the limited presence of archaea in uranium wastes is related to their lower resistance to U(VI) which is determined by their cell wall structure and possibly also by some particular physiological and biochemical characteristics.

Novel Thermochronometric Techniques Applied to the Lavrion Detachment, Lavrion Peninsula, Attica, Greece

SPENCER SEMAN[1*], KONSTANTINOS SOUKIS[2], DANIEL STOCKLI[1], EMMANUEL SKOURTSOS[2], HARALAMPOS KRANIS[2]AND STYLIANOS LOZIOS[2]

[1]University of Texas at Austin, Jackson School of Geoscience, Texas, USA, spencer.seman@utexas.edu (*)
[2]National and Kapodistrian University of Athens, Athens, Greece,

The Lavrion Peninsula (SE Attica) is situated at the western boundary of the Attic-Cycladic Crystalline Complex (ACCC). The ACCC underwent blueschist to eclogite facies metamorphism during the Eocene followed by a greenschist facies overprint coincident with broad regional extension during the Miocene. This extension is generally attributed to the process of slab rollback and led to the formation of crustal scale detachments in the Aegean. In Lavrion, the dominant structure is a sub-horizontal detachment which juxtaposes lower plate rocks of the Kamariza Unit against the Lavrion Unit of the upper plate. Both units are dominated by greenschist facies calc-schists and marbles. The Lavrion Detachment (LD) is defined by a mylonitic zone which displays a top-to-SSW sense of shear. This is consistent with the overall sense of shear of the larger West Cycladic Detachment System (WCDS) exposed on the islands of Kea, Kythnos, Serifos and Makronisos directly to the east of the Lavrion Peninsula The LD, therefore, may represent the western most exposure of the larger WCDS. Exhumation of lower plate rocks along the WCDS on Kea, Kythnos, and Serifos occurred between 5-8Ma, 11-15Ma, and 5-8Ma, respectively[1]. In order to further constrain timing of movement on the LD and how it correlates to the WCDS, (U-Th)/He dating was conducted to understand the low temperature evolution of the lower plate and proximal upper plate rocks. Many upper and lower plate rocks (e.g. low grade calc-schists and marbles) of the LD are not conducive to traditional low temperature thermochronometric techniques so this study will employ titanite (U-Th)/He dating coupled with zircon and apatite (U-Th)/He where appropriate lithologies are present. Titanite is a common phase in greenschist facies calc-schists and possesses a closure temperature similar to zircon, making it an ideal chronometer for this study.[2]

Modeling reactive transport of biogenic uraninite and its re-oxidation by Fe(III)-(hydr)oxides

S. S. ŞENGÖR[1*], J. GRESKOWIAK[2], H. PROMMER[3]

[1]Southern Methodist University, Dallas, USA, (* correspondence: sssengor@gmail.com)

Uranium contamination in the subsurface is a global problem in surface and groundwater, soils, sediments and related ecosystems due to its chemical and radioactive toxicity to human and ecosystem health. A promising strategy for in-situ remediation of U-contaminated subsurface is through stimulating iron and/or sulfate reducing indigenous bacterial species to catalyze the reduction of soluble U(VI) to insoluble U(IV) – uraninite (UO_2), typically accomplished by amending the groundwater with an organic electron donor. Thus, uraninite is generally regarded as the most desirable end product of this bioreductive process due to its low solubility, and hence stability under reducing conditions. However, it has recently been shown that once the electron donor is entirely consumed, the biogenic uraninite can be can be reoxidized (and remobilized) by Fe(III)-(hydr)oxides, which may potentially impede the cleanup efforts. Therefore, it is vital to understand the governing factors that control the redox behavior of the bioreduced uraninite with respect to uranium fate, transport, and long-term stability. Based on the experiments [1], a suitable biogeochemical reaction network was developed to integrate the experimental data and simulate these interactions in subsurface environments focusing on the role of sulfide, Fe(II), Fe(III) (hydr)oxides, and the effect of nanoscale particle size on the stability of biogenic uraninite and its reoxidation [2]. Model results showed that the oxidation of sulfide by Fe(III) directly competed with UO_2 reoxidation as thermodynamically, Fe(III) oxidizes sulfide preferentially to UO_2. The re-oxidation of UO_2 is thus shown to depend on the relative rates of UO_2 and sulfide oxidation by Fe(III), as well as to the activity of Fe(II) in solution [2]. The developed reaction network and the interplay that emerges between flow, physical transport and reactions has been further studied in 2-D numerical experiments that were based on the setting found at the South Oyster site, Eeastern Virgina [3]. These simulations included surface complexation of U(VI) and Fe(II) onto Fe(III) oxides, microbial sulfate reduction using acetate with reductive dissolution of ferrihydrite and considered a highly heterogeneous property distributions.

The Subarctic North Pacific (SNP) is one of the three principal HNLC (high nutrient low chlorophyll) regions in the modern ocean where biological production is limited. More than 20 years ago, John Martin and co-workers suggested that phytoplankton growth in the SNP is limited by iron which is mainly brought in by atmospheric eolian dust input from East Asian dust sources [1].

Productivity proxies (e.g., opal, carbonate, biogenic barium) show discrepancies in their interpretation from sediment cores in the SNP and Bering Sea for the last ~150 kyr. We will present results from a spatial survey of core-top sediments from 37 stations of the INOPEX cruise, with an extensive coverage of the whole SNP and Bering Sea. We will map and compare results from different productivity proxies (^{230}Th-normalized fluxes of opal, carbonate and biogenic barium) to evaluate the efficiency of the different proxies to reconstruct the spatial pattern in primary and export production with strong gradients across the SNP, as shown in studies of annual primary productivity estimated from the climatology of satellite ocean color observations [2] and of biological drawdown of pCO_2 [3]. Further, comparison with results from sediment trap studies will help to identify possible preservation problems for the different productivity proxies. First results indicate a good correlation between opal fluxes and published data of biological drawdown of pCO_2 in the northwestern and northeastern SNP. Results from this core-top study will be crucial for our ultimate goal to test the dust fertilization hypothesis over the last deglaciation using different dust flux and biological productivity proxies in sediment cores from the SNP.

The iron isotopic imprint of benthic iron release in suspended particles from the African oxygen minimum zone

SILKE SEVERMANN[1], DANIEL OHNEMUS[2] AND PHOEBE J. LAM[2]

[1]Institute for Marine and Coastal Sciences (IMCS), Rutgers University, New Brunswick, NJ, USA, silke@marine.rutgers.edu

[2]Woods Hole Oceanographic Insitution, 266 WOODS HOLE RD, Woods Hole, MA 02543

Continental margin sediments are increasingly being recognized as an important source of bioavailable iron to the open ocean. Benthic iron fluxes are particularly high in oxygen deficient ocean regions, such as the major Oxygen Minimum Zones (OMZs) off the African and South American west coasts. In these highly productive regions of the oceans, benthic (diagenetic) iron sources may be of similar importance to atmospheric iron sources. Iron isotopes are emerging as a powerful tool to trace the influence of reducing margins as a supply of iron to the open ocean. Redox recycling of reactive iron in the organic-rich shelf sediments imparts a characteristically light iron isotope signature on the benthic iron efflux. Aerosol iron, in contrast, typically resembles crustal material and shows no distinct isotope fractionation relative to average igneous rock. To examine the isotopic imprint of benthic iron release in oxygen deficient ocean regions we have measured the iron concentrations and isotope composition of suspended particles along two transects through the southern African OMZ at 13°S and 26°S. Dissolved and particulate iron concentrations are strongly elevated along the northern transect, which passes near the core of the OMZ. This pattern of high iron concentrations at intermediate depth suggests significant release of iron from the shelf sediments at bottom water oxyen concentrations <40μM. Despite this strong benthic release signal, iron isotope compositions of highly reactive Fe (0.5 M HCl leach at 60°C overnight) does not vary significantly from 0 ‰. At the southern sites, in contrast, overall sediment iron fluxes are smaller, but isotope compositions as low as -0.54 ‰ ($\delta^{56/54}$Fe, normalized to igneous rocks) are consistent with a diagenetic iron source from suboxic or anoxic sediments. Previous porewater studies have revealed a reversal in iron isotope fractionation during progression from suboxic/anoxic to sulfidic early diagentic reactions, potentially producing an iron efflux with isotope compositions close to 0 ‰ or even slightly positive. Consequently, rather than invoking an atmospheric signal at the northern site, we suggest a greater role for sulfides in the reduction and release of Fe^{2+} in the most oxygen-depleted regions of the OMZ. Light particulate isotope compositions at the southern site suggests that a significant proportion of dissolved Fe^{2+} is adsorbed or forms authigenic iron phases, and that particles are potentially an important vector for the transfer of reduced iron from the shelf to the open ocean. Results from this study provides a useful framework for the investigation of particles and their ispotope composition in the forthcomming GEOTRACES Pacific Section, which cosses the Peru OMZ.

Disturbance of the U/Pb and Th/Pb chronometers during low-T alteration of monazite.

Low-temperature alteration of monazite is documented in three centimetric monazite crystals from Norway (Arendal), Madagascar (Ambato), and Srilanka. The three crystals have different chemical compositions, especially regarding U, Th, Y and Pb contents and have ages ranging from 491 to 900 Ma. Optical and Electron microscope (SEM and TEM) images and electron microprobe analyses (EPMA) show that all of them share the same texture, suggesting an alteration reaction following which unaltered monazite (Mnz1) reacts to form a secondary, Th-U(-Y)-depleted, high-Th/U-monazite (Mnz2) associated with variable proportions of thorite ($ThSiO_4$), thorianite (ThO_2) and xenotime (YPO_4), depending on the initial composition of Mnz1. Images reveal variably intense fracturing, with cracks filled with Th-rich +/- Fe-rich phases. Monazite-xenotime thermometry demonstrates that Mnz1 interacted with a low temperature fluid. The alteration process is interpreted to follow a mechanism of fluid-present coupled dissolution-precipitation. Chemical dating with EPMA show no isochron age difference between primary and secondary monazite, except for the Ambato monazite, where altered domains are apparently older (750 Ma). U/Pb and Th/Pb isotope dating using LA-ICP-MS give dates consistent with EPMA dates, in pristine zones. However, in Mnz2, the systems are disturbed. In the case of Srilanka and Arendal, only $^{232}Th/^{208}Pb$ dates give a reasonable estimate of alteration age, respectively 450 and 864 Ma. U/Pb systems are disturbed due to common Pb contamination (up to 40%) and U fractionation relative to Th, responsible for depletion of U in altered monazites (and increase of Th/U). In contrast, for the Ambato monazite, both U/Pb and Th/Pb systems were affected and give inconsistent older dates for altered zones. This is attributed to significant common Pb contamination (up to 80%), also affecting all Pb isotopes and explained why electron probe ages were disturbed as well. Secondly disturbance results from Th-U-silicate contamination during measurement, due to the presence of high density of nano-phases and nano-fractures filled with Th-U-silicates, only visible using TEM. Finally, these results demonstrate the important role of radiation damage effects, in particular swelling-induced fracturing, and the essential role of porosity and cracks, which allow fluid (charged with elements) migration through the sample during this process.

Micron-scale imaging of the distribution of bio-available metals (Fe, Zn, Ni, Co) in modern and ancient microbial mats

[3]Department of Marine Sciences, University of Connecticut, Groton, Connecticut, USA

Metals are essential micronutrients for all living organisms since they are used as structural elements or as catalytic centers in enzymes. Some, like Fe, are universally used, while others, such as Ni or Co, have a more limited biological function. Yet, they can be associated with enzymes that catalyze specific types of metabolism (e.g. N-assimilation). The evolution of these metalloenzymes likely reflects the variable paleogeochemistry of metals throughout Earth history. However, in addition to direct uptake for biological use, metals can be incorporated in bacterial exopolymer (EPS) constituting the biofilm matrix in microbial mats. The high chemical reactivity of such surfaces is ideal for metal cation scavenging, and thus leads to metal enrichment during diagenesis. Therefore, in order to use metals as tracers of past biological activity in the ancient rock record, knowledge of the mechanisms of metal uptake in living and diagenitically-modified microbial mats is required.

Here we present a study of the distribution of metals in modern and ancient stromatolites. These structures, ubiquitous in the rock record for the last 3.5Ga, have the potential to preserve biosignatures and are an excellent target for studies of metal tracers. We focused our study on 2.7Ga old stromatolites from the Tumbiana Formation (Western Australia) and on three modern stromatolites from the Bahamas (Storr's Lake, Big Pond and Highborne Cay).

In order to detect metal variation in the laminated organic fraction of stromatolite structures we used synchrotron-based scanning X-ray fluorescence technique. It was applied at the X-ray fluorescence microscopy line of the Australian Synchrotron. We used the Maia detector which consists of 384 detectors-elements. This permitted to perform multielemental imaging of ~cm sample areas with 2µm spatial resolution.

In modern stromatolites organic layers are enriched in metal with a general distribution of Fe, Zn >> Ni and Co. This enrichment becomes higher with increased degree of diagenesis. Indeed, the top of Big Pond's stromatolite contains high organic content linked to a low Fe content whereas the bottom shows lower organic content (diagenetic effect) and higher Fe content. Modern stromatolites, then, show clear evidence of early diagenesis where metals such as Fe, Zn display strong affinity for the organic layers. The ancient stromatolites from the Tumbiana Formation also show a strong metal enrichment in the organic fractions. In organic layers, Fe >Ni, Co > As, V, Ti > Zn are presents. Disseminated organic globules also show this general metal distribution. This could be evidence for pervasive fluid diagenesis in organic layers and of the preservation of the early diagenesis in organic globules. The high metal content in these samples confirms the strong affinity for organic fractions incorporating more and more type of metals with time.

Experimentally Determined Fe Isotope Fractionation between Metal and Silicate

[3]EAFIT University, Medellin, Antioquia, Colombia

There has been much work done on quantifying the iron isotopic fractionation of naural samples but the mechanism(s) responsible for the measured fractionations is still largely unknown. Iron is not striaghtforward to understand because of its differing redox states and compatibility constraints. In this study we aim to understand the mechanism(s) responsible for iron isotope fractionation by performing high pressure and temperature experiments. We have varied the composition, temperature, and duration of the experiments. In particular we have examined the iron isotopic fractionation between metal and silicate with and without the influence of sulfur to represent a possible core formation model for Earth and Mars.

Experiments were conducted in a ½ inch piston cylinder apparatus at temperatures ranging from 1600°C – 1800°C at 1 GPa and for times ranging from 5 to 240 minutes. The run products were characterized, mechanically separated, dissolved and purified by anion exchange before introduction into a Nu Plasma II MC-ICPMS for isotopic analyses. It is crucial in these experiments to prove isotopic equilibrium so microprobe analyses, the three-isotope technique, and textures of run products were all utilized. Of the 50+ experiments conducted so far, fewer than 10% have passed all the requirements for isotopic equilibrium. However, in the experiments in which we are confident that equilibrium was achieved we find that there is a small but resolvable equilibrium iron isotopic fractionation factor between metal and silicate at high temperature, with the metal phase more enriched in $^{57}Fe/^{54}Fe$ than coexisting silicate.

Determining whether there is an equilibrium iron isotope fractionation between metal and silicate is central to understanding the Fe isotope signatures found within different meteorites and planetary bodies. The initial set of experiments duplicate the magnitude and direction of data from pallasite meteorites with higher $^{57}Fe/^{54}Fe$ in the metal than in coexisting olivine. And extrapolation of our results to the temperature of the Earth during core formation (~3000 K) results in an iron isotopic fractionaton of 0.08‰ between the core and mantle. By adding sulfur to the second set of experiments we can test how sensitive the iron isotopic fractionation is to a change in the surrounding ions as well as provide an analog to Mars.

luke_ootes@gov.nt.ca

Abstract

A well-preserved 1.9 Ga regolith that formed from a quartz-feldspar porphyry of dacitic composition at Beaverlodge Ridge, NWT, Canada, is overlain by a quartz arenite and has been overprinted by a greenschist facies regional metamorphism. Continental reconstruction placed Beaverlodge Ridge near the equator and thus tropical paleolatitude conditions at ~ 1.8 Ga [1]. The maximum AI and PIA values of 77 and 96, respectively, indicate heavy weathering during the formation of the Beaverlodge Ridge regolith. While Si, Fe, K, Ca, and Ti display an upward increase towards the unconformity, Na and Mg have been removed from the profile. Aluminum, Mn, and P remain relatively constant throughout the profile. These major element trends are inconsistent with other Paleoproterozoic regoliths (Gall, 1994; Pan and Stauffer, 2000) and are also inconsistent with a modern-day dacite weathering profile (Shangyi et al., 2007). Both of these show an upward loss in Ca. Subsequent analysis of the weathering rinds of porphyry in the quartz arenite shows a depletion in Ca relative to the altered porphyry. This suggests that the upward increase in Ca observed in the porphyry might be due to later overprinting events.

Electron microprobe analysis and back-scattered electron imaging reveal that accessory minerals such as zircon, allanite, and fluoroapatite in the Beaverlodge Ridge regolith are well preserved, whereas Fe and Ti oxides such as magnetite and rutile often display extensive weathering and show evidence of surface weathering such as etching and pitting. Zircon grains are sub- to euhedral, whereas allanite grains are anhedral. Fluoroapatite occurs in two different morphologies: 1) distinctly zoned, sub- to euhedral grains with overgrowth rims that often containing monazite inclusions within or adjacent to these overgrowths, and 2) lacking growthzones and monazite inclusions. Further morphological and compositional analyses of accessory minerals are underway to examine their roles in controlling the major and trace elements in the Beaverlodge Ridge regolith. These results are expected to shed new light on the oxic atmosphere ca. 1.9 Ga and lead to a greater understanding of GOE.

[3]Eawag, Überlandstrasse 133, 8600 Dübendorf, Switzerland.

A low blank-high yield procedure for the accurate determination of seawater osmium concentration and isotope composition has been developed. The resulting improvement in the detection limit reveals a subtle but significant temporal increase in the concentration of samples obtained during the GEOTRACES expeditions. This increase in Os concentration is accompanied by a decrease in the $^{187}Os/^{188}Os$ ratio of the water indicating contamination of waters from the storage bottles. These samples were stored in HDPE bottles. In comparison, analyses of another aliquot of water stored in a Teflon bottle show no Os contamination. Extending our analyses further to samples collected in LDPE bottles during SAFe expedition we find that the water has been contaminated. Additional investigations reveal that LDPE bottles could contribute large amounts of Os with an $^{187}Os/^{188}Os$ ratio that is distinctly lower than seawater. We also find that an acidified melted snow sample stored in an acid washed Teflon bottle is not contaminated after two years of storage. We conclude that the acidified seawater samples need to be stored in Teflon bottles for accurate and precise estimate of Os concentration and isotope composition. Consideration of reliable Os isotope data indicates that Os is not a conservative element and that the $^{187}Os/^{188}Os$ ratio of the surface water of the interior of the north Atlantic and north Pacific gyres is ~2-3% lower than that of the deep oceans. Additional analyses from the recently completed GEOTRACES cruise in the Atlantic are underway and will be presented.

Evidence of transport of Composition B colloids/nano-colloids in range soils

PRASESH SHARMA[1,*], MELANIE MAYES[1], AND GUOPING TANG[1]

[1]Oak Ridge National Lab, Subsurface Sciences Group, sharmap@ornl.gov (*presenting author), mayesma@ornl.gov and tangg@ornl.gov

Abstract

Munition constituents (explosive particles such as Composition B or simply Comp B) distributed heterogeneously at operational range sites from low-order denotations may be the source of contamination of TNT, RDX and HMX to underlying aquifers. Comp B consists of ~59% RDX, 40% TNT and 1% HMX. Mobility of these compounds in soils/groundwater may occur via dissolution of Comp B and/or via transport of Comp B particles/colloids. To determine this, we collected soils from the E horizon of Massachusetts Military Range (MMR) where RDX and TNT contamination was recently observed. Column experiments were conducted where Comp B particles (<2 μm) were applied on top of the MMR-E soil filled column and leached with background solution of 1 mM NaCl. Effluents were collected every hour and separated into two aliquots: 1) <1 μm (or total), 2) dissolved (<2nm) fractions. Each aliquot was analysed with HPLC to quantify TNT, RDX and HMX. Difference between the <1 μm and <2 nm fraction denotes the amount of TNT, RDX and HMX in the colloidal/nano-colloidal fraction.

Results showed that up to ~80% of TNT and between 40-50% of RDX and HMX in the system were transported in colloidal/nano-colloidal (>2 nm -1 μm). While comparing the breakthrough in <1 μm fractions, the breakthrough of RDX was the fastest followed by HMX and then TNT. While comparing breakthrough of dissolved vs colloidal/nano-colloidal fractions, the breakthrough of the colloidal fraction for TNT, RDX and HMX was relatively faster than the dissolved fraction. Using ATR-FTIR spectroscopy we were also able to identify Comp B colloids in column effluents.

Results conclude that: 1) Comp B particles may move as colloids/nano-colloids in soils, 2) Faster breakthrough of RDX and HMX suggests lower binding affinity whereas TNT binds more strongly to the soil matrix regardless of particle size and 3) The faster breakthrough of TNT, RDX and HMX in <1 μm fraction compared to the dissolved fraction suggests that Comp B colloids/particles may move in the subsurface with less retardation compared to dissolved TNT, RDX and HMX.

The results, for the first time, show evidence of colloidal transport of munition constituents in column systems. Transport of Comp B as colloids should thus be considered while studying contaminated field sites such as MMR. Current results will be compared with column experiments in which Comp B will be applied to intact MMR-E columns collected from the same site. Intact columns may contain fractures and macropores likely to enhance the propagation of colloidal phases.

Precise, accurate measurement of U-Th isotopes in a single solution by ICP-MS

REGINA MERTZ-KRAUS[1], KENNETH R. LUDWIG[1], AND WARREN D. SHARP[1*]

[1]Berkeley Geochronology Center, Berkeley, USA, rmertz@bgc.org, kludwig@bgc.org, wsharp@bgc.org (*presenting author)

U-series isotope measurements by ICP-MS commonly utilize separate runs for U and Th, and standard-sample bracketing to determine corrections for mass fractionation and ion counter yield. Here we present an approach where all information necessary to calculate a sample's age (aside from background/baseline levels) is determined while analyzing a single solution containing both U and Th. Such an internally calibrated procedure reduces any bias caused by distinct behavior of samples versus standards (e.g., matrix effects), eliminates drift, and offers simplicity of operation, calculation of preliminary ages in real time, and simplified analysis of errors and their sources. Hellstrom [1] developed a single-solution, internally calibrated technique for an ICP-MS with multiple ion counters (Nu Plasma), but to our knowledge such a technique has not been available previously for an ICP-MS with a single ion counter. We use a Thermo Neptune *Plus* multi-collector ICP-MS with eight movable Faraday cups and a fixed center cup/ion counter equipped with a high abundance-sensitivity filter (RPQ). We use Faraday cups to measure all masses except 230 and 234, which are generally measured on the ion counter with the RPQ detuned (i.e., set 50 volts below the acceleration voltage). Analyses are dynamic, with sequential axial masses of circa 229, 230, 233, 234, and 239. ^{238}U is maintained in cups throughout the analysis to avoid reflections and is used to normalize signal instabilities related to sample introduction. Each analysis has a three-part structure in which 1) background/baseline levels, 2) sample composition, and 3) peak-tails are sequentially measured. In step 1, multiplier dark noise/Faraday baselines plus background intensities at each mass are determined while aspirating running solution. During sample measurement in step 2, ion counter yields for Th and U are determined using signals of 300-500 kcps for ^{229}Th and ^{233}U by measuring ^{229}Th/^{238}U and ^{233}U/^{238}U ratios with the minor masses first on the ion counter and then in cups. Mass bias can be determined using the ^{233}U/^{236}U ratio of the spike, allowing the sample's ^{238}U/^{235}U ratio to be measured. In step 3, we monitor peak-tails at half-mass positions (229.5, 231.5, 234.5) and on mass 237 while aspirating sample solution. Tail measurement requires a distinct cup configuration to maintain 238 in the cups; however, no sample is consumed during automated cup reconfiguration.

We monitor the accuracy of ^{234}U/^{238}U ratios using CRM 145, which gives a weighted mean atom ratio of $(5.2899 \pm 0.0021) \times 10^{-5}$ (all errors 2 SEM), consistent with published and reference values. The reproducibility of ^{230}Th/^{238}U ratios is monitored using the Schwartzwalder Mine secular-equilibrium standard (SM). We detect no bias in ^{230}Th/^{238}U or ^{234}U/^{238}U ratios measured for SM at beam intensities ranging over a factor of four, consistent with accurate correction for IC yields. Aladdin's cave coral (AC-1), analyzed to check our method on carbonate, yields a mean age of 124.42 ± 0.37 ka, in agreement with published values. We are currently applying the method to corals, speleothems, pedogenic coatings, and tufas.

Session 22a. Tracing Groundwater Variability

Geochemical and isotopic tracers in groundwater and surface water studies in montane catchments have become increasingly popular because monitoring wells are often sparse and terrain is complex (e.g. fractures and folds), which makes physical hydrogeologic methods difficult to characterize quantitatively. In this study several geochemical tracers (^{222}Rn, δ^2H, δ^{18}O, and major ions) were collected spatially in Georgetown Lake, Granite County Montana, a large montane lake with a surface area of 1489 ha. The geochemistry of nearby precipitation, surface water, and groundwater was also characterized to assess the chemistry of source waters mixing with the lake. Physical and chemical measurements were used to i) construct a water balance for the lake, ii) characterize groundwater flow locations and amounts with the lake, and iii) develop a conceptual model for geologic controls on groundwater-lake interactions. Stable isotopes were used in an endmember mixing analysis to separate the relative fractions of source waters mixing with the lake, a physical water budget was used to quantify the difference between groundwater inflows and outflows, and a radon mass balance was used to characterize the groundwater flow locations and amounts to the lake.

Results from the stable isotopes show three endmembers mix with the lake. They are precipitation (39%), groundwater (26%), and a strongly evaporated endmember (35%). The evaporated endmember is most likely groundwater and/or surface water that later evaporated after entering the lake. The physical water budget suggests little difference between groundwater inflows and outflows, but could not be used to quantify groundwater inflow or outflow amounts. The radon mass balance suggests that groundwater inflows to the lake are substantial. Based on the physical water budget, this implies that groundwater outflows are also significant and the lake is a through-flow lake. Radon measurements also show that nearly all of the groundwater inflows occur along the eastern side of the lake, which is underlain by carbonate bedrock. The western portion of the lake (~75% area) is underlain by western dipping Precambrian metasedimentary bedrock. The steep dip and limited groundwater elevations suggest that the western portion of the lake is losing. It appears that groundwater enters through fractures, caverns, and shallow alluvium from the carbonates, and groundwater exits through the western dipping bedding planes and fractures in the metasedimentary rocks.

The use of ^{222}Rn for determining groundwater discharge locations and amounts provides a simple, but crucial, method for developing the conceptual model in this study. The spatial measurements of ^{222}Rn elucidate groundwater interactions that could not be assessed by geology, water levels and physical water budgets alone. Even conservative water isotope mass balances were limited in characterizing the nature of groundwater-lake interactions.

The crystallization of Amorphous Calcium Carbonate (ACC), and the effects of magnesium and sulfate

SAM SHAW[1*], PIETER BOTS[1], JUAN-DIEGO RODRIGUEZ-BLANCO[1], CLIVE WOOD[1,2], ANDREW P. BROWN[2] AND LIANE G. BENNING[1]

[1]Earth Surface Science Institute, School of Earth and Environment, University of Leeds, Leeds, UK, s.shaw@see.leeds.ac.uk (* presenting author)

[2]Institute for Materials Research, University of Leeds, Leeds, UK

Many organisms use transient ACC during biomineralization, as a means to control the particle shape/size and structure (e.g. calcite, aragonite or vaterite) of the crystalline calcium carbonate formed. For example, sea urchin larvae produce highly elongated single crystals of calcite by the controlled deposition and transformation of ACC [1]. Organisms also adjust or control the crystallization pathway using inorganic ions, organic molecules and/or membrane structures. Resolving the mechanisms and kinetics of ACC crystallization in abiotic systems, and evaluating the role of inorganic additives (e.g. Mg and SO_4) is key to underpinning our understanding of biologically-controlled calcium carbonate formation. In particular, the pathway of crystallization from disordered hydrated ACC to fully crystalline calcite needs to be quantified.

Using *in situ* small and wide angle X-ray scattering (SAXS/WAXS) at fast time resolution (1 sec.) we studied the crystallization of ACC to vaterite/calcite in the absence and presence of variable Mg and SO_4 concentrations. We show that pure ACC crystallizes via a multi-stage process [2]. Firstly, hydrated and disordered ACC forms, then rapidly transforms to more ordered and dehydrated ACC; in conjunction with this, vaterite forms via a spherulitic growth mechanism. This is followed by Ostwald ripening of the vaterite particles, and finally transformation to calcite via a surface controlled growth mechanism. The presence of Mg in ACC significantly reduced the rate of crystallization and led to the direct formation of calcite (Mg = 10%), or various Ca-Mg-CO_3 polymorphs (Mg > 10%), including monohydrocalcite and dolomite (T>60°C) [3]. The presence of SO_4 did not alter the overall ACC crystallization mechanism, but reduced the rate of vaterite nucleation, growth and ripening due to surface adsorption [2]. Also, SO_4 dramatically increased the stability of vaterite compared to the pure system (i.e. stable for hours/days).

These results provide a comprehensive mechanistic description of the abiotic ACC crystallization pathway, with the final crystalline product being controlled by the initial ACC composition (e.g., Mg or SO_4 content). These abiotic crystallization mechanisms are similar to those observed in marine organisms [1], where it has been shown that secondary calcite nucleates within ACC, a process comparable to the secondary (vaterite) and tertiary (calcite) nucleation and growth observed in our systems.

Bioaccessibility and bioavailability of arsenic-bearing mine wastes via the inhalation pathway

SHDO, S.M.[1*], MOLINA, R.[2], BRAIN, J.[2] KIM, C.S.[1]

[1] Schmid College of Science, Chapman University, Orange, CA 92866, USA

[2]Harvard School of Public Health, Boston, MA 02114, USA

Due to extensive processing of ore from gold and silver mines in the Mojave Desert, CA, elevated concentrations of associated toxic metal(loid)s including arsenic (As) are often mobilized by the transport of mine wastes into surrounding communities. The fine-grained fraction of mine waste particles can readily become airborne and inhaled. making their bioaccesibility and bioavailibility extremely relevant.

Bulk samples were collected from a number of mines throughout the Mojave Desert and sieved to obtain fine size fractions. The size fraction was then ground using a ball mill to a size fraction (≤2.5 μm in particle diameter). The bioaccessibility of As as a function of pH was examined in phagolysosomal simulant fluid (PSF) Finally, the bioavailability of As was analyzed *in vivo* by intratracheally instilling the material.

Results from four different mine sites indicate that the mine wastes showed similar trends of arsenic dissolution within PSF, with the percent As released decreasing from pH 1.8-4.2 and then slightly increasing pH 5 (Figure 1). The As solubility at low pH is likely due to the dissolution of As-bearing mineral phases while the solubility at higher pH is likely due to the desorption of As sorbed to Fe-oxides. The *in vivo* studies will provide organ-specific bioavailability information which can be correlated with results from the PSF experiments.

This information will help to determine the operational pH for a PSF extraction that most accurately the *in vivo* outcome, with the eventual goal of developing a predictive bench-top bioaccessibility assay that can be used to estimate bioavailability of arsenic in mine wastes as introduced through the inhalation pathway.

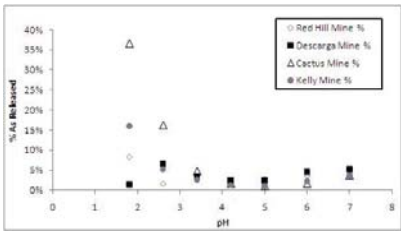

Figure 1: Percentage As released vs. pH

Extensive life on land ~1.1 Ga ago

NATHAN D. SHELDON[1*] AND MICHAEL T. HREN[2]

[1]Department of Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI, USA, nsheldon@umich.edu* (presenting author)

[2]Department of Earth and Planetary Sciences, University of Tennessee, Knoxville, TN, USA, mhren@utk.edu

The precise timing of life's move onto land in the Precambrian, along with the extent of the terrestrial biosphere, is poorly constrained, with only a sparse record before the Neoproterozoic, known primarily from paleokarsts [1]. A recent study by Strother and colleagues [2] described the earliest non-marine eukaryotes from the ~1 Ga old lacustrine Diabaig Formation (Torridon Group, Scotland). Penecontemporaneous lakeshore and alluvial deposits well away from marine shorelines from Scotland also record microbially induced sedimentary structures [3]. Thus, at least locally, a significant and potentially diverse terrestrial biosphere was present, but the extent of the Mesoproterozoic terrestrial biosphere remains an open question.

Here, we present sedimentological and isotopic evidence for an extensive terrestrial biosphere preserved in sediments that are part of the ~1.1 Ga old Midcontinent Rift (MCR) of North America. The active rifting phase of the MCR was short-lived, from 1109 to 1087 Ma [4], and clastic sediments were deposited both as intrabasaltic units and as post-emplacement units. Rifting ceased due to Grenvillian compression to the East, which resulted in a partial re-closure of the rift. Penecontemporaneous intrabasaltic units from both sides of the rift in Minnesota and Michigan record a variety of sedimentary environments including paleosols [5-6], braid plains, alluvial fans, and lacustrine units; sites are currently >150 km apart, a distance that would have been significantly larger prior to the tectonic reversal caused by the Grenvillian compression. The sedimentary units have never been deeply buried or experienced any significant metasomatic alteration [5-6]. Microbially induced sedimentary structures including abraded Kinneyia, pustulose mound structures, multi-directional wave ripples, textured bedding planes, and stromatolites were recently documented [7]. Organic matter is also preserved on both sides of the rift in paleosols and microbial mat structures, as detrital carbon in laminated fluvial sediments, and occluded with the carbonate of lacustrine stromatolites in Michigan. "Clumped isotope" (Δ_{47}) analyses of stromatolitic carbonate range from 0.513–0.603 (± 0.004), which indicates carbonate formation temperatures of 35–60°C (±4°C), and that there was no significant post-burial heating of the preserved organic matter. $\delta^{13}C_{org}$ values range from -29.6 to -24.0‰, suggesting C fixation by photosynthesis. Some $\delta^{13}C_{org}$ depth profiles through paleosols indicate diffusive enrichment comparable to modern soils, which suggests that the microbial communities were present both at the soil surfaces and subsurface. Together, these various lines of evidence indicate an extensive terrestrial biosphere by ~1.1 Ga ago.

Abstract

The Panjal Traps of northern India represent a significant outpouring of mafic and felsic volcanic rocks during the Early Permian and are synchronous with the opening of the Neotethys Ocean. Previous studies have suggested that the felsic volcanic rocks are derived by differentiation of mafic magmas. Dacites and rhyolites collected from the lower-middle portion of the volcanic pile near Pampore, Kashmir are peraluminous (ANCK > 1.0) in composition. Their whole rock I_{Sr} values are variable (I_{Sr} = 0.69307 to 0.71825) and indicate open system behavior of either Rb or Sr or both whereas their Nd isotopic compositions ($\varepsilon Nd_{(T)}$ = -8.6 to -8.9) are nearly uniform. The $\varepsilon Nd_{(T)}$ values and trace element (Th/Nb_{PM} > 4; Nb/U < 10; Th/Ta > 8) ratios suggest the rocks are derived from the crust. Major and trace elemental modeling suggest the likely source was from the middle crust rather than the lower or upper crust. Furthermore, the felsic Panjal Traps have trace element compositions similar to some felsic volcanic rocks and A-type granitic rocks from other large igneous provinces (e.g. Karoo, Parana and CAMP) and that they were likely derived by partial melting of an ancient crustal (i.e. T_{DM} = 1836 to 1937 Ma) source which experienced multiple episodes of crustal recycling. In contrast to other LIP felsic volcanic rocks, the acidic Panjal Traps are unique in that they were not derived from a mafic mantle source material. The heat required to melt the crust was likely due to the continuous injection of contemporaneous basaltic magmas which formed the majority of the mafic Panjal Traps.

Biogeochemistry Improves Prediction of Metal Bioaccessibility of Yard Soils in Tar Creek, USA

Introduction

Heavy metal contamination in soils is ubiquitously observed due to mining, smelting, and industrial processes. Current approaches to determine the risk of metals via oral ingestion from soils are through operationally defined in-vivo or in-vitro tests. In addition, regulatory agencies often assume a default value as the bioavailable proportion of total metal. However, metal bioavailability in soil varies greatly based on their chemical forms, retention and releasing process, as well as exposure pathways. In order to better assess risks, it is necessary to bridge the gap between geochemistry, bioaccessibility and risk assessment of metals.

Method

In-vitro simple bioaccessibility extraction tests (SBET) and sequential extractions were conducted on yard soil samples collected from the Tar Creek Superfund Site, OK, a former lead and zinc mining area. In addition, we conducted SBET and sequential extraction on pure phase metal minerals and metal minerals spiked in a reference soil to determine the role of both speciation and soil matrix effects on metal bioaccessibility. X-ray absorption spectroscopy techniques were also used as a supplementary tool on a subset of yard soil samples. We applied statistic models to predict metal bioaccessibility in soils given metal distribution in the soil matrix.

Conclusion

Sequential extraction enables one to identify direct and potential hazardous metal fractions in soil in terms of being bioaccessible. Compared with total metal content, taking into account metal speciation in soil improves the estimation of the extent of bioaccessibility to different extents for different metals (Pb, Mn, Zn, Cd, Cu). The results help figure out the profound effects of mineralogical composition of metals, soil properties and particle size on determining metal bioaccessibility. Based on the results, site-specific metal biogeochemistry information might be able to be utilized to make metal bioavailability assessment more accurate.

Uranium adsorption by *Shewanella oneidensis* MR-1 in the presence of $NaHCO_3$

LING SHENG *, JEREMY B. FEIN

Civil Engineering and Geological Sciences, University of Notre Dame, Notre Dame. * lsheng@nd.edu (* presenting author)

There have been several previous studies that have measured the adsorption behavior of U(VI) onto non-metabolizing bacteria in experiments either devoid of dissolved CO2 or in systems open to the atmosphere. There is considerable evidence for extensive adsorption of U(VI) above pH 6-7 where the aqueous uranyl-tricarbonate aqueous complex dominates the aqueous budget of uranium. However, there is considerable uncertainty regarding the identity and thermodynamic stability of the bacterial surface complexes that cause this adsorption. It is particularly important to determine these parameters in order to model the effect of bacterial adsorption of U(VI) in a range of natural or engineered carbonate-bearing aqueous systems.

In order to constrain the stoichiometry and stability of the important U(VI)-bacterial surface complexes, we measured the adsorption of 60 ppm aqueous U(VI) as a function of $NaHCO_3$ concentration in solution from 0.0 to 30.0 mM. Experiments were conducted in 0.1 $NaClO_4$ to buffer ionic strength, and pH was varied from 3 to 9 in order to vary the extent of protonation of bacterial surface sites so that the sites that are important in U(VI) binding could be identified. All the experiments were conducted open to the atmosphere. The observed extents of U(VI) adsorption are independent of $NaHCO_3$ concentration in the system below pH 5. Above pH 5, the extent of adsorption decreases with increasing $NaHCO_3$ concentration, but the observed extent of adsorption in each case is greater than that predicted assuming only aqueous uranyl-carbonate complexation and neglecting ternary uranyl-carbonate-bacterial complexation.

We used a non-electrostatic surface complexation approach to model the adsorption data. The data require the existence of at least two uranyl-carbonate-bacterial surface complexes, and we use the observed adsorption measurements to constrain values for the stability constants for each of these complexes. The modeling results suggest the presence of additional uranyl-carbonate bacterial surface complexes than have been previously identified under conditions with elevated carbonate concentrations. These complexes can control the U(VI) adsorption behavior in systems with high carbonate concentrations and hence our results can be used to predict the extent of U(VI) adsorption onto bacteria in a range of natural and engineered systems.

Environmental monitoring of tungsten in Fallon, Nevada

PAUL R. SHEPPARD[1*], GARY RIDENOUR[2], AND MARK L. WITTEN[3]

[1]University of Arizona, Laboratory of Tree-Ring Research, Tucson, AZ USA, sheppard@ltrr.arizona.edu (* presenting author)
[2]Physician, Fallon, NV USA, docridenour@charter.net
[3]Odyssey Research, Tucson, AZ USA, mlwitten@yahoo.com

Environmental Monitoring in Fallon

Fallon, Nevada, USA, experienced a cluster of childhood leukemia beginning in 1997 [1]. Extensive research was conducted in Fallon by multiple entities to determine what might have caused this childhood leukemia cluster. For our part, we employed multiple techniques of environmental monitoring for metals in Fallon, including chemistry of airborne dust, lichens, surface dust, surfaces of tree leaves, and tree rings [2].

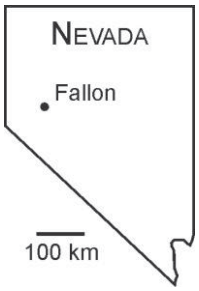

Figure 1: Map showing location of Fallon, Nevada, USA

Results

Tungsten and cobalt were elevated in airborne dust of Fallon relative to comparison towns. Tungsten and cobalt were elevated in lichen tissues within Fallon relative to desert sites outside of town. Surface dust showed tungsten and cobalt concentrations peaking just northwest of the center of Fallon relative to the outskirts of town. Leaf surfaces confirmed this spatial pattern of tungsten and cobalt peaking just northwest of the center of Fallon. Tree rings, a technique that emphasizes temporal resolvability, showed tungsten increasing in central Fallon by the mid to late 1990s, coinciding roughly with the onset of the cluster of childhood leukemia. Tree rings also showed high inter-tree variability in tungsten and cobalt across sampled trees within Fallon relative to comparison towns.

Conclusion

Fallon is distinctive by experiencing a cluster of childhood leukemia and having elevated airborne tungsten and cobalt. Linkage between a disease and an environmental condition cannot be made from environmental data alone. However, the co-occurrence in Fallon of elevated airborne tungsten and cobalt and a cluster of childhood leukemia logically should prompt biomedical research to evaluate the potential linkage between leukemia and the combined exposure to airborne tungsten and cobalt.

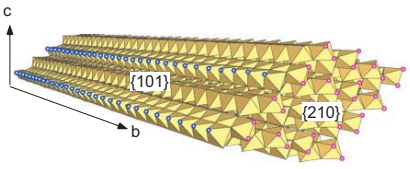
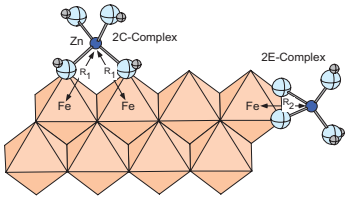
Multisite Surface-Complexation of Zn and Cu on Goethite

DAVID M SHERMAN*[1], DAVID MOORE

[3]School of Earth Sciences, University of Bristol, Bristol, BS8 1RJ, UK dave.sherman@bris.ac.uk (* presenting author)

Goethite (α-FeOOH) is the paradigm mineral for the scavenging of metals in terrestrial environments. The structure of goethite is based on edge-sharing FeO_6 octahedra which form double chains along the **b**-direction (using space-group setting Pnma); the double chains are linked to each other via corner-sharing in the **a**- and **c**-directions. At the nano-scale, goethite forms long needles along the **b**-direction with the {101} surfaces being dominant (Fig 1). The {101} surfaces have singly coordinated surface oxygens which can complex to metals via the formation of a bidentate double corner-sharing (2C) complex. However, the goethite needles are terminated by a {210} surface; on this surface, Zn and Cu could bind by forming an edge-sharing 2E complex (Fig. 2). The {210} surfaces comprise only a few per-cent of the surface area of goethite but we can infer that the {210} surfaces would be much more reactive than the {101} surfaces. We hypothesise that sorption of metals such as Zn and Cu to goethite will first take place on the more reactive {210} surface. However, since this surface only comprises a few percent of the total surface area the sorption capacity of the {210} surface will be limited to ~0.01wt % Cu or Zn.





We have measured the sorption of Cu and Zn to goethite as a function of surface loading (0.008 to 0.8 wt. %). We find that our sorption edges can only be simultaneously modelled if we invoke several different surface complexes. For both Cu and Zn, the strong edge-sharing 2E complex on the {210} surface dominates at loadings < 0.01 wt. %. The weaker double corner-sharing 2C complex on the {101} surface dominates at loadings near 0.1 wt. %. Above 0.1 wt. %, both Cu and Zn form polynuclear complexes. Previous EXAFS studies of Cu [1] and Zn [2], at surface loadings > 0.1 wt %, only resolved 2C and polynuclear complexes of Zn or Cu on the {101} surface. However, at more environmentally relevant surface loadings, the 2E complexes on the {210} surface should be dominant. More powerful synchrotron sources (e.g., I20 at Diamond) will enable us to confirm the existence of the 2E complexes, at least for Zn.

Mercury in precipitation, sediments, and largemouth bass in FL: Insights using mercury stable isotopes

LAURA S. SHERMAN[1*] AND JOEL D. BLUM[2]

[1]University of Michigan, Earth and Environmental Sciences, Ann Arbor, MI, USA, lsaylors@umich.edu (*presenting author)

[2](Same as 1), jdblum@umich.edu

Mercury (Hg) concentrations in precipitation and fish are elevated across Florida (FL), U.S.A.[1] However, it is difficult to determine the specific biogeochemical pathways by which fish aquire Hg. Recent studies suggest that newly deposited Hg can be more bioavailable than Hg in sediments and that this Hg can rapidly enter aquatic food webs.[2] To gain insight into the sources of Hg to fish in FL, we analyzed Hg stable isotope ratios in precipitation, lake sediments, and largemouth bass collected across central FL.

We sampled surface sediments from freshwater lakes in central FL that are impacted by a mixutre of local and regional Hg sources. These surface sediments displayed a wide range of δ^{202}Hg values from -1.19 to -0.46‰ (mean = -0.72‰, 1 s.d. = 0.24‰, n = 18) and did not display significant mass-independent fractionation (MIF). Largemouth bass collected from a subset of these lakes displayed a range of δ^{202}Hg values and significant positive MIF (Δ^{199}Hg up to 4.43‰). We suggest that this MIF is due to photochemical degredation of methylmercury[3] prior to uptake into the food web. By using an experimentally derived fractionation relationship[3], we estimated δ^{202}Hg values of the fish methylmercury prior to photochemical processing and uptake. These δ^{202}Hg values were consistently offset from those of the corresponding sediments by 0.50‰ (1 s.d. = 0.14‰, n = 8). In addition, δ^{202}Hg values in the sediments were found to be correlated with the calculated δ^{202}Hg values for the fish methylmercury (r^2 = 0.47). These data suggest that methylmercury in the fish originates in large part from Hg in the sediments, which represents a mixture of historic Hg and modern atmospheric Hg. Prior to uptake by fish, non-photochemical processes[4, 5] cause an increase in δ^{202}Hg of ~0.50‰ and photochemical demethylation causes further increases in δ^{202}Hg values as well as large increases in Δ^{199}Hg values.

To examine the impact of a single, isolated source of Hg deposition on these relationships, we collected precipitation samples, lake sediments, and largemouth bass near a large coal-fired power plant in Crystal River, FL. These precipitation samples were uniquely characterized by large negative δ^{202}Hg values (mean = -2.56‰, 1 s.d. = 1.10‰, n = 28).[6] However, we did not observe similarly negative δ^{202}Hg values in sediments or fish collected in the area. Instead, δ^{202}Hg values of sediments and fish from the Crystal River area were comparable to those of the other lakes and were similarly offset and correlated. If emissions from the power plant have been isotopically consistent through time, this suggests that these emissions are not more rapidly bioavailable and are instead mixed with Hg in sediments prior to uptake by largemouth bass.

Natural Fe fertilization mechanisms in the Amundsen Sea Polynya, Antarctica

ROBERT M. SHERRELL[1,2]*, SILKE SEVERMANN[1,2], MARIA LAGERSTRÖM[1], KATHERINE ESSWEIN[1], KURIA NDUNGU[3], PER ANDERSSON[4], SHARON STAMMERJOHN[5], PATRICIA YAGER[6]

[1]Rutgers University, Institute of Marine and Coastal Sciences sherrell@marine.rutgers.edu (* presenting author) lagerstrom@marine.rutgers.edu kesswein@marine.rutgers.edu
[2]Rutgers University, Department of Earth and Planetary Sciences silke@marine.rutgers.edu

[4]Swedish Museum of Natural History Per.Andersson@nrm.se
[5]INSTAAR, University of Colorado Sharon.Stammerjohn@Colorado.EDU
[6] University of Georgia, Sch. of Marine Programs pyager@uga.edu

The polynya of the Amundsen Sea, West Antarctica, is the most productive region of the Antarctic Shelf (~40 mg/m3 Chl-a in Dec. 2010), and is a test case for natural Fe fertilization, in stark contrast to the Fe-limited Antarctic Circumpolar Current (ACC) that borders this shelf region. ASPIRE (Amundsen Sea Polynya International Research Expedition, field work completed 2010-11), is an multidisciplinary study with a core emphasis on the mechanisms and pathways of bioavailable Fe delivery to the polynya euphotic zone. Candidate Fe sources include atmospheric deposition, upwelling of Modified Circumplar Deep Water, sea ice melting, glacier and iceberg melting, and inputs from shallow sediments. Samples for dissolved and particulate (>0.45um) trace metals and for Nd isotopes were collected at 35 stations in Dec. to early Jan. using a Geotraces-type CTD-rosette and in-situ pumps. Dissolved Fe (dFe) concentrations varying widely, and generally increase with depth. High values (up to 2nM) occur in near-bottom (~700m) waters of the western bathymetric trough and in the outflow from under the Dotson ice shelf (1nM at 150-600m). Lowest values (<0.1nM) are found in surface waters of the most productive central polynya region. Suspended particulate Fe (pFe), ranging 5-60nM, exceeds dissolved Fe throughout. Leachable fractions (LpFe; 25% acetic acid) range 0.2-16nM (2-35% of pFe), are lowest in the euphotic zone and highest in two important regions: at 50-600m where glacial meltwater-influenced flow emanates from under the ice shelf, and at ~300m adjacent to a drifting iceberg encountered in the southern polynya. Euphotic zone leachable Fe/P ratios are generally >10 mmol/mol, suggesting Fe-replete phytoplankton at most stations. Strikingly, Fe/P is very high (>1000 mmol/mol) and nearly identical at 50-150m in both the ice shelf and iceberg stations, suggesting that these are regions of injection of potentially bioavaible glacially-sourced LpFe into the upper water column. Dissolved Nd isotopes (<0.2um), a quasi-conservative tracer of continental sources, support the importance of glacial terrigenous inputs, with values as low as -6.0 at the ice-shelf outflow station (compare to adjacent ACC at ~ -8.0), tracing Fe inputs from radiogenic source rocks to shelf waters.

Inputs of dissolved and especially of labile particulate Fe resulting from flow under glacial ice-shelves are a major source of bioavailable Fe fueling productivity in the Amundsen Sea polynya.

Like the Lost City Hydrothermal Vents or Rainbow field, at depths of 2-3 km below the Earth's surface, saline fracture waters in the Precambrian Shields of Canada, Fennoscandia and South Africa are some of the most H_2 –rich on the planet and hence an important setting to investigate the planet's habitability – but significantly under investigated compared to the higher temperature hydrothermal systems and marine analog sites. The deep fracture waters host some of the deepest microbial communities yet identified on the planet: a low biomass, low biodiversity ecosystem subsisting at maintenance rates far from the photosphere – dominated by H_2-utilizing sulphate-reducing bacteria and H_2 derived from radiolysis and serpentinization [1,2]. These subsurface sites represent a critical environment in which to determine whether the types of chemolithotrophic life recognized at the vents are supported in the much larger segments of the Earth's crust where lower temperatures and hence slower rates of water-rock reaction prevail.

The tectonically quiescent, ancient fractured rock subsurface is directly relevant to single plate planets such as Mars, where surface expressions of volcanism such as hydrothermal vents are unlikely. Many of the investigated sites are located in northern regions in areas of continuous or semi-continuous permafrost, providing the opportunity to investigate psychrophilic life and hence as analogs for potential extinct or extant life on the icy planets and moons. Unlike high temperature seafloor systems like Lost City, where rapid fluid circulation and mixing means that the products of water-rock reaction such as H_2 rapidly diffuse away, the hydrogeologically isolated fracture waters in Precambrian Shield rock provide virtual "time capsules" in which, despite the slower rates of reaction, the products of water rock reaction and potential substrates for microbial life can accumulate and build up high concentration gradients over geological long time scales. The deepest and oldest fracture networks have residence time estimates derived from noble gas studies on the order of tens of millions of years [3], preserving a geochemical and microbial environment minimally impacted by hydrogeological mixing with the surface. They may provide a window into a different aspect of the Earth's biodiversity, but most significantly may preserve a more deeply branched and potentially evolutionarily older component of the Earth's life history with important implications for the origin and radiation of life on Earth. The deepest fracture water may even provide the opportunity to investigate controls on the biotic-abiotic transition and limits to life in the deep Earth.

High pressure constraints core formation from x-ray nanoscale tomography

YINGXIA SHI[1]*, WENDY L MAO[1, 2], LI ZHANG[3], WENGE YANG[4], YIJIN LIU[2], JUNYUE WANG[4]

[4]Argonne National Laboratory, Argonne, USA

Core-formation represents the most significant differentiation event in Earth's history. Percolation of liquid iron-rich alloy through a crystalline silicate matrix has been suggested as a possible core formation mechanism, especially for the differentiation of planetesimals during the early history of our solar system, since radioactive decay of short-lived isotopes in the small accreting bodies cannot provide enough heat to form extensive melting (i.e. magma ocean) [1-2]. Previous experimental results looking at dihedral angles in silicate metal samples synthetized at elevated pressures and temperatures suggest that percolation is unlikely to be an efficient mechanism in our planet [3-4]. However, experimental conditions in previous work have been limited in upper mantle conditions (<30GPa). Moreover the measurement of dihedral angles using transmission electron microscopy or backscattered electron microscopy may not generate satisfactory statistics. Nanoscale x-ray computed tomography (nanoXCT) has exciting potential as an accurate probe to study the 3D connectivity and permeability of core forming melts in crystalline silicates. Using a laser-heated diamond anvil cell, experimental conditions over the entire pressure-temperature range in the lower mantle can be accessed. In this study, we compressed and heated the mixture of iron-rich alloy + orthopyroxene, and then used a focused ion beam (FIB) to mill the quenched samples to extract a portion for nano-XCT. Pilot studies from our group using 3D nano XCT have demonstrated the ability to image the detailed morphology of the iron-alloy and silicates, along with details of Fe-FeS eutectic intergrowth patterns, which help to distinguish the relative Fe content in Fe and FeS. Data resulting from the combination of these techniques could improve our understanding of planetary core-forming processes.

Lead Adsorption on Iron-amended Composts

ZHENQING SHI,*[1] YEEWEI CHAN[1], AND JAMES HARSH[1]

[1]Washington State University, Pullman WA, USA, zhenqing.shi@wsu.edu (* presenting author)

Biosolids high in Fe have been shown to reduce the bioavailability of soil Pb both to plants and, when ingested or inhaled, to humans. We characterizing an Fe-rich compost that was developed to serve the same role as Fe-rich biosolids. The objectives of this work are (1) to determine the effectiveness of this material in lowering the bioavailability of Pb in soils (2) to characterize the nature of the reactive sites and their mechanism of metal sequestration. In this study, we (1) determine the capacity for Pb as a function of Fe concentration and Fe source, (2) assess the ability of Fe-compost to transform Pb in contaminated soils to highly recalcitrant states, and (3) model the distribution of Fe between organic- and Fe-sites.

Batch experiments were conducted to study the capacity of the iron-amended compost to adsorb Pb, including adsorption isotherms at various pH and adsorption edges at various initial Pb concentrations. For some selected experiments, the compost samples with varying iron contents were used to evaluate the effect of iron-amendment. Generally, the iron-amended composts showed high Pb adsorption capacity (> 3% Pb in composts), suggesting high concentrations of reactive organic matter and iron oxides in these compost samples. Lead adsorption increased with Fe concentration, suggesting that Fe sites played a role in increased adsorption.

The ability of iron-amended composts to sequester Pb in contaminated soils was investigated by incubating two contaminated soils with the compost samples at the field moisture content. We are evaluating the extractability of Pb in these treated soils with sequential extraction methods.

The preliminary modeling results with WHAM VI described the Pb adsorption results well using humic material and iron oxides as adsorbents. The modeling results also suggested that organic matter dominated adsorption at high Pb concentrations and adsorption to iron oxides was greatest at lower Pb concentrations. We are currently calibrating the model parameters with more data and comparing the performance of different speciation models, such as SHM and CD-MUSIC. We hope to acquire a quantitative understanding of the roles of both organic matter and iron minerals on Pb sequestration by the composts.

Uranium isotope fractionation associated with biostimulation experiments at the Old Rifle mill site

ALYSSA E. SHIEL[1]*, PARKER LAUBACH[1], THOMAS M. JOHNSON[1], CRAIG C. LUNDSTROM[1], KENNETH H. WILLIAMS[2] AND PHILIP E. LONG[2]

[1]Dept. of Geology, University of Illinois at Urbana–Champaign, Urbana, IL USA; ashiel@illinois.edu (*presenting author)
[2]Lawrence Berkeley National Laboratory, Berkeley, CA USA

Microbial and geochemical factors controlling subsurface U mobility are evaluated in the U contaminated aquifer at the former U mill site in Rifle, CO USA. Biotic reduction of U(VI) is induced by the injection of acetate (electron donor) into the contaminated aquifer and is used to immobilize U as U(IV). Experimental plots consist of monitoring wells both upgradient and downgradient of an injection gallery. The 2010–11 experiment (Plot C) was designed to isolate the impacts of reduction and sorption processes. Previous work has shown large shifts in $^{238}U/^{235}U$ (hereafter discussed as $\delta^{238}U$) accompany U(VI) bioreduction ($\Delta^{238}U = 1.05‰$) [1]. We provide the results of a more detailed study to increase confidence in the use of $\delta^{238}U$ as an indicator of U(VI) reduction and seek to apply this method to bioremediation experiments in which groundwaters are treated with acetate only or both acetate and bicarbonate (desorbs U from aquifer solids). In addition, this data set gives us, for the first time, $\delta^{238}U$ measurements during rebound of U(VI) concentrations as reduction wanes. This is particularly important as the long-term success of this remediation technique depends on the stability of sequestered U(IV).

We present groundwater U(VI) concentration and $\delta^{238}U$ results for two wells downgradient of the injection gallery; one of the wells (CD-01) was amended with acetate and the other (CD-14) with both acetate and bicarbonate. Preinjection values for the two wells are identical to those upgradient, within the uncertainties. For CD-01, the acetate injection upgradient led to a dramatic drop in [U(VI)] (from 165 to 10.6 ppb) and $\delta^{238}U$ (from 0.03 to -1.32‰), resulting from the preferential removal of ^{238}U as reduced U(IV). An excursion to greater $\delta^{238}U$ values during the period when [U(VI)] was at a minimum may be related to a contribution of relatively heavy U from nano-colloidal U(IV) in the filtered groundwater. After the amendment ceased, the groundwater [U(VI)] and $\delta^{238}U$ returned to approximately preinjection values. Lack of an increase of $\delta^{238}U$ above preinjection values is consistent with advection of U(VI) from upgradient, rather than reoxidation of U(IV), as the primary source.

For CD-14, a large increase in the [U(VI)] was induced by the bicarbonate injection (up to 415 ppb), while no change was observed in $\delta^{238}U$. This is in agreement with previous Rifle field experiments that revealed the absence of significant U isotope fractionation with adsorption–desorption of U(VI) [2]. The acetate injection led to a dramatic decrease in the [U(VI)] and $\delta^{238}U$ values (to 15 ppb and -1.19‰). The recovery of [U(VI)] and $\delta^{238}U$ is much slower for CD-14. Despite the return of [U(VI)] to preinjection values by the end of the field season, sustained U isotope fractionation (-0.43‰) is observed.

Dissolved rhenium and molybdenum in rivers

ALAN SHILLER[1]*

[1]University of Southern Mississippi, Stennis Space Center, MS, USA, alan.shiller@usm.edu

Various workers have reported dissolved concentrations of Re and Mo in rivers and have generally concluded that sulfide weathering is the dominant source of these elements. This is based both on the well-known association of these elements with Black Shales as well as correlation with fluvial sulfate. We have examined the dissolved concentrations of Re and Mo in the Yukon River Basin in Alaska, the Loch Vale watershed, the lower Mississippi River, and the East Pearl River (Miss.). We find that fluvial sulfate correlates nearly 1:1 with estimates of non-carbonate calcium, suggesting that the fluvial Re- and Mo-sulfate correlations are not necessarily conclusive of a sulfide source. We also observe significant seasonal variability of Mo and sometimes Re in some rivers, suggestive of seasonal redox effects on element mobilization and transport.

Electrolyte Ion Adsorption at the Hematite/Water Interface: Cryogenic X-ray Photoelectron and Electrochemical Impedance Spectroscopic Studies

KENICHI SHIMIZU[1]*, ANDREY SHCHUKAREV[1], ANDRZEJ LASIA[2], JOSEPHINA NYSTRÖM[1], PAUL GELADI[3], BRITTA LINDHOLM-SETHSON[1], JEAN-FRANÇOIS BOILY[1]

[3]Unit of Biomass Technology and Chemistry, Swedish University of Agrecultural Sciences, Sweden

Hematite (α-Fe_2O_3) is a commonly occurring mineral in natural environments and its (electro)chemical attributes are of great importance to various geochemical and technological settings. A fundamental understanding of reactions taking place on hematite surfaces is particularly important in this regard. In this study, electrolyte ion adsorption and electrostatic potential development across the hematite/water interface are respectively probed by cryogenic X-ray photoelectron spectroscopy (XPS) and by electrochemical impedance spectroscopy (EIS).

Cryogenic XPS measurements are carried out on colloidal hematite particle surfaces equilibrated in 50 mM aqueous solutions of monovalent ions (Na^+, K^+, Rb^+, Cs^+, NH_4^+, F^-, Cl^-, Br^-, I^-) at pH 2-11. Results consistently reveal coexisting cations and anions both below and above the point of zero charge of hematite. Inverse correlation between pH dependent surface loadings and hydrous ionic radii is observed in both alkali metal ($Na^+ > K^+ > Rb^+ \approx Cs^+$) and halide ($F^- > Cl^- \approx I^- > Br^-$) ions. Ammonium ion sorption occurs through surface-bound NH_3 species (*e.g.* ≡Fe-OH···NH_3) shifting the protonation constant of the cation from pK = 9.3 in bulk solution to pK = 8.4 at the interface.

Hematite single crystal electrodes with various crystallographic orientations are used to obtain the pH dependence of electric surface potentials in NaCl and NH_4Cl solutions. Three distinct interfacial processes, space charging, electrical double layer, and adsorption of proton and/or electrolyte ions, are extracted by fitting experimental impedance data using an equivalent circuit model (Fig. 1). Double layer capacitance values vary with pH and exhibit a minimum at pH around 8.7, close to the point of zero charge of this mineral. This capacitance-pH behavior closely resembles that of the interfacial concentrations of electrolyte ions on colloidal hematite particles obtained by XPS. Our results reveal systematic effects of pH and electrolyte ion identity on the intrinsic activity of hematite surfaces.

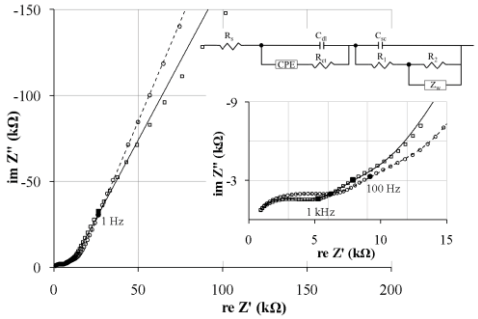

Fig. 1 *Complex plane plots of hematite in 0.1 M NaCl (pH 3.8, ○) and NH_4Cl (pH 3.5, □), including an equivalent circuit model.*

The Structure and reactivity of iron-organic matter coprecipitates

MASAYUKI SHIMIZU[1*], MARTIN OBST[2], ANDREAS KAPPLER[3], THOMAS BORCH[1,4]

Introduction

Iron (Fe) (oxy)(hydr)oxides can have large specific surface areas and reactive functional groups, which make them important sorbents for soil nutrients, contaminants, and organic matter (OM). Thus, Fe oxides play a critical role in stabilizing soil organic matter. In the natural environment, pure Fe oxides, such as ferrihydrite, are rarely formed. For instance, OM can be incorporated in the ferrihydrite structure via coprecipitation, likely resulting inboth structual and reactivity changes. Despite the high natural abundance of Fe-OM coprecipitates, only few studies have attempted to determine their reactivity and characterize their chemical and physical properties. In this study, we synthesized Fe-OM coprecipitate with various methods, such as hydrolysis vs. oxidation and with different composition of OM, such as humic acid or fulvic acid. We then characterized the morphology, structure, and reactivity of these coprecipitates to gain new insight into how OM controls the biogeochemical cycling of Fe oxides.

Results and Conclusion

X-ray diffractometry (XRD) analysis indicated that coprecipitated OM did not change the crystal structure of 2-line ferrihydrite. Electrophoretic mobility (EM) analysis was conducted to study the impact of coprecipitated OM on the zeta potential of suspended Fe oxide particles between pH 5 and 9. The EM measurements clearly showed that the addition of OM resulted in more negatively charged partiles of coprecipitates compared to ferrihydrite. Particles with higher C/Fe ratios were more negatively charged than particles with lower C/Fe ratios. Scanning transmission X-ray microscopy (STXM) was used to obtain both two and three dimensional chemical maps of the Fe-OM coprecipitates as well as information about the most likely bounds formed between specific C and Fe surface functional groups. The STXM analysis indicated that Fe and C are evenly distributed within particles and that carboxylic-C may play an important role in complexation with Fe oxides. Complementary techniques, such as X-ray absorption spectroscopy, Mössbauer spectroscopy, TEM, SEM, specific surface area analysis were also conducted for the additional characterization. Our results indicate that both the ferrihydrite morphology and reactivity is strongly influenced when coprecipitated with soil organic matter.

Elucidating the Deep Sulfur Cycle: A Progress Report of Techniques and Findings

N. SHIMIZU*[1] AND C. W. MANDEVILLE [2]

[1] Woods Hole Oceanographic Institution, Woods Hole, USA, nshimizu@whoi.edu
[2] USGS, Reston, USA, cmandeville@usgs.gov

We have developed a SIMS method for in-situ determination of sulfur isotopic composition in silicate glasses has been developed, using a Cameca IMS 1280 ion microprobe. Calibrations were carried out for instrumental mass fractionation against well-documented natural and synthetic glasses with $\delta^{34}S$ ranging from -6 to +12‰. $\delta^{34}S$ in silicate glasses can be obtained with internal and external precisions ranging 0.4 – 0.7‰ (2σ). Accuracy is controlled by bracketing unknowns by repeated analyses of standards.

We used this method to determine ranges of natural variability in sulfur isotopic compositions in olivine-hosted melt inclusions from MORB, IAB and OIB to investigate how deep recycling of sulphur from oxidized and reduced surface reservoirs influences the sulfur isotopic compositions of mantle-derived melts. We found that (1) $\delta^{34}S$ of undegassed basalt MIs from arcs are most commonly heavy; Galunggung (Indonesia) ranging up to +10.7‰, Krakatau (Indonesia) to +8.8‰, and hydrous and highly oxidized (SO_4/total S =1) MIs from Augustine (Alaska) to +17.2‰, reflecting efficient recycling of oxidized sulfur into mantle wedge melting regions; and (2) Olivine-hosted melt inclusions from MORB and OIB display large variations in individual lavas; -10 to +10‰ for primitive FAMOUS MIs, -5 ~ +5‰ for depleted MIs from17°N (MAR), -6 ~ +2‰ for 26 – 29°N (MAR), among others, and MIs from 1960 Kilauea picrite range from -10 to -2‰. The variations are largest for MIs in Fo 90 – 91 olivines and appear to diminish as Fo decreases to Fo 82, reflecting the presence of large sulfur isotopic variability on local scales in the mantle and the effect of averaging during mixing of melt fractions prior to eruption of lavas.

It is evident that isotopic variations characterizing surface reservoirs survive during deep recycling. Elucidating co-variations with radiogenic isotopes and trace element abundance patterns will require a systematic approach to obtain sample suites that represent mantle endmember components.

U-Pb zircon ages of Early Archean gneisses from northern Labrador

M. SHIMOJO[1]*, S. YAMAMOTO[1], K. MAKI[2], T. HIRATA[2], Y. SAWAKI[3], K. AOKI[1], A. ISHIKAWA[1], Y. OKADA[4], K.D. COLLERSON[5], AND T. KOMIYA[1]

[4]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan
[5]School of Earth Sciences, The University of Queensland, Brisbane, Qld. Australia

Early Archean crustal records are rare, but contiguous units are best preserved in N. Labrador and the NWT (Canada) and in SW Greenland. The Saglek-Hebron area (N. Labrador), located at the W. extension of the North Atlantic Craton (NAC), contains well-preserved Eo-Paleoarchean suites including pre-3.8 Ga Nanok Fe-rich monzodioritic gneiss, the Nulliak supracrustal assemblage (*ca.* 3.8 Ga), 3.7-3.6 Ga Uivak I TTG gneisses, 3.5-3.4 Ga Uivak II augen gneisses and Mesoarchean 3.2 Ga Lister gneiss [1-3]. Saglek dykes are present in the Eo and Paleoarchean gneisses, but not in the younger Lister gneisses. Despite confirmation of the antiquity of the area [3,4] a comprehensive zircon U-Pb dating with LA-ICPMS employing cathodluminescence (CL) imaging has not been undertaken for orthogneisses and supracrustal suites. CL images are essential to discuss inherited grains, pristine core and overgrowth.

We conducted LA-ICPMS U-Pb geochronological study of zircons from TTG Uivak I gneiss from the Saglek-Hebron area. The CL images of zircon grains display internal structures of oscillatory zoning and homogeneous core with overgrowth rim. Results show that samples collected as Uivak I TTG gneisses can be classified into three groups based on the distribution of zircon ages. The first group of TTGs is characterized by both presence of older zircons than 3.8 Ga, with the maximum age of 3914 ± 40 Ma in $^{207}Pb/^{206}Pb$ age, and apparent lack of 3.6 to 3.8 Ga zircons. These are obviously members of the Nanok gneiss. Based on intrusive relationships observed in the field, the Nanok gneiss is pre-date emplacement of the protoliths of the Uivak I gneisses. The second and third groups have clear peaks at 3.7-3.6 Ga and *ca.* 3.3 Ga in their age distribution of zircon cores, indicating that TTGs of the second and third groups correspond to Uivak I gneiss and the Lister gneiss, respectively. Importantly, overgrowth rims of zircons we analyzed here show *ca.* 2.7 Ga, which reflect zircon growth during late Archean thermal event in the NAC, possibly associated with assembly of different terranes within the gneiss complex. We show that the combination of *in-situ* U-Pb dating and CL imaging can reveal the tectonothermal history of early Archean from the gneisses in N. Labrador.

Volatile inventory of excess degassing

HIROSHI SHINOHARA[1*]

[1]Geological Survey of Japan, AIST, Tsukuba, Japan.
shinohara-h@aist.go.jp (* presenting author)

Overview

Excess degassing is heterogeneous emission of volatiles and magma caused by gas-magma decoupling in the upper crust. There are two types of excess degassing caused by different mechanisms. Excess degassing by eruption is considered as the result of eruption of bubble accumulated magma [1] whereas excess degassing by non-erupting persistant degassing is driven by conduit magma convection [2]. Sulfur budgets of eruptions, in particular of silicic magmas at subduction zones, suggest that one to two orders of magnitude larger amount of sulfur than in the erupted magma was accumulated prior to the eruption. Composition of the accumulated gas phase can be estimated based on melt inclusion and solubility studies [1, 3], however, bulk volatile composition of the magma supplied to the shallow crust is hard to constrain based on those studies.

Persistent degassing emits about ten times larger amount of SO_2 than degassing by erutpion at subduction zone and is the major source of crustal degassing [2]. Conduit magma convection continuously transports magams stored at a deep chamber to a shallow vent and causes low-pressure degassing, resulting in almost complete magma degassing of volatiles species with low solubility, such as H_2O, CO_2 and S. Therefore, compositions of the persistent degassing would be a good approximate of bulk volatile composition of original magmas and provied important constraints to volcatile budget of the shallow crust.

Composition of Persistent Degassing

Quantitative estimates of Composition of persistent degassing became possible by application of FT-IR and Multi-GAS techniques to volcanic plume observation. Accumulation of such data for Japanese volcanoes suggests that magmas with a similar volatile comosition are supplied to different volcanoes. One of the most intensively degassed volcano in this century, is Miyakejima volcano, Japan, which emitted about 24 Mt of SO_2. The intensive degassing of started in 2000 and the SO_2 flux decreased by almost 100 times during ten years but gas compositions remained similar; H_2O/CO_2 (mol ratio) =50, CO_2/SO_2 = 0.7. Based on H_2O content of basalt melt inclusions, volatile contents in the original basaltic magma are estimated as H_2O=3.0, CO_2=0.15 and S=0.17 (wt.%) [4]. Other persistently degassing volcanoes in Japan have similar CO_2/SO_2 ratio of 0.5-2, indicating that subduction zone magmas are not always CO_2-rich. In contrast, there are some other subduction volcanoes, such as Stromboli, Masaya and Sourfiere Hills, which persistently discharge gases with larger CO_2/SO_2 ratios of 6-10. If the CO_2-rich magma is necessary to cause bubble accumilation at a deep chamber resulting in the excess degassing by erutpion, occurrece of the excess degassing might be coincident with the CO_2-rich persistent degassing. Further accumulation of the composition data of persistent degassing might reveal such coincidence, if any, and constrain the volatile budget in the upper crust.

Characteristic of the long-term accumulation of lanthanides on *Saccharomyces cerevisiae*

H. SHIOTSU[1], M. JIANG[1], Y. NAKAMATSU[1], T. OHNUKI[2] AND S. UTSUNOMIYA[1]

[1]Department of Chemistry, Kyushu University, Fukuoka 812-8581, Japan (utu@chem.rc.kyushu-u.ac.jp)
[2]Advanced Science Research Center, Japan Atomic Energy Agency, Tokai, Ibaraki 319-1195, Japan (ohnuki.toshihiko@jaea.go.jp)

Interaction between actinides and fissiogenic rare earth elements (REEs) and microorganisms have attracted increasing attention due to the ubiquitous occurrence of microorganisms in the subsurface environment and to implication to the safety assessment of nuclear waste disposal. Although the post-adsorption nanomineralization process of individual REE was proposed by a recent study [1], the contaminating fluid may contain a series of actinides and fission products. Hence, the present study has investigated the post-adsorption process on microorganisms in the system containing a series of lanthanides (Ln) to understand the effect of coexisting Ln on the adsorption and post-adsorption process.

S. cerevisiae (yeast) was harvested in a YPD (P-rich) media prior to the experiment. The yeast was then contacted with a P-free solution containing 14 lanthanide elements (La-Lu) upto 72 h, in which the concentration of individual Ln was 0.0063 mM with the total Ln concentration of 0.085 mM. The experiment was conducted at three pHs, 3, 4, and 5, and at two different temperatures, 25 and 4 ^{o}C (no metabolism). The analytical techniques include ICP-MS -AES, FESEM-EDX, and TEM.

During exposure in the solution at 25 ^{o}C, all Ln were eliminated from the solution by 24 h at pH 4 and 5, while 50 % of the initial amount remained in the solution at pH 3 after 24 h. Particle at the size of ~100 nm precipitated on the cell surfaces at pH 3, while ~30 nm-sized nanoparticles were observed at pH 4 and 5. These nanoparticles are phosphate containing a series of Ln. The nanoparticles at pH 3 had monazite strucure, while the particles formining at pH 4 and 5 were amorphous, indicating that crystallization took place only at pH 3. Deprotonation merely occurs at the funcional group at pH 3 as evidenced by the other experiments at 4 ^{o}C, and the nanocrystallites possibly nucleated from the locally saturated solution adjacent to the cell surfaces. In contrast, Ln electrostatically adsorbed to the functional group was bound to P released from inside cell at pH 4 and 5. Most likely the geometry of Ln complex formation prevented the crystallization.

As for the Ln pattern, the greater amount of light REEs was removed from the solution than that of heavy REEs. The difference between the distribution coefficient, K_d(ml/g), of LREE and of HREE increased with time increasing. At 24 h, the K_d rate Nd to Tm ($K_{d,\,Nd}/K_{d,\,Tm}$) is 1.72, 4.61, and 6.86 at pH 3, 4, and 5, respectively. The K_d ratios greater than 1 indicate the preferential uptake of LREE by the microorganisms, which may be attributed to the lower solubility products of REE phosphate [2]. The present study demonstrated that the cell surfaces play a key role on kinetics and crystal formation in the post-adsorption biomineralization.

Abstract

A combined metagenomic, geochemical, and statistical investigation was used to characterize a groundwater spring with a dramatic electrochemical gradient. Eh, pH, precipitated iron, and sulfate concentration increased downstream of the source. The ferrihydrite saturation index, as well as ferrous iron, ferric iron, sulfide, ammonium, and nitrite concentration decreased downstream. A total of 672 clones were compiled into a cDNA library, with taxonomic identities across 9 phyla, including *Acidobacteria, Actinobacteria, Bacteroidetes, Chlorobi, Chloroflexi, Firmicutes, Nitrospirae, Planctomycetes,* and *Proteobacteria.* The variation in the relative abundance of the OTU phyla in response to geochemical parameters was modeled using coenoclines. *Alpha-proteobacteria* were the most sensitive to geochemical change, while *Acidobacteria* were least sensitive. Spearman's rank correlation coefficients were used to evaluate the relationship between geochemical variables and relative abundance of microbial OTU. Reduction-oxidation potential appears to be an overarching parameter in the stream, controlling the distribution of redox species and leading to strong segregation of microbial functional groups. Our study of Ogilvie Creek represents one of the first to combine geochemical, metagenomic, and statistical analysis in an effort to gain insight on the interrelationships between biogeochemical processes in natural systems.

Determining reactive thiol concentration in naturally occuring organic molecules

ELIZABETH M. SHOENFELT[1], CLARESTA M. JOE-WONG[2*], NYSSA M. CROMPTON[3], EMILY A. JAYNE[3], SATISH C. B. MYNENI[3]

[1] Department of Geosciences, Princeton University, Princeton, USA, eshoenfe@princeton.edu
[2]Departments of Geosciences & Chemistry, Princeton University, Princeton, USA, cmjoe@princeton.edu (*presenting author)
[3]Departments of Geosciences & Chemistry, Princeton University, Princeton, USA

Thiols, components of soil and aquatic organic molecules, exhibit high affinity for soft Lewis acids such as Cd^{2+} and Hg^{2+} and play an important role in metal speciation in natural waters. However, thiols' low abundance, high reactivity, and structural similarity to other reduced-S ligands such as methionine make their detection difficult. We propose a novel method to measure thiol concentrations in natural systems using the water soluble, charged, thiol-sensitive fluorophore monobromo(trimethylammonio)bimane (qBBr), which fluoresces upon binding to a thiol. Once the sample's natural fluorescence is subtracted out, a solution's fluorescence intensity is proportional to the concentration of thiol-bound fluorophore. By measuring the fluorescence intensities of a series of solutions with fixed sample concentration and increasing fluorophore concentrations, the saturation point can be calculated, giving the sample's thiol concentration. This method accurately estimates thiol concentrations in pure thiol-containing solutions, dissolved organic matter (DOM), and microbial cell membranes. Moreover, the presence of other chemical species often found in natural systems does not influence this method's sensitivity.

When pure glutathione or cysteine solutions were examined, this method produced an estimated thiol concentration within 1.85% of the expected value at micromolar concentrations, and within 7.40% at nanomolar concentrations. Although species such as dissolved salts, carboxylic acids, and other organo-sulfide groups might affect the absolute fluorescence intensity of the thiol-bound fluorophore, we found that these species do not interfere with determining the thiol concentration. Testing glutathione solutions with dissolved magnesium chloride in 500-fold excess resulted in calculated saturation values accurate to 6.40%. Likewise, adding up to 15-fold excess malate, a surrogate for carboxylic acids common in DOM, does not affect accuracy. Similar tests show that qBBr does not react with other sulfur groups such as disulfides and thioesters.

Using the technique developed for model systems, thiol concentrations in the DOM pool and microbial biopolymers can be calculated. The cell membrane thiol concentrations of three model microorganisms common to natural systems—*Bacillus subtilis*, *Shewanella oneidensis*, and *Geobacter sulfurreducens*—were estimated. *G. sulfurreducens* exhibited the highest thiol concentration, and *B. subtilis* the lowest. The calculated thiol: dissolved organic carbon ratio in surface water DOM from the Pine Barrens in New Jersey is approximately 10^{-3}-10^{-4}. Estimation of thiol concentration is necessary to understand the role of thiols in contaminant and nutrient speciation and transformation, and this method offers a simple way to measure thiol concentrations in natural systems.

Compositional trends of Icelandic basalts: Implications for short-length scale lithological heterogeneity in mantle plumes

OLIVER SHORTTLE* AND JOHN MACLENNAN

University of Cambridge, Department of Earth Sciences, Cambridge, UK, os258@cam.ac.uk (* presenting author), jcm1004@cam.ac.uk

Lithological variations in the mantle source beneath mid-ocean ridges and ocean islands have been proposed to play a key role in controlling melt generation and basalt composition. Iceland, as an extremum of oceanic crustal thickness and positioned at the centre of a long wavelength geochemical enrichment in Mid-Atlantic Ridge basalt chemistry, is an excellent place to study the relative importance of source lithology, mantle potential temperature and mantle flow field in generating melting and compositional anomalies on the Earth.

We begin by looking specifically at the major element composition of the end-member Icelandic melts, to constrain the lithologies contributing to melting. End-member melt compositions are identified using a plot of whole rock Nb/Zr against MgO, and coloring the points by a second major element. With a large dataset, as exists for Iceland, a plot such as this allows the effect of concurrent mixing and crystallisation on basalt major element chemistry to be separated from the geochemical variability which is mantle in origin. Applying this technique we identify the enriched end-member melt on Iceland to have higher FeO (11.3 wt%) and lower CaO (11.2 wt%) than the depleted melts (9.2 wt% FeO and 12.9 wt% CaO). To relate these end-member melt characteristics to source lithology we compare their compositions to a dataset of experimental partial melt compositions from the literature, produced from melting at a range of pressures, melt fractions and of peridotitic and pyroxenitic starting lithologies. Traditionally, experimental partial melts and natural melts have been compared graphically. In contrast, we quantify the difference between the basalt compositions across the major oxides (CaO-FeO-MgO-Al_2O_3-SiO_2) and, accounting for uncertainties, identify those experimental melts most like the end-member Icelandic basalts. The key result of this analysis is that no single source lithology available in the literature can account for the major element variability observed on Iceland, with the enriched Icelandic melt compositions requiring their source to have been refertilized by addition of up to 40% mid-ocean ridge basalt.

Significant refertilization of the enriched source beneath Iceland means that it will be more fusible than a KLB1-like peridotite, and as such will be over-represented in accumulated melts compared with its abundance in the source. The likely abundance of enriched material in the Icelandic source was estimated to be ~10%, by taking this bias into account and weighting observed compositions by erupted volume. To investigate whether this fraction of enriched material can account for the high crustal thickness at Iceland (up to 35 km) we develop a bi-lithologic peridotite-pyroxenite melting model in which the latent heat of melting of both the enriched and depleted material are considered - allowing for the effect of significant amounts of fusible source material on melt production to be assessed. This modelling demonstrates that with 10% pyroxenite in the source, significant temperature anomalies (+200K) and a plume driven mantle flow field are required to generate crustal thickness as high as observed in central Iceland.

A dedicated “clean lab” sampling facility for studying the natural filtration of trace metals by soils: the artesian springs of the Elmvale Groundwater Observatory

WILLIAM SHOTYK, BOCOCK CHAIR FOR AGRICULTURE AND THE ENVIRONMENT

Department of Renewable Resources, University of Alberta, 839 General Services Building, Edmonton, Alberta T6G 2H1 shotyk@ualberta.ca

Increasing, elevated concentrations of trace metals in the surface layers of soils may result from a diverse array of anthropogenic, atmospheric sources, in addition to chemical weathering of parent material and other natural sources. There is considerable, ongoing concern about the fate and transformations of these elements, and their eventual release to surface waters and groundwaters. The first step in this process is their release to the soil solution, and the first step in beginning to understand these processes is to obtain representative water samples for testing and analysis. The Elmvale Groundwater Observatory (Springwater Township, Ontario) consists of two dedicated groundwater sampling systems designed exclusively for the analysis of trace metals. One well was constructed entirely of surgical stainless steel, the other made using acid-washed high density polyethylene (HDPE). Both wells are artesian flow systems. Using ICP-SMS and the clean lab methods developed for polar snow and ice, it is possible to measure all of the trace metals of contemporary environmental interest. Sampling the water within a laminar flow clean air cabinet helps to eliminate variability by protecting the samples from anthropogenic aerosols in ambient air. Many trace metals such as Cr and Pb are found at concentrations (1 ng/L) significantly lower than the Arctic ice from the mid-Holocene (ca. 4 K to 8 K yr BP). Groundwater quality monitoring programs undertaken in the same region typically show “concentrations” for the same trace metals which are three orders of magnitude greater (1 µg/L) because of the introduction of colloids during sampling. The purpose of our studies is analytical and academic whereas the monitoring studies are intended to ensure that metal concentrations in groundwaters do not exceed the relevant water quality guidelines. Illustrative results of the two approaches are presented and their implications compared, with a view to better understanding the mechanisms of natural filtration of water by soils as well as analytical procedures to better characterize soil water quality.

Reconstructing anthropogenic, atmospheric emissions of trace metals using environmental archives: comparison of polar snow and ice, ombrotrophic peat bogs, *Sphagnum* moss from herbaria, and lake sediments

WILLIAM SHOTYK, BOCOCK CHAIR FOR AGRICULTURE AND THE ENVIRONMENT
Department of Renewable Resources, University of Alberta, Edmonton, Alberta, Canada T6G 2H1
shotyk@ualberta.ca

Given the long history of mining and metallurgy, many trace elements of contemporary environmental interest have been released to the environment since Antiquity. Reconstructing anthropogenic emissions requires suitable archives to provide records extending sufficiently far back in time to allow the natural fluxes and sources to be determined, for comparison with modern values. A number of archives have been employed to reconstruct historical records of atmospheric trace elements, each with its inherent advantages and disadvantages.

Ice cores from the Arctic and peat cores from ombrotrophic bogs both receive inputs of Pb exclusively from the atmosphere. Using examples from Devon Island, Nunavut, Canada and Etang de la Gruére, Jura Mountains, Switzerland, it was found that

1) the natural ratio of Pb to Sc was effectively constant for thousands of years and comparable values were found in both archives; this supports the hypothesis that natural atmospheric Pb was effectively dominated by soil dust particles supplied by weathering of crustal rocks.

2) anthropogenic Pb inputs to the Arctic are clearly seen in ice layers ca. 3,000 years old, with pronounced Pb enrichments and declines in $^{206}Pb/^{207}Pb$ ratios in samples from the Roman and Medieval periods, supporting the hypothesis that human activities have dominated atmospheric Pb inputs for three millenia.

3) although Pb enrichments have declined during recent decades, even in the most recent snow samples, the Pb/Sc and Pb isotope data show that 90 to 95% of the Pb is still anthropogenic.

Although *Sphagnum* moss from herbaria do not extend back in time further than ca. 200 years, they received trace metals exclusively from the atmosphere, the date of sample collection is known exactly, and they are not affected by chemical diagenesis in acidic, anoxic bog waters. The isotopic composition of atmospheric Pb obtained using peat cores from Europe (dated for the past ca. 150 years using ^{210}Pb) are in excellent agreement with the records for the same interval preserved in *Sphagnum* moss from herbaria.

Comparing the isotopic composition of Pb in recent layers of lake sediments from the Kawagama Lake watershed in central Ontario with a peat core from a local bog shows that the sediments are a much less sensitive indicator of atmospheric change, largely failing to record the declines in $^{206}Pb/^{207}Pb$ ratios since the elimination of leaded gasoline, and the growing relative importance of Pb from smelters in northern Ontario and Quebec.

The *in situ* occurrence of bacteria on gold grain surfaces: Implications for bacterial contributions to gold nugget structure and chemistry

JEREMIAH SHUSTER[1*], CHAD JOHNSTON[2], NATHAN MAGARVEY[2], ROBERT GORDON[3] NEIL BANERJEE[1] AND GORDON SOUTHAM[1]

16a. Microbe-mineral interactions in time and space

Natural gold grains often possess secondary gold as colloidal particles, crystalline gold and bacteriomorphic structures. The latter form known as 'biogenic' gold that was first reported as structures resembling gold-encrusted microfossils on placer gold specimens [1]. Recent research suggest that Bacteria and Archaea are involved in the biogeochemical cycling of gold [2, 3, 4]. In this study gold grains from sediment sampled from Rio Saldana, Colombia were analyzed for the purpose of better understanding the formation of secondary gold in a tropical placer environment. Morphological analysis, using scanning electron microscopy, demonstrated that gold grains appeared as elongated disk shapes with articulated surfaces occurring predominantly on the perimeter. Bacteria were directly and indirectly attached as biofilms on the articulated surfaces of all gold grains. Iron oxide occurred on some grains as globular and patina coatings possessing casts of bacteria. The grains also possessed micron size secondary gold textures occuring on the outer periphery of the grains. Compositional analysis, inferred from energy dispersive spectroscopy and x-ray absorption fine structure, indicated that trace silver, mercury and copper was associated with gold. Unlike silver, mercury and copper appeared to have localized regions of heterogenous distributions throughout the gold grain. A pure bacterial culture, isolated from a single gold grain, was identified as *Nitrobacter* sp. 263 based on 16S sequencing. This *Nitrobacter* sp. removed gold from a gold (III) chloride solution within an hour. Transmission electron microscopy and scanning electron microscopy demonstrated that gold immobilization occurred as abundanct colloids and octahedral platelets less than 100 nm in diameter concentrated within the cell envelope. The occurrence of secondary gold on the surface of these grains and the ability of *Nitrobacter* to form crystalline gold suggests that this organism may contribute to the growth of gold grains in this placer environment. Gold biomineralization would be continuous if concentrations of aqueous gold input are low and bacterial metabolic growth is maintained by reproducing biomass lost to biomineralization.

Did I lose some LA-ICP-MS data somewhere?

STEPHEN SHUTTLEWORTH[1*], STUART GEORGITIS[2]

[1]Photon Machines, Redsmond, WA, USA, Shutts@photon-machines.com (* presenting author)
[2]Spectro Analytical Instruments, Mahwah, NJ, USA, Stuart.Georgitis@ametek.com

The combination of Laser Ablation (LA) and Inductively Coupled Plasma Mass Spectrometry (ICP-MS) provides an analytical tool capable of both high sensitivity elemental analysis and high precision isotopic analysis in a wide variety of matrices. Since its introduction in the mid 1980's LA-ICP-MS has been applied to a very broad range of applications across science in order to provide high spatially resolved chemical and isotopic information at the micron scale in the solid. The technique is now commonly used by researchers across the geochemical sciences.

As a destructive technique, data not captured as a consequence of detection duty cycle and dead time will be forever lost. Only now has a truly simultaneous ICP-MS been coupled to a laser thus eliminating the prior limitations that single spot analysis can only best be done with a restricted number of isotopes or a restricted section of the mass range. This paper will discuss the merits of laser ablation coupled with a truly simultaneous ICP-MS capable of analysing the entire periodic table for each indivudual laser shot. The use of a simultaneous dual detection range ICP-MS for laser ablation is investigated as a means to capture the whole ICP-MS spectrum of a single laser transient signal. The technique will be applied for both elemental mapping and isotopic analysis of mineral phases.

The Early Paleozoic of the Argentine Precordillera: C-isotope Excursions

A. N. SIAL[1*], S. PERALTA[2], C. GAUCHER[3], A.J. TOSELLI[4], V.P. FERREIRA[1], R. FREI[5], M. M. PIMENTEL[6]

[5] Inst. Geogr. Geol., Geol. Section, Univ. Copenhagen, Denmark
[6] Inst. Geosc., Fed. Univ. Rio Grande do Sul, Porto Alegre, Brazil

Introduction. We have searched for the register of C-isotope excursions in the Upper Cambrian and Ordovician of the Argentine Precordillera. We report the register of the SPICE and SNICE in one same section in the Precordillera. The Darriwilian positive excursion (MDICE) and a Late Sandbian positive C-isotope excursion (GICE) have been registered in two sections. A pre-GICE positive C-isotope excursion (Sandbian S1, *N. gracilis* biozone) with $\delta^{13}C$ peak of ~ +3‰ is, perhaps, equivalent to the positive Spechts Ferry excursion of N. America. A positive $\delta^{13}C$ excursion registered at the base of the Upper Hirnantian La Chilca Fm. probably corresponds to HICE. **Causes**. These C-isotope excursions are probably related to oceanographic events: (a) sea-level rise and vigorous fluctuations in the Steptoean (SPICE), (b) sea-level fall in the Sunwaptan (SNICE), (c) important transgression in the Sandbian (pre-GICE and GICE), and (d) sea-level fall in the Late Hirnantian (HICE). In the Darriwilian and Sandbian stages, organic burial has led to a large ^{12}C sequestration in deep-ocean anoxia with saline bottom water, recorded by the graptoliferous black shales in the Gualcamayo and Los Azules formations, helped the building of the MDICE, one pre-GICE and GICE anomalies. O-isotope values for the Upper Cambrian are likely near-primary signals that point to progressive cooling from the SPICE to the SNICE, whereas for Sandbian carbonates they indicate strong T fluctuations. The $\delta^{13}C$ peaks of the GICE coincide with cooler periods with T progressively cooler towards Late Hirnantian. In the Zonda Fm., $^{87}Sr/^{86}Sr$ ratios vary from 0.7090 to 0.7109 while in Los Azules and Las Aguaditas Fms., they are ~ 0.7090. εNd values plot along the Nd isotopic evolution trend of the Iapetus Ocean.

Conclusions. The register of these excursions in the Precordillera is valuable proxy for the Early Paleozoic stratigraphy, regional/global high-resolution correlations, and sea-level change history.

Kinetics of phosphorus adsorption on iron oxyhydroxide residuals

PHILIP L. SIBRELL[1*]

[1]U.S. Geological Survey, Leetown Science Center, Kearneysville, West Virginia, USA, psibrell@usgs.gov (* presenting author)

Experimental Research and Findings

We have investigated the use of iron oxide media generated from mine drainage residuals for the removal of oxyanions from waste water, with a special emphasis on phosphorus (P) [1]. The use of packed column or fixed bed sorption systems allows treatment of waste water without requiring subsequent solid-liquid separation, and has been the focus of our research. In these trials we used 2.5 cm diameter glass columns packed with air-dried iron oxyhydroxides for treatment of wastewater with a variety of influent P concentrations, flow rates and media particle sizes. We then used Adsorption Design Software from the Michigan Technological University [2] to model results, estimate test parameters and to predict future outcomes. Results of several fixed bed trials are shown in Figure 1, where the effluent P concentration (normalized by the influent concentration C_i) has been plotted as a function of treatment time. It is clear that early breakthrough of the P was experienced in many of the column tests. In the most successful test (Run 7), we removed over 96% of the P from the influent waste stream over a period of 46 days of continuous operation. We have also observed that performance was strongly related to the value of the surface diffusion modulus *Ed*, enabling prediction of column performance based on test conditions.

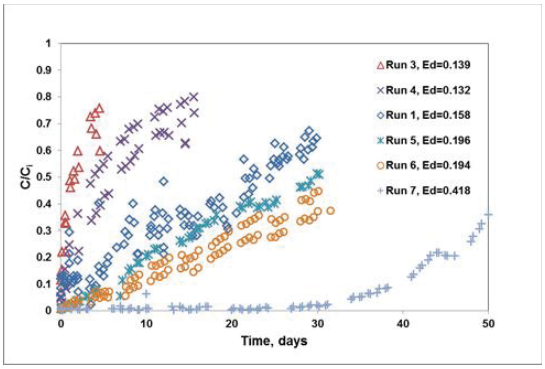

Figure 1: Fixed bed performance based on treatment time

Summary and Conclusions

Test results show that very good removal of P is possible using fixed bed columns packed with iron oxyhydroxide media. Conversion of test parameters into dimensionless forms enables prediction of the shape of the breakthrough curve based on the value of the surface diffusion modulus *Ed*. Preliminary batch tests with arsenic suggest that similar results may be possible for other metalloids as well, including arsenic and selenium.

Zircon U–Pb, O and Hf isotope characteristics of granites emplaced during Cretaceous wrench to transtension in West Antarctica

CHRISTINE S. SIDDOWAY[1*], C. YAKYMCHUK[2], C. MARK FANNING[3], AND MICHAEL BROWN[2]

[1] Geology Dept., Colorado College, Colorado Springs, CO 80903, USA, csiddoway@coloradocollege.edu (*presenting author)
[2]Laboratory for Crustal Petrology, Department of Geology, University of Maryland, College Park, MD 20742, USA
[3]Research School of Earth Sciences, The Australian National University, Mills Road, Canberra, ACT 0200, Australia

The Fosdick Mountains in West Antarctica expose a migmatitic gneiss dome emplaced within a wrench setting during the Cretaceous dextral oblique convergence along the East Gondwana margin that affected both West Antarctica and once-contiguous New Zealand. Kilometer-scale, three-dimensional outcrop offers expansive views of a region of formerly melt-rich middle crust that responded to changes in strain during sequential wrench, transtension and oblique detachment [1]. Consistent with temperatures >800°C attained during metamorphism [2, 3], there is pervasive evidence for the prior presence of melt across a range of scales, including granite within foliation-parallel sheets and interboudin partitions, magmatic folds, and conjugate magmatic shear bands. Microstructures include euhedral to subhedral phases bordered by thin, delicate residual melt pseudomorph structures in interstices and on grain boundaries.

Based on SHRIMP U-Pb zircon and monazite geochronology for anatectic granites and residual migmatites, crustal melting, and melt transfer and accumulation occurred from c. 130 to 96 Ma, with the possibility that these processes were underway as early as c. 140 Ma [1, 3]. This previous work has revealed three phases of anatectic granite that occupy distinct structural settings. To evaluate whether there are distinctions in source for these three generations of granite, a Lu–Hf and O isotope study of previously dated zircon grains from 8 granite samples was undertaken. Taken together, zircons from Cretaceous granites show a comparatively large spread in εHf(t), with values from -14 to +5, and a wide range of $\delta^{18}O$ values between 6‰ and 14‰. In zircon of c. 120–99 Ma age, there is a trend toward higher $\delta^{18}O$ with greater homogeneity of zircon populations. An exception is one of the youngest granites, which has lower $\delta^{18}O$ values of 6.4 to 7.8. The isotopic characteristics of zircon from the three granite phases change with time. Zircon in c. 117–114 Ma granites, emplaced in steep foliation-parallel panels during *wrench* tectonics, has a wide range of $\delta^{18}O$ values from 6.2 to 11.6, reflecting a low degree of homogeneity of the zircon populations. Zircon in leucogranites that occur in subhorizontal sheets emplaced during *transtension* at c. 107–102 Ma, have elevated $\delta^{18}O$ values and more enriched εHf(t), attributed to a greater contribution of metasedimentary rocks in the source. Finally, zircon of c. 102 Ma age from a *detachment*-hosted granite records input from a source with more juvenile εHf(t) and $\delta^{18}O$, which may mark the availability of a less-evolved, mantle-like source due to lithosphere thinning.

Stable isotope geochemistry of the Varuträsk rare-element pegmatite (northern Sweden)

KARIN SIEGEL[1*], THOMAS WAGNER[2], ROBERT TRUMBULL[3], ERIK JONSSON[4], CHRISTOPH A. HEINRICH[2]

[1]McGill University, Earth and Planetary Sciences, Montreal, Canada, karin.siegel@mail.mcgill.ca (* presenting author)
[2]ETH Zurich, Institute of Geochemistry and Petrology, Zurich, Switzerland, thomas.wagner@erdw.ethz.ch, heinrich@erdw.ethz.ch
[3]GFZ Potsdam, Inorganic and Isotope Geochemistry, Potsdam, Germany, bobby@gfz-potsdam.de
[4]Swedish Geological Survey, Mineral Resources, Uppsala, Sweden, erik.jonsson@sgu.se

The Varuträsk pegmatite, located in the Skellefte district in northern Sweden, is a classical representative of highly fractionated LCT-type rare-element pegmatites [1,2]. The Varuträsk pegmatite shows a typical primary zonation pattern, composed of well-developed border, wall and intermediate zones and a quartz core [3]. Major rare-element enrichment is mainly related to late-stage assemblages such as albite-lepidolite and pollucite units. Previous work [4] has focused on the major and trace element characteristics of key minerals (feldspars, micas, tourmaline, columbite-tantalite), demonstrating progressive magmatic fractionation trends in the primary pegmatite zones. Significant compositional changes observed in the late-stage mineral assemblages (reversals of magmatic fractionation trends, depletion in elements typically enriched in aqueous fluids) indicate that a magmatic fluid exsolved after the development of the primary pegmatite zonation.

The results of the present stable isotope (B, H, O) study further constrain the role of a magmatic fluid phase in formation of rare-element enrichment. Stable isotope analysis (O, H, B) has been performed on quartz, mica and tourmaline from all principal mineral assemblages in the pegmatite body. Boron isotope data of tourmalines using SIMS microanalysis are in the range between –14.6 and –6.2 ‰. The $\delta^{11}B$ data of different tourmaline types conforming to the primary pegmatite zonation show a clear magmatic fractionation trend. By contrast, tourmalines related to late-stage assemblages show a reversed fractionation that is correlated with the behavior shown by several major and minor elements in the tourmaline (Na, Fe, Mn, F). The B isotope evolution cannot be modeled by purely magmatic melt-tourmaline fractionation, but requires fluid-tourmaline partitioning to be operative for the late-stage assemblages. Hydrogen isotope data of micas indicate a substantial increase in δD from –76 to –53 ‰ from the wall to the innermost zones, requiring closed-system fractionation processes that involved melt and fluid. Taken together, the stable isotope data demonstrate that rare-element enrichment in the most fractionated assemblages is related to the transition from purely magmatic crystallization to conditions where a magmatic fluid phase was important.

Deep ocean mixing, the bipolar seesaw, and polar ocean biogeochemical change

D.M. SIGMAN [1*], A.S. STUDER[2], M. TREMBLAY[3], M. STRAUB[2], M.P. HAIN[1], G.H. HAUG[2]

[1]Department of Geosciences, Princeton University, Princeton, USA (*sigman@princeton.edu, mhain@princeton.edu)
[2]Department of Earth Sciences, ETH Zurich, Zurich, Switzerland (anja.studer@erdw.ethz.ch, marietta.straub@erdw.ethz.ch, gerald.haug@erdw.ethz.ch)
[3]Barnard College, New York, USA (mmt2130@barnard.edu)

At the scale of the global ocean, deep water formation is coupled to processes – most notably, vertical mixing and wind-driven upwelling – that reduce the density of deep water or otherwise remove dense water from the deep ocean. This formation/removal coupling may play a critical role in glacial/interglacial changes in polar ocean circulation and in atmospheric carbon dioxide. Considering the two regions of modern deep water formation, the North Atlantic and the Antarctic, if deep water formation ceases in one region but the loss of dense deep water does not decrease equivalently, then the other polar region must increase its deep water formation rate. This is one proposed physical mechanism behind the observed "bipolar seesaw" in high latitude temperatures on millennial time scales. Since deep water formation in the North Atlantic and the Antarctic have opposite effects on the efficiency of the global biological pump, any tendency for anti-correlation in their rates has a major effect on atmospheric CO_2. Accordingly, there is intense focus on an ocean seesaw mechanism for the CO_2 rises at the end of ice ages. However, there are divergent views as to the importance of deep ocean mixing *versus* the winds in driving such a North Atlantic/Antarctic seesaw. If the biogeochemical conditions of the polar ocean surface can be reconstructed back through time, we will have greater insight into how the polar regions have changed in their ventilation of the ocean interior and their impact on deep ocean carbon storage. In this talk, in addition to drawing upon numerical model experiments to lay out the arguments above, we will describe new diatom- and foraminifera-bound nitrogen isotope data from the Antarctic and the North Atlantic that support the view of seesaw-like behaviour between the two regions over major glacial/interglacial transitions and on millennial time scales. In this context, we will revisit the question of deep mixing *versus* the winds as driving this pattern.

Characterizing vadose zone hydrocarbon biodegradation using CO_2 effluxes, isotopes, and reactive transport modeling

NATASHA J. SIHOTA[1] AND K. ULRICH MAYER[1]*

[1]University of British Columbia, Department of Earth and Ocean Sciences, Vancouver, Canada, nsihota@eos.ubc.ca , umayer@eos.ubc.ca (* presenting author)

Introduction

Biodegradation in the vadose zone may result in substantial mass removal at hydrocarbon spill sites. At these sites, estimates of contaminant loss rates are needed to evaluate source zone longevity and long-term impact on the environment. Recently, Sihota et al. [1] showed that the measurement of CO_2 effluxes at the ground surface is a suitable method to derive depth-integrated rates of contaminant degradation. However, the accuracy of loss rate estimates obtained from CO_2 effluxes is limited by the ability to quantitatively separate CO_2 effluxes from contaminant destruction and naturally occuring soil respiration. To address this gap, measured CO_2 effluxes were complemented with detailed analysis of vadose zone gas composition, including stable and radioisotope analysis in CO_2. Results of field measurements were integrated using the reactive transport code MIN3P-DUSTY [2], which accounts for advective and multicomponent diffusive gas transport.

Results and Conclusions

Comparison of measured pore gas distributions to previous observations at the Bemijdi site [3] show biodegradation has approached a quasi steady state within the vadose zone. Radiocarbon results prove that, in the source zone, the majority of CO_2 is produced from contaminant destruction and indicate that the CO_2 efflux method provides an adequate estimate of contaminant mass loss rates.

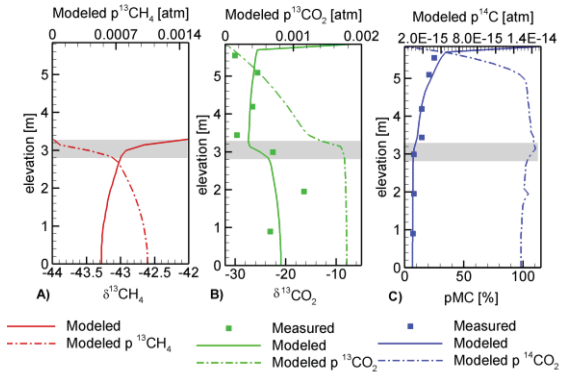

Figure 1: Comparison of measured and simulated isotopic values for a 1D vertical profile in the vadose zone at the Bemidji site.

Highly constrained simulations for a 1D vertical profile in the source zone are able to closely reproduce historical saturations, field observed fluxes, concentration profiles, and isotopic signatures. Simulation results also showcase that gas transport is diffusion-dominated and strongly affects measured isotopic signatures, in addition to effects caused by biogeochemical reactions.

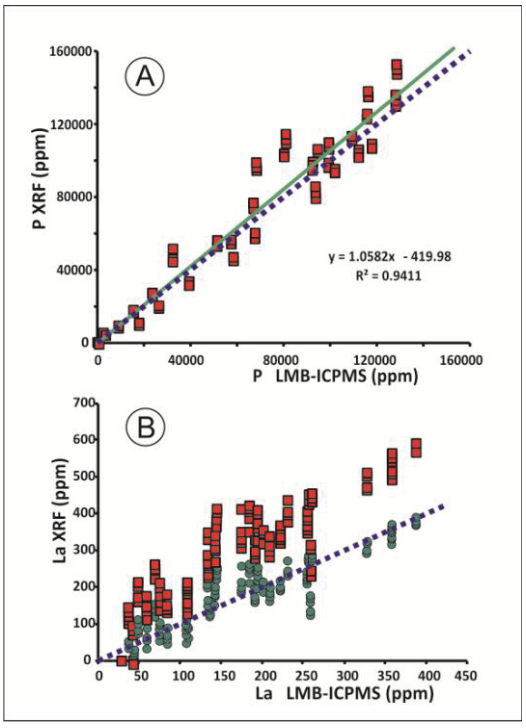
[4]Elemental Controls Limited, Mississauga, Canada

Sedimentary phosphate deposits consist of francolite [$(Ca_5(PO_4)_3(OH,F,Cl)$] and gangue minerals. They supply most of the phosphate raw materials used by the phosphate fertilizer industry and they are also considered as potential sources of F, REE, and/or U. Samples of phosphate rocks from the Fernie Formation (British Columbia) were analysed using a hand-held XRF analyser (HhXRF) and by lithium metaborate fusion–inductively coupled plasma (LMB-ICPMS) method. The results from both methods were compared; and correction factors for the HhXRF analyser were developed. HhXRFs can be used in exploration for phosphate deposits by analyzing samples directly for phosphorus (P) and if correction factors are applied for vectoring towards REE-rich zones, and/or delineating zones with high levels of deleterious elements such as U, Th, Cr, As, Hg, Cd and Se. Figures 1 illustrates two examples of relationships between hhXRF and LMB-ICPMS methods. Following a successful orientation survey, HhXRF does become fast and reliable vectoring tool that is easily incorporated into integrated exploration programs.



Figures 1: Comparison of the HhXRF and LMB-ICPMS for P (A) and La (B). Raw data as red squares. Corrected values as green circles. No correction was required for P.

[5]Universityof Kansas, Lawrence, Kansas, U.S.A.

Melt inclusions provide much more detailed samples of melt compositions than can be accessed with whole rock analyses alone. As such, melt inclusions have become an increasingly powerful tool for improving our understanding of magmatic processes owing to their ability to record discrete time steps during the polybaric and polythermal evolution of a particular magmatic system. In this study, we report and discuss melt inclusion data for samples from Mutnovsky Volcano, located on the Kamchatka island arc, that elucidate the causes for compositional diversity, and the iterative assembly of the pre-eruptive subvolcanic magma chamber.

Mutnovsky has formed a series of four stratocones over its ~100 ka history. Erupted rocks are dominantly basalt and basaltic andesite, and also include andesite, dacite and rhyodacite. We analyzed melt inclusions from all erupted compositions and eruptive centers to investigate the causes of the compositional heterogeneity, melt evolution, and pre-eruptive magma storage system. Melt inclusion compositions range from low silica (44 wt. %), hosted in olivine and clinopyroxene and plagioclase, to high silica (78 wt. %), hosted mainly in plagioclase and orthopyroxene. The melt inclusion compositions span a wider range than whole rocks. Geochemical modeling of the melt inclusion data, combined with field evidence and plagioclase phenocryst zoning, indicate that fractional crystallization and magma mixing operated in tandem to produce compositional diversity of the rocks erupted at Mutnovsky. The data are consistent with a model wherein fractional crystallization of individual aliquots of magma in an evolved subvolcanic magma chamber drove the melt(s) toward more felsic bulk compositions. Textural and compositional evidence also indicate that the subvolcanic magma chamber was effected by periodic injection and admixture of new olivine- ± clinopyroxene-saturated basaltic magma. This finding is consistent with observations from other volcanic systems.

The new twist that we employed was to calculate apparent pressures and temperatures of entrapment of orthopyroxene- and clinopyroxene-hosted melt inclusions by using the chemistry of melt inclusions and host mineral with the mineral-liquid thermobarometry equations from [1,2]. The results suggest that orthopyroxene and clinopyroxene crystallized at distinctly different levels in the magma plumbing system, which allows us to assess the variation in melt compositions as a function of vertical position in the evolving magma plumbing system. We will discuss these results, and the role that post-entrapment modification of melt inclusions may have on the model thermobarometry results, in the context of the iterative assembly and evolution of crustal magma chambers.

*quentin.simon@gmx.com

A terrigenous sedimentary sequence from central Baffin Bay (core HU2008-029-016PC – 70°46.14'N/-64°65.77W – 2063 m) was analyzed for its magnetic, mineralogical and geochemical (μXRF - Itrax) properties in order to 1) link the sedimentary history to ice-margin dynamics along the surrounding coastlines (W. Greenland, E. Baffin Island and N.E. Ellesmere Island), and 2) eventually associate the continental ice dynamics to specific climate events of the last glacial cycle. A chronology based on relative paleointensity (RPI) and paleomagnetic secular variation (PSV) has been set. It provides an age model for a site where current chronological approaches (^{14}C and isotope stratigraphy) failed for various reasons. This age-model indicates a mean sedimentation rate of ~6.5 cm/ka, but also illustrates increases (> 15 cm/ka) linked to major sedimentological events of local origin. The timing and properties of these sedimentological events are discussed with special emphasis on their source and mode of deposition, as well as their linkage with specific ice margin responses to climate changes along surrounding islands. On one hand, coarse-grained and rapidly-deposited detrital carbonate-rich layers seem broadly coeval with major interstadials of the GISP2 ice core record. This suggests fast retreat episodes along related ice-stream routes during major interstadials. Rock magnetic data point to coarser magnetic grain size in these layers. This is especially the case during the 11– 12 ka (~YD) and 14.8–16 ka (H1) intervals. On the other hand, feldspar-rich layers also depicting high clay and silt size material contents are characterized by a finer magnetic grain size in the pseudo single domain to single domain ranges. Magnetic grain size ratios such as k_{ARM}/k_{LF} and Fe/k_{LF} show finer magnetic grains during the locally extendedLast Glacial Maximum interval (16 – 24 cal ka BP). This suggests that, during glacial maxima, mechanical grinding of the bedrock by surrounding ice sheets (in particular along the continental shelves of Greenland and Baffin Island) released large amounts of “glacial flour” characterized by feldspar-rich and finer magnetic supplies.

Introduction

25 years have passed since the accident at the Chernobyl NPP, but up to now scientists are still working on answering the question "what are the consequences of the accident?", and in particular, can we define radionuclide (RN) migration processes today and for the future in soils, vegetation and possibly air re-suspension?. Following the Chernobyl accident (26/04/1986), the contaminated topsoil layers containing fuel particles and contaminated organic matter, coming from the Red forest, were buried in trenches only a few meters deep in the Chernobyl exclusion zone in order to prevent RN dispersion and especially to diminish the exposure dose to workers (liquidators) on site in 1987. Since 1999, the French Institute of Radioprotection and Nuclear Safety (IRSN), in collaboration with the Ukrainian Institute of Agricultural Radiology (UIAR/NUBiP) and the Ukrainian Institute of GeoSciences (IGS), has been studying the impact of the contaminated waste trench T-22, located 2.5 km South-West from Chernobyl NPP, on the aquifers below. The Chernobyl Pilot Site (CPS), which includes the trench T-22, was equipped to carry out in situ radioecological and hydrogeological investigations. The objectives of the research are devoted to the characterization of RN migration both upward into the vegetation and downward to the aquifer, in order to validate RN's transfer models in the environment.

Results and Conclusion

To this end, flow and transport mechanisms were first decoupled. Water flow only studies are still carried out in the different soil layers and in the aquifer. Soil –RN interactions are still studied first in the laboratory (especially for Cs-137 and Sr-90) and analogues were/are also studied on the field. In a second step, these processes were re-coupled by calculating, the reactive transport of RN both at the laboratory scale, under well controlled conditions, and in the CPS where the Sr-90 migration's plume is surveyed for 20 years. In connection to the dynamic of RN migration, our studies also addressed: (i) the nature of the waste material in order to better estimate the amount of the RN stock and its release properties over time; (ii) the possible evidence of enhanced transport down to the aquifer and in the saturated zone due to specific and stable aqueous species of RN and/or to the presence of colloidal substances, and (iii) the upward migration of RN due to the root system of the plants that grow mainly over the trench as such export fluxes from the trench probably constitute one of the main hazards for the near future. The future investigation at CPS and extended to the larger Chernobyl Exclusion Zone include a better understanding of the joint biogeochemical, radioecological and hydrological processes.

Local structure and crystallization pathways of amorphous calcium carbonate

JARED WESLEY SINGER[1]*, A. ÖZGÜR YAZAYDIN[2,3], GEOFFREY M. BOWERS[1,4], AND R. JAMES KIRKPATRICK[5]

We compare local structures of synthetic amorphous calcium carbonate (ACC) by ^{43}Ca- and ^{25}Mg-nuclear magnetic resonance (NMR) to long-range order by low-angle and conventional x-ray diffraction and to characterization by thermal gravimetric analysis, scanning electron microscopy, and energy dispersive spectroscopy. The range of parent solution compositions, temperatures, and $Na_2CO_{3(s)}$ induced precipitation yields ACC compositions of 10-40 weight percent water and 0-50% Mg. Subsequent crystallization can yield all anhydrous and hydrous polymorphs of $CaCO_3$, mixed assemblages, and dolomite. In spite of this variability, the ^{43}Ca NMR spectra of ACC collected immediately after synthesis consist of broad, featureless resonances with Gaussian line shapes (mean chemical shift = -0.4±0.5ppm, FWHH = 27.6±1ppm) that do not depend on Mg^{2+} or H_2O content. We derive indistinguishable maximum mean Ca-O bond distances of 2.45 Å for all samples and our analysis suggest that spectral widths are dominated by chemical shift dispersion that arises from local disorder. Preliminary ^{25}Mg-NMR suggests the presence of rigid and mobile ^{25}Mg populations. [Mg] of the parent solution correlates with ACC stability, though our data suggest Mg^{2+} incorporation in the solid phase is not responsible for the observed stabilization. Within experimental ranges we also observe ACC mesocrystallization, ikaite ($CaCO_3 \bullet 6H_2O$) decomposition to monohydrocalcite ($CaCO_3 \bullet H_2O$), and low-temperature proto-dolomite.

Extracellular *c*-Type Cytochromes from *Geobacter bemidjiensis*

CINDY J. CASTELLE[1], KELLY C. WRIGHTON[2], MICHAEL J. WILKINS[3], MARY S. LIPTON[3], JILLIAN F. BANFIELD[2], STEVEN W. SINGER[1*]

[L]Lawrence Berkeley National Laboratory, Berkeley, CA, USA; SWSinger@lbl.gov

[3]Pacific Northwest National Laboratory, Richland, WA, USA

The subsurface clade 1 of the *Geobacteraceae* often predominates during acetate-stimulated bioremediation of uranium-contaminated sites. The metabolic activity of this clade has been linked to solid phase U(VI) and Fe(III) reduction in the subsurface. Despite its importance for subsurface metal reduction, the complement of electron transfer proteins expressed by members of this clade have not been identified. *Geobacter bemidjiensis* is a cultured representative of subsurface clade 1 and is an excellent model system to begin to understand electron transfer in the subsurface *Geobacteracae* clade 1. Inspection of the genome of *G. bemidjiensis* identified 84 proteins predicted to encode for *c*-type cytochromes. To identify the dominant *c*-type cytochromes expressed by *G. bemidjiensis*, proteomics was performed on cultures grown with fumarate as an electron acceptor. A substantial fraction of *c*-type cytochromes were localized in the extracellular medium or were easily sheared from the outer-membrane. The most abundant of these *c*-type cytochromes was a flavocytochrome that clustered with fumarate reductases from *Shewanella* species. Other abundant *c*-type cytochromes included a homolog of OmcB, a cytochrome required for optimal reduction of Fe(III) oxides in *G. sulfurreducens*, and a nonaheme cytochrome whose only homologs were found in *Geobacter* species from subsurface clade 1. Seven expressed *c*-type cytochromes were predicted to have >25 heme prosethetic groups. Peptides from the abundant *G. bemidjiensis* cytochromes were also found in proteomic measurements of groundwater from a uranium-contaminated site at Rifle, CO undergoing acetate stimulation. The extracellular *c*-type cytochromes are distinct from those cytochromes identifed for *G. sulfurreducens* and suggest that the *Geobacteraceae* from subsurface clade 1 may possess novel pathways for electron transfer.

Dissolution of uranyl precipitates in contaminated vadose zone sediments

ABHAS SINGH[1*], JOHN M. ZACHARA[1], JAMES P. MCKINLEY[1], CHONGXUAN LIU[1], MAXIM I. BOYANOV[2], KENNETH M. KEMNER[2], DEAN A. MOORE[1]

[1]Pacific Northwest National Laboratory, Richland, WA 99354 USA; abhas.singh@pnnl.gov (* presenting author), john.zachara@pnnl.gov, james.mckinley@pnnl.gov, chongxuan.liu@pnnl.gov, damoore@pnnl.gov
[2]Argonne National Laboratory, Argonne, IL 60439 USA; mboyanov@anl.gov, kemner@anl.gov

Metatorbernite, $Cu(UO_2PO_4)_2 \cdot 8H_2O_{(s)}$, was idenified as the dominant form of uranium in contaminated sediments below former nuclear waste disposal ponds in the Hanford 300-Area (Washington State) in past microscopic and synchrotron-based spectroscopic and diffraction studies [1-3]. Uranium(VI) release from these sediments to groundwater, however, could not be explained by metatorbernite solubility determined from pure mineral studies at acidic conditions [4]. This work aims to reconcile these differences between known solid-phase speciation and the aqueous phase composition generated. Carbonate and synthetic groundwater extractions on metatorbernite and variable sediment:solution ratios and sediment sizes were peformed in different experimental settings (e.g., batch, stir-flow) to quantify uranium(VI) release. Solid phase speciation before and after these extractions was investigated using scanning and transmission electron microscopy, micro X-ray diffraction and X-ray absorption techniques.

Preliminary results indicate that metatorbernite dissolution in synthetic groundwater is slow and is facilitated by secondary precipitation of an unidentified copper phase that limits the dissolved copper concentration (Figure 1). Metatorbernite in sediments may be gradually tranforming to a uranyl carbonate phase as indicated by X-ray absorption spectroscopy. These results will be combined with other solid-phase characterization results and interpreted within a reaction-based modeling framework including dissolution-precipitation and aqueous speciation reactions.

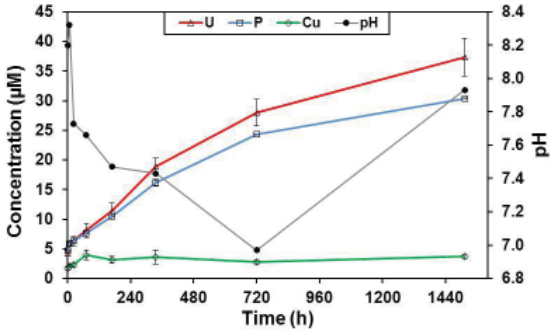

Figure 1: Measured dissolved concentrations and pH from metatorbernite dissolution in synthetic groundwater.

Distribution of dissolved neodymium and ε_{Nd} in the Bay of Bengal

SATINDER PAL SINGH[1] AND SUNIL KUMAR SINGH[2*]

[1]Physical Research Laboartory, Ahmedabad, India, satinder@prl.res.in
[2]Physical Research Laboartory, Ahmedabad, India, sunil@prl.res.in (* presenting author)

The concentrations and isotope composition of dissolved Nd have been measured in the water column along 87°E transect in the Bay of Bengal to investigate the impact of water mass mixing and desorption of Nd from particulates in determining their distribution in the Bay. The concentration of Nd in surface waters of the BoB shows a North-South decreasing trend (~ 46 to ~ 22 pmol/kg) with increasing salinity, whereas its depth profiles typically show a high value in surface waters, a minimum (~ 15 to ~ 23 pmol/kg) in shallow subsurface (~ 50-200 m) followed by a gradual increase with depth. The Nd concentration of the BoB waters is generally higher than that at corresponding depth in nearby oceanic basins. The ε_{Nd} of the northern BoB waters ~ -15 ± 1 overlaps with that of dissolved and particulate phases of the Ganga-Brahmaputra (G-B) Rivers, but less radiogenic than those reported for other regions of global oceans, except the Baffin Bay and the North Atlantic Subpolar Gyre. The abundance and distribution of dissolved Nd and its unradiogenic isotope composition suggests that the dominant source of Nd in the BoB is the dissolved and/or particulate phase of the G-B river system.

The ε_{Nd} values in the BoB show greater variation in the upper water column with more radiogenic values ~ -8 in surface waters of the southernmost profile (~ 6°N), which decreases to -15 in the northernmost profile (~ 20°N). This latitudinal trend is most likely a result of the variation in mixing proportion between the Indonesian Throughflow surface waters (IW) and the G-B river water. Inverse model calculations suggest that excess Nd of the order of ~1 to 65 % of measured Nd concentration is required from other source(s) in addition to various water masses. The calculations also show that ε_{Nd} of the additional source(s) has to be in the range of ~ -16 ± 2, typical of G-B river sediments. These observations coupled with the North-South distribution of dissolved Nd and ε_{Nd} indicate that this additional source is release from particulate phases supplied by the G-B river system and the continental margin sediments. This study underscores the significant role of dissolved/particulate Nd from the Ganga-Brhamputra river system in contributing to the dissolved Nd budget of the global ocean.

LA-MC-ICPMS iron isotopic measurements of zoned olivine

C.K. SIO [1*], N. DAUPHAS[1], F.Z. TENG[2], M. CHAUSSIDON[3], R.T. HELZ[4], M. ROSKOSZ[5], Y. XIAO[6], AND T. IRELAND[1]

[5]UMET, Université de Lille 1, France
[6]Institute of Geology and Geophysics, Chinese Academy of Sciences

Previous studies have revealed that iron and magnesium isotopes may be used to identify diffusion-driven zoning in olivine crystals [1-3]. In magmatic systems, Mg-rich olivine is an early crystallizing phase. As the melt evolves, it becomes more Fe-rich, so that in reaching equilibrium, Fe diffuses into and Mg diffuses out of the initial olivine crystal. Because light isotopes diffuse faster than heavy isotopes [4-5], such diffusion-driven mechanism is accompanied with 1) a negative correlation of Fe and Mg isotopes, and 2) a negative correlation of Fe isotopes and a postive correlation of Mg isotopes with Fo#. Teng et al. [1] showed these correlations in olivine fragments from Kilauea Iki lava lake. Sio et al. [3] used microdrilling techniques to spatially resolve the same correlations in a single olivine crystal.

Many zoned olivine crystals are smaller than or comparable to the size of a drill bit (300 μm used in [3]). Hence, it is imperative to develop *in-situ* techniques that provide better spatial resolution. Using a UP193HE laser, we conducted LA-MC-ICPMS iron isotopic measurements on the same sample analyzed in [3]. The spot sizes used in the sessions were 40-55 μm, an improvement of lateral and depth spatial resolution by approximately an order of magnitude relative to microdrilling. Smaller spot sizes may be used if ^{57}Fe is not analyzed.

Numerous tests were conducted to evaluate sample mount orientation and matrix effects. These tests suggest that the orientation effect must be carefully evaluated in order to obtain accurate data and true errors, which can be three times greater than the error taken only from measured isotopic variations on a single crystal. The typical precision is 0.2 ‰ (1 SD) based on repeat analyses of the same profile. The final iron isotopic profile agrees with the microdrilling results, with the rim at δ^{56}Fe -0.2 ‰ and the core at -1.2 ‰. A plot of δ^{56}Fe versus Fo# is also in perfect agreement with microdrilling data.

LA-MC-ICPMS provides the means to measure iron isotopic compositions with high spatial resolution in olivines. Such techniques can be employed on zoned crystals to better understand their crystallization and cooling histories. Our work establishes LA-ICPMS Fe isotopic analyses as a powerful tool of petrology in the study of igneous zoned minerals.

Effects of water on the nucleation of Li-rich granitic melts

MONA-LIZA C. SIRBESCU[1*], MAX WILKE[2], ILYA VEKSLER[2], AND ALAN G. WHITTINGTON[3]

[1]Central Michigan University, Earth and Atmospheric Sciences, Mt. Pleasant, MI, USA, sirbe1mc@cmich.edu (* presenting author)
[2]Deutsches GeoForschungsZentrum, Potsdam, Germany
[3] University of Missouri, Geological Sciences, Columbia, MO, USA

The amount of dissolved water controls the nucleation and crystallization of granitic melts by lowering their liquidus and glass transition temperature, their free energy relative to crystals, and viscosity. Although pegmatites and rhyolites are similarly affected by undercooling and cooling rate, they are at the opposite ends of the spectrum of igneous texture because pegmatite melts have incorporated and retained H_2O whereas rhyolites have lost H_2O [1].

Sixty nucleation-crystallization experiments on Li-B-haplogranite-H_2O compositions confirm that igneous texture is strongly controlled by the concentration of water. Time-series, isothermal runs (from 1 to 30 days) were performed at temperatures ranging from 400 to 700°C at 300 MPa, coresponding to variable degrees of undercooling between liquidus and glass transition. H_2O contents ranged from 2.6 to 8.3%, and kept below fluid saturation. Although metastable, mineral assemblages are reproducible. Viscosity data collected via the parallel-plate method indicate that the glass transition of both melts containing 6.5 % H_2O is just under 300°C, indicating that nucleation and crystallization took place in a liquid not in glass.

Clearly, H_2O concentration influences the time of incubation, nucleation densities, and crystal growth rates, but the effects are a nonlinear function of dissolved H_2O. For example, at 600°, nucleation delays are >5 days for a concentration of 8.3 % H_2O, decrease to a minimum of only one day for 6.5 % H_2O, and increase again to 2.5 days at 3.0 % H_2O. Growth and nucleation rates follow a similar parabolic behavior, as a consequence of the double role played by H_2O. On one hand, H_2O stimulates development of large crystals because of increased diffusion rate. On the other hand, H_2O decreases the liquidus temperature of the melt, therefore reducing the value of effective undercooling, which has the opposite effect of slowing down crystal growth. A "Goldilocks" behavior rules the development of pegmatite texture including large, skeletal crystals, graphic intergrowth, and low nucleation density. Ultimately, the value of effective undercooling has to be "just right".

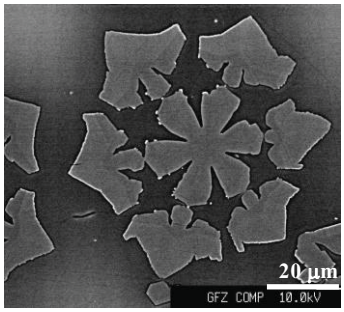

Figure 1: Skeletal "stuffed" beta-quartz produced in 30-day long run, at 500°C, in a haplogranitic melt with 3.0% (g/g) H_2O, 1% Li_2O, and 2.3 % B_2O_3

Geological storage of CO_2 in basic rocks relies on the dissolution of its silicate components, followed by the precipitation of carbonates. However, the slow dissolution kinetics of Mg-rich silicates has proven a critical issue. Previous batch carbonation studies on separated olivine grains[1] ($(Mg,Fe)_2SiO_4$), have emphasized the deleterious role of secondary phases, such as amorphous silica layers (SiO_2(am)) in controlling the dissolution rate of the parent mineral and the transport of reactants from and to the reactive surface.

We show here that carbonation processes and kinetics are strongly different for olivine within a tholeiitic basalt than for separated olivine. Batch experiments were conducted (at 150°C and P_{CO2} = 280 bars) on an Mg-rich (9.3 wt.% MgO and 12.2 wt.% CaO) tholeiitic basalt from Iceland, composed of olivine, Ti-magnetite, plagioclase and clinopyroxene. After 45 days of reaction, carbonation rates were quantified by CO_2 extraction with phosphoric acid, yielding up to 60 wt.% carbonation of Mg-rich phases as $MgCO_3$, but less than 0.5 wt.% of Ca-rich phases as $CaCO_3$.

Such observations diverge noticeably from those previously reported in lower T carbonation studies on Ca-rich, Mg-poor basalts[2]. In addition, X-ray diffraction analysis on the reaction products reveals a substantial decrease in olivine content, supporting the idea that magnesite formation mainly follows from olivine dissolution. Therefore, these results suggest that in our experiments, no passivating silica layer was formed on the surface of olivine. Instead, investigations by transmission electron microscopy reveal that a thin layer (~100 nm) of porous, iron-bearing, aluminous phyllosilicate has formed on the surface of the remaining primary silicates. Taken together, these observations suggest that, in an Al rich-medium, the formation of clay minerals may consume the silicon of potential silica-rich surface layers, or directly inhibit their formation. Those phyllosilicates would therefore represent the ultimate sink for Si, with lesser impact on the transport of reactants than SiO_2(am). By providing a constant driving force for Si removal, we eventually propose that such phases allow olivine to dissolve as rapidly as it is known to occur in open natural systems, and therefore to reach higher carbonation rates[3].

Nanoparticle remediation through porous media

R.L. SKUCE[1]*, D.J. TOBLER[1], M.R. LEE[1] AND V.R. PHOENIX

[1]School of Geographical and Earth Sciences, University of Glasgow, Glasgow, G12 8QQ, UK (*correspondence: r.skuce.1@research.gla.ac.uk)

The use of engineered nanoparticles continues to expand rapidly. As this intensifies, so does the environmental risk posed if they are released into the environment. This is of particular concern due to the potential toxicity of some nanoparticles. As it stands, we are poorly prepared to deal with nanoparticle pollution and thus remediation strategies must be developed Here, ureolysis-driven calcium carbonate precipitation by the urease positive bacterium *Sporosarcina pasteurii* is investigated as a means of removing nanoparticles from aquatic systems. This technology has been investigated for the solid phase capture of radionuclide and trace element contaminants in groundwater systems [1]. However its potential to capture nanoparticles has yet to be examined.

Batch experiments show the successful removal of highly stable organo-metallic nanoparticles at concentrations up to 10mg/l (the highest concentration tested thus far). Over 90% of nanoparticles where captured within 24 hours and capture efficiency appeared to be inversely proportional to calcite precipitation rate. As calcite precipitates, the nanoparticles become trapped within the growing calcite crystal. As the calcite-nanoparticle composite continues to grow, it adheres to surfaces (such as the edge of the reaction flask, or the edge of a pore space), immobilizing the nanoparticles from solution.

Following this an experiment was devised to determine the capture efficiency of nanoparticles through saturated porous media. It has been demonstrated that nanoparticles act as nucleation sites to the precipitating calcite, it is now imperative to determine whether nanoparticles are preferentially incorporated into the precipitating calcite when multiple nucleation sites are available, that is the sand grains. Breakthrough curves obtained determine the capture efficiency of nanoparticles in saturated porous media.

This technology has the potential for application in contaminated groundwater and soil as an in-situ remediation technique for nanoparticle pollutants.

Bottom water redox conditions and sea level changes during Zn-Pb and phosphate mineralization, Howards Pass district, Yukon Territory

JOHN F. SLACK[1]*, HENDRIK FALCK[2], KAREN D. KELLEY[3], GABRIEL G. XUE[4]

[1]U.S. Geological Survey, MS 954, Reston, VA 20192, USA, jfslack@usgs.gov (*presenting author)
[2]NWT Geoscience Office, P.O. Box 1500, Yellowknife, NWT X1A 2R3, Canada
[3]U.S. Geological Survey, MS 973, Denver, CO 80225 USA
[4]Selwyn Resources Ltd., 509 Richards St., Vancouver, BC V6B 2Z6, Canada

Stratabound Zn-Pb sulphide deposits of the Howards Pass district occur in the Middle Ordovician-Early Silurian Duo Lake Formation (DLF). From base to top, the DLF in the district comprises four principal members: pyritic mudstone, calcareous mudstone, active (Zn-Pb), and upper siliceous mudstone. Sulphide lenses in the active member consist of layered, laminated, and massive sphalerite ± galena. Pyrite forms thin laminae of fine-grained framboids. The upper calcareous mudstone and the base of the active member locally contain apatite-rich units; the upper siliceous member has abundant apatite laminae 0.1-1.5 cm thick.

Whole-rock analyses for Zn- and Pb-poor DLF mudstones (n = 58) from three drill cores in relatively undeformed parts of the XYC and HCW deposits contain variable silica (to 90 wt % SiO_2), phosphate (to 24.7 wt % P_2O_5), and carbonaceous material (to 16.5 wt % Corg). V concentrations are highest in the calcareous mudstone member (to 3000 ppm), implying sedimentation near the suboxic-anoxic boundary; large variations in marine V/Mo ratios (0.74-209) reflect fluctuating bottom-water redox over time [1]. Re/Mo ratios [2], considered the best paleoredox proxy, record sulphidic or anoxic conditions (Re/Mo <0.001) in bottom waters during deposition of the pyritic mudstone, most of the calcareous mudstone, and active members; these conditions predominated in the basin prior to and during Zn-Pb mineralization, aiding accumulation and preservation of sulphides. In the upper siliceous member, Re/Mo ratios are mostly higher (0.004-0.013), indicating suboxic (<5 μM O_2) bottom waters. Suboxic conditions within the upper part of the calcareous mudstone and the base of the active member, and especially in the upper siliceous member, promoted deposition of abundant phosphate and correlate temporally with two periods of global sea level rise [3]; falling sea level may have facilitated the development of crucial anoxic to sulphidic bottom waters during Zn-Pb mineralization. Lithologic similarity to part of the Monterey Formation (Miocene) of coastal California suggests that the DLF and its contained Zn-Pb deposits formed in a restricted basin near a continental margin, accompanied by high productivity required for the accumulation of abundant phosphate, biogenic silica, and organic matter.

Exploring Water Quality and Flow Paths Using Boron Isotope Data

A.T. SLADE[1]*, N.R. WARNER[2], A. VENGOSH[2] AND B. WHITEHEAD[1]

[1] School of Environment, The University of Auckland, 23 Symonds Street, Auckland 1142, New Zealand, a.slade@auckland.ac.nz (* presenting author)

[2] Division of Earth and Ocean Sciences Nicholas School of the Environment, Duke University, Durham, NC 27708

Boron isotope data is rarely used by water quality (WQ) authorities to elucidate processes occurring in hydrologic systems in order to improve WQ management protocols. In concert with a suite of chemicals this study explores the use of boron as a tracer in a WQ study that also helps reveal potential flow paths for water in a pulp and paper waste site. The results not only provide the local WQ authorities with a tool for improving the management of their waterways, they come at a critical stage in the history of the site as the parties legally responsible for the waste and management of the site will change in December of 2012.

Study Site

A pulp and paper waste site, located on top of active geothermal features, in the Bay of Plenty region of New Zealand is at risk of having a sustained and detrimental impact on the environment given the following historical and contemporary issues: 1) the waste site floods periodically causing temporary ponding, which in the past has resulted in the banks of the adjacent Tarawera River (TR) to breach; 2) the natural underlying geologic units and waste material generated by the pulp and paper mill are highly permeable; and 3) the two shallow unconfined aquifers in and under the waste are thought to house substantial volumes of water that are connected to the TR. As such, it is important to identify the source, provenance, and chemical profile of the water as it migrates through the geologic units and waste material in an effort to assist in mitigating any future environmental impacts.

Results of Study

This study involves a comprehensive chemical evaluation of water samples collected between 2009 and 2011, from the pulp and paper waste site, with an emphasis placed on boron isotope data. The types of water sampled and their associated $\delta^{11}B$ values collected from the 1 km^2 area that encompasses the waste site were: surface water (10.1-15.4‰); groundwater (-5.0-0.0‰); leachate (-1.5-6.7‰); geothermal water (-1.2‰); natural spring water (11.9‰); and rain water (25.9-28.9‰). The collation of the data provides a final assessment of the waste site's hydrologic system through the lens of boron isotope chemistry and showcases the ability to use it to improve WQ management protocols.

Timing and carbon sources for microbial processses in the deep terrestrial carbon cycle

SLATER, G.F.*[1], MAILLOUX, B[2]., SILVERN, R.[2], LI, L[3], SHERWOOD LOLLAR B[3]., ONSTOTT T.C.[4],

[1]McMaster University, Hamilton, Canada, gslater@mcmaster.ca,
[2]Bernard College, New York, USA
[3]University of Toronto, Toronto, Canada
[4]Princeton University, USA

The presence of microbial communities living in ancient, fractured rock in deep (2-3+ km) subsurface terrestrial environments suggests that the metabolic activities of these organisms may play a role in fluxes of carbon moving into, or out of, these deep Earth environments. This study investigated the carbon source and metabolic activities in fracture water feeding an artesian borehole located 1.3 deep in the Beatrix mine, South Africa. Isotopic analysis of the ^{18}O and ^{2}H of the waters lie along the GMWL but offset from modern precipitation indicating a paleometeoric origin confirmed by noble gas derived residence times on the order of a few Ma (1).

Multiple isotope analysis of carbon isotopes (^{13}C, ^{14}C) was applied to microbial cellular components (PLFA, DNA) and potential carbon sources and/or metabolites including dissolved inorganic carbon (DIC) and CH_4. $\Delta^{14}C$ of DIC was observed to be -980 ‰, slightly enriched above expectation for geologically old carbon ($\Delta^{14}C$ = -1000 ‰). Concurrently, PLFA and DNA $\Delta^{14}C$ were -940 ‰ demonstrating microbial utilization of highly ^{14}C depleted carbon sources. This is the first study we are aware of to compare two such distinct cellular components. The close agreement of these independent measurements supports the accuracy of both approaches. The fact that these microbial cellular components were slightly isotopically enriched related to the DIC suggests inputs from a ^{14}C enriched carbon source. The potential role of methane ($\delta^{13}C$ =-52 ‰ at this site) as a C source in this ecosystem is suggested by the $\delta^{13}C$ of PLFA from these communities (-50 to -65 ‰). This hypothesis will be investigated by on-going isotopic analysis of the ^{14}C methane and ^{13}C DIC pools.

Subduction-driven growth and modification of cratons: examples from Canada and Greenland

K. A.SMART[1, 2*], S.TAPPE[1, 2], A.SIMONETTI[1,3] AND S.KLEMME[2]

[1]University of Alberta, Edmonton, Canada
[2]WWU, Münster, Germany kasmart@uni-muenster.de (*presenting author) sebastian.tappe@uni-muenster.de, stephan.klemme@uni-muenster.de
[3]Univ. of Notre Dame, Notre Dame, USA simonetti.tony@gmail.com

Cratonic crust and underlying mantle roots are thought to have a shared history of growth and modification since the Archean. However, debate continues on whether their coupled growth was due to mantle plumes or early forms of subduction. Cratonic mantle eclogites are central to this debate and here we present evidence from two such xenolith suites from Canada and Greenland for subduction-driven growth and modification of cratonic lithosphere.

We have determined the Pb isotope compositions of clinopyroxenes from eclogite xenoliths from the northern Slave and the West Greenland North Atlantic craton (NAC). Clinopyroxenes from NAC eclogites define a secondary isochron with an age of 2.7±0.3 Ga, which intersects a terrestrial Pb isotope evolution curve at ca. 2.62 Ga. This suggests Late Archean eclogite formation via melt extraction during subduction of oceanic crust [1]. Pb isotope compositions of the Slave clinopyroxenes do not define a statistically meaningful isochron. Instead, they appear to form a mixing array extending from clinopyroxene with unradiogenic Pb ($^{206}Pb/^{204}Pb$ ~ 14.3) to the host Jurassic kimberlite ($^{206}Pb/^{204}Pb$ ~ 19.2). We believe this array was produced by mixing between kimberlitic- and eclogitic derived Pb. Hence, the least radiogenic Pb isotope composition that intersects the Stacey-Kramers evolution curve at ca. 2.2 Ga has age significance. Importantly, this model age falls within the age range of 2.3-1.8 Ga shown by other eclogites from the Slave craton [2].

Both the Slave and NAC eclogite xenoliths have geochemical signatures that indicate oceanic crust protoliths, including $\delta^{18}O$ values that range above the mantle average (5.2-6.4‰). Moreover, the eclogite ages coincide with putative subduction events in each craton. NAC eclogite formation coincides with 2.9-2.7 Ga crustal growth marked by the intrusion of TTG granitoids in West Greenland. These TTGs are interpreted as melts of subducted oceanic basalts from their complementary relationship with the refractory NAC eclogites. The Slave eclogites coincide in age with the ca. 1.9 Ga subduction event that affected the western craton margin. Unlike Greenland, this subduction event did not add significantly to the Slave cratonic crust, and instead introduced eclogitic material to the craton root [2]. Furthermore, ca. 1.9 Ga eclogitic diamonds from the Slave craton [3] suggest that this subduction event introduced appreciable amounts of carbon into the mantle lithosphere. Thus, while both eclogite suites record craton evolution events, major crustal growth was only associated with the Archean Greenland eclogites, whereas late-stage cratonic root modifcation including metasomatism and diamond growth are marked by the Paleoproterozoic Slave eclogites.

Formation of eclogites and pyroxenites below Attawapiskat, Superior Craton (Canada)

KAREN V. SMIT*[1], THOMAS STACHEL[1], ROBERT A. CREASER[1], S. ANDREW DUFRANE[1], RYAN B. ICKERT[2], RICHARD A. STERN[2] AND MICHAEL SELLER[3]

[1] Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Canada, kvsmit@ualberta.ca*
[2] Canadian Centre for Isotopic Microanalysis, Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Canada
[2] De Beers Canada, Toronto, Canada

Seventeen eclogite and 16 pyroxenite xenoliths from the Victor kimberlite at Attawapiskat will be used to assess whether they show evidence for a shallow origin as oceanic crust, emplaced into the Superior SCLM by tectonic stacking. Eclogites contain omphacite + garnet, whereas the pyroxenites contain diopside + garnet ± enstatite; three broad groups (Ca, Fe or Mg-rich) are recognised through their reconstructed whole rock major and rare earth element chemistry.

The sole high-Ca kyanite-bearing eclogite is the only sample with a positive Eu anomaly and has a subchondritic REE_N pattern consistent with an oceanic crust precursor undergoing dehydration/low degree partial melting during subduction. Fe-rich eclogites have flat $MREE_N$ to $HREE_N$ –indicative of a low-pressure origin – and depleted $LREE_N$. The high Mg eclogites and pyroxenites have similar flat $MREE_N$ to $HREE_N$, but enriched $LREE_N$ indicating a shallow origin and a subsequent stage of fluid metasomatic enrichment. Reconstructed whole rock compositions for these high Mg eclogites and pyroxenites rocks overlap with orogenic pyroxenites [1], suggesting a possible primary origin as basaltic intrusives in the shallow lithosphere.

Cpx from all the compositional groups have depleted Sr isotopic compositions (0.7019-0.7039) relative to present day bulk earth (0.7045). The majority of the samples have $\delta^{18}O$ overlapping, within uncertainty, to the mantle value. Mantle-like $\delta^{18}O$ values do not rule out oceanic crust as protoliths [2,3], and therefore these data cannot be used to distinguish between a low versus a high pressure origin. Evidence for involvement of crustal components in the genesis of the Superior's lithospheric mantle are flat $MREE_N$ to $HREE_N$ patterns and a positive Eu anomaly in the kyanite-bearing eclogite. Re-Os analyses and in-situ cpx Pb-Pb dating of these eclogites and pyroxenites are currently underway.

Iron isotope fractionation in stromatolitic oncoidal iron formation, Mesoarchean Witwatersrand-Mozaan Basin, South Africa

ALBERTUS J.B. SMITH[1*], NICOLAS J. BEUKES[1], JENS GUTZMER[1,2], CLARK M. JOHNSON[3], AND ANREW D. CZAJA[3]

[1]PPM, Department of Geology, University of Johannesburg, Johannesburg, South Africa, bertuss@uj.ac.za (* presenting author), nbeukes@uj.ac.za

[2]Department of Mineralogy, Techische Universität Bergakademie Freiberg, Freiberg, Germany, jens.gutzmer@mineral.tu-freiberg.de

[3]Deparment of Geoscience, University of Wisconsin-Madison, Madison, Wisconsin, USA, clarkj@geology.wisc.edu, aczaja@geology.wisc.edu

Iron isotope fractionation in an Archean marine basin through biological and abiological processes is well illustrated in an iron rich unit in the Mesoarchean (2.96-2.92 Ga) Witwatersrand-Mozaan Succession [1] of South Africa and Swaziland. The unit comprises the oldest known shallow water oncoidal granular iron formation interbedded with magnetite- and stilpnomelane-rich mudstone and mixed mineralogical facies banded iron formation. The banded iron formation marks the most distal and the oncoidal iron formation the most proximal depositional settings. The oncoidal iron formation shows domal and columnar micro-stromatolite rims composed of magnetite around chert and calcite grains in a matrix of chert and minor iron-rich silicate. The more distal banded iron formations and iron-rich mudstones have δ^{56}Fe values ranging from slightly positive to strongly negative depending on the dominant iron-rich phase. The stromatolitic oncoidal iron formation has δ^{56}Fe values from zero to strongly positive. Moreover, the δ^{13}C values of the calcite in the latter are strongly negative, suggesting the carbonates formed through the oxidation of organic carbon.

The geochemical evidence along with the depositional facies reconstrution show that the mode of iron deposition varied from the distal to proximal depositional settings, and is the most dominant control on iron isotope fractionation. The limited iron source that reached the proximal setting of the stromatolitic oncoidal iron formation had zero to positive δ^{56}Fe values. Textural and geochemical evidence suggest that iron oxidizing microbes [2] living on the rims of reworked chert grains used the limited ferrous iron in the shallower part of the basin in their metabolism to precipitate ferrihydrite, which would concentrate heavy iron isotopes [3]. The ferrihydrite underwent a redox reaction with organic carbon during diagenesis to form magnetite that retains the heavy iron isotopic signature and isotopically light calcite. The lighter iron isotopes remaining in solution were incorporated into iron-rich silicates in the matrix.

The pyroxene sponge: amphibole signatures and controls on water in arc magmas

D. J. SMITH[1*]

[1]University of Leicester, Leicester, UK, djs40@le.ac.uk (* presenting author)

Many arc magmas show evidence of amphibole fractionation, in the form of characteristic REE profiles and exhumed amphibole cumulates. However, amphibole is not always a major modal phase in the erupted suites: thus, fractionation is cryptic [1]. In water-rich (>4 wt% H_2O) magmas where amphibole fractionation is most pronounced, high Sr/Y signatures develop [2]. Elevated Sr/Y magmas have an association with porphyry mineralisation (e.g. [3]) – most likely an indicator that water-rich, amphibole stable melts are fertile for porphyry formation [4].

Clinopyroxene is an early and abundant fractionating phase in most arc magmas, and unlike amphibole is common in the erupted rocks. New data from the Solomon Islands suggest that the early-formed clinopyroxene cumulates can react with evolving magmas, forming amphibole as a secondary metasomatic phase. The "cryptic" fractionation of amphibole may in fact be clinopyroxene cumulate–melt reactions, generating REE profiles characteristic of amphibole removal without it being a major modal phase in the crystallising magma.

Furthermore, the Solomon Islands data show that these metasomatic amphibole cumulates can be contrasted with true amphibole cumulates (i.e. directly crystallised and fractionated amphibole), with only the true amphiboles generating strong Y depletion (and by extension, high Sr/Y) in the daughter magmas.

The clinopyroxene cumulates are potentially acting as a sponge, modifying the daughter magma's REE signature, and locking up water as they react to form amphibole. More hydrous magmas, able to directly crystallise amphibole and generate high Sr/Y, may only form where the sponge has been entirely metasomatised, and is no longer capable of locking up water. The clinopyroxene sponge possibly limits water content and magma fertility under normal arc-fractionation conditions. Fertile magmas are either more hydrous at source (able to directly crystallise amphibole), or only develop after repeated cycles of intrusion and cumulate–melt reaction.

Enhanced multicollector ICP-MS coupled with a desolvating nebulizer system for geochronology

FRED G. SMITH[1*], VICTOR POLYAK[2]

[1]CETAC Technologies, Omaha NE USA, fsmith@cetac.com(* presenting author)
[2]University of New Mexico, Earth and Planetary Sciences, Albuquerque NM, USA, polyak@unm.edu

Abstract

Multicollector ICP-MS instruments are very specialized devices for high precision isotope ratio measurements. For accurate measurement of low abundance isotopes, signal enhancement is often required. In addition, sample preparation and/or sample aerosol desolvation may be necessary to reduce or eliminate mass spectral interferences such as oxides and hydrides.

This paper will examine the coupling of an enhanced multicollector ICP-MS instrument with a dedsolvating nebulizer system for geochronology. The hardware specification of the ICP-MS will be detailed, including a revised vacuum system and special sampler and skimmer interface cones. Important operating conditions of the desolvating nebulizer system include argon sweep gas and nitrogen addition gas flows.

Application of this coupled system to U-series dating will be described.

Mineralogy and porewater geochemistry of processed kimberlite: implications for acid rock drainage and metal releases

LIANNA J.D. SMITH[1*], MICHAEL C. MONCUR[2], DOGAN PAKTUNC[3], AND YVES THIBAULT[3]

[1]Rio Tinto - Diavik Diamond Mines, Yellowknife, YK, Canada, Lianna.smith@riotinto.com (*presenting author)
[2]Alberta Innovates-Technology Futures, Calgary, AB, Canada, michael.moncur@albertainnovates.ca
[3]CANMET Mining and Mineral Sciences Laboratory, Ottawa, ON, Canada, dpaktunc@NRCan.gc.ca, ythibaul@nrcan.gc.ca

The development of diamond mines in Canada's North emphasizes the need to assess the environmental implications of storing processed kimberlite tailings (PK) in regions with continuous permafrost. The Diavik Diamond Mine (Diavik) is located in the barren lands on an island in Lac de Gras, 300 km northeast of Yellowknife, NT, Canada. During the life of the mine, up to 42 million tonnes of PK will be produced and disposed on site for permanent storage. In 2009, a study was initiated to understand the mineralogy and evolution of porewater geochemistry in the PK tailings impoundment. Porewater was collected and analyzed from a number of core and drive-point piezometers located across an exposed PK beach and in the central pond. The core samples were analyzed and characterized in detail. The samples collected from the tailings pond are composed of Ni-bearing olivine, calcite, quartz, garnet, lizardite, biotite, albite, saponite and both framboidal and massive pyrite. Olivine and its alteration products made of lizardite, iron oxides and magnesian aluminosilicates are the dominant minerals. Neutralization potentials of the samples are between 39 to 85 kg $CaCO_3$ eq/t, far exceeding the acid generating potentials in the 5 to 12 kg $CaCO_3$ eq/t range due to the presence of pyrite. Porewater samples from the unsaturated zone of the impoundment have the lowest pH values and highest concentrations of dissolved SO_4 and metals. With depth, pH values increase and dissolved SO_4 and metals concentrations decrease towards the water table. In the saturated zone, average dissolved concentrations decrease by almost an order of magnitude compared to the unsaturated zone for SO_4, major cations and most metals (e.g SO_4: 3500 to 350 mg/L; Mg: 730 to 80 mg /L, Ni: 0.82 mg/L to 0.038 mg/L). Sulfur isotope ratios measured from the porewater are strongly depleted averaging -17.9 ‰ and show minimal fractionation from the unprocessed kimberlite, suggesting dissolved sulfate concentrations are resulting from sulfide oxidation; however, there are no apparent mineralogical features on pyrite grains indicative of oxidative dissolution. Except for a single grain of $BaSO_4$, no other sulfate minerals were identified in the PK. Porewaters from the underlying frost zone show further increases in pH and decreases in dissolved SO_4 and metal concentrations. Groundwaters collected from piezometers installed in PK stored below a water cover revealed dissolved concentrations of major ions and metals which are comparable to those measured from the frost zone. Results from this study show that subaqueous disposal and freezing of the PK material would restrict oxidation and dissolution processes and limit the release of dissolved concentrations of metals and SO_4.

Solubilities of arsenic oxy- and thio–compounds in calcium rich waters

MATT SMITH[1*] AND DIRK WALLSCHLÄGER[2]

[1]Trent University ENLS Graduate Program, Peterborough, Canada, mattsmith@trentu.ca (* presenting author)
[2]Trent University Department of Chemistry, Peterborough, Canada, DWallsch@trentu.ca

16l. Biogeochemistry of Oxyanion-Forming Trace Elements in the Environment

The mobilisation of arsenic by thiolation is a significant driver of As solubility in sulphidic, reducing systems and alkaline environments [1, 2]. The determination of the chemistry of arsenic thioanions requires specific analytical methods to for detection. The complex chemistries of environments containing thioarsenicals create problems with regard to preservation of *in situ* arsenic speciation. Co-precipitation of arsenic with iron[3] or other minerals salts has been shown to occur during the lag time between *in situ* sampling and laboratory analyses. Calcium (Ca) is a ubiquitous element in alkaline natural systems containing As. The insolubility of Ca-arsenate salts has been documented[4] thus quantitative losses of As from *in situ* samples containing Ca is a probable mechanism.

Interactions between Ca and arsenic oxy- and thioanions were studied under anoxic, alkaline conditions. We have studied the precipitation of Ca-thioarsenate salts, and have been able to experimentally determine the K_{SP}, $\Delta G°_f$, $\Delta H°_f$, and $\Delta S°$, for Ca-monothioarsenate, Ca-arsenite, and Ca-arsenate. Trithioarsenite, trithioarsenate and tetrathioarsenate do not form Ca-arsenic salts or absorb to Ca carbonate ($CaCO_3$), Ca hydroxide or Ca sulphate, indicating that these species are the most soluble anionic arsenic species. Dithioarsenate is more soluble than monothioarsenate and arsenate, and arsenite is the least soluble As species. The solubilities of Ca sulphate and $CaCO_3$ are less than those of the Ca-arsenic salts, thus adsorption of arsenite and arsenate to Ca sulphate and $CaCO_3$ can be a significant mechanism of removal of As oxyanions in the environment. Increasing thiolation enhances the solubility of As anions such that no chemical interaction exists between As and Ca in the environment for tri- and tetra-thiolated species.

Ionic force fields for electrolytes and molecular simulation of chemical potentials and aqueous solubility

WILLIAM R. SMITH[1*] AND FILIP MOUČKA,[1,2]

[1]University of Ontrio Institute of Technology, Oshawa, Canada, william.smith@uoit.ca*
[2]J.E. Purkinje University, Ústí n. Labem, Czech Republic, fmoucka@seznam.cz

We have recently [1,2] developed the Osmotic Ensemble Monte Carlo (OEMC) method for calculating the chemical potentials and solubility of aqueous electrolytes and their mixtures by molecular simulation. OEMC is a computationally efficient algorithm that uses a type of semi grand canonical ensemble, with a fixed number of water molecules at temperature T and pressure P, and electrolyte chemical potentials specified by the inter-phase equilibrium reaction involving the ions and their crystalline solid. To calculate solubility, we use accurate chemical potential data for the solid from thermochemical tables[3]. By appropriately setting the solid's chemical potential to other values, the entire chemical potential vs concentration curve of the ions in solution can be mapped out.

Although our results show good qualitative and reasonable quantitative accuracy, improvements depend on the use of more accurate ionic force fields. In this talk, we describe calculation strategies and show results for new force-field models for Na^+ and Cl^- compatible with SPC/E water. Our new force fields demonstrate good accuracy for the combined ion pair chemical potentials, the solution density, the predicted solubility and the solid chemical potential and density. Preliminary results are shown in the figure.

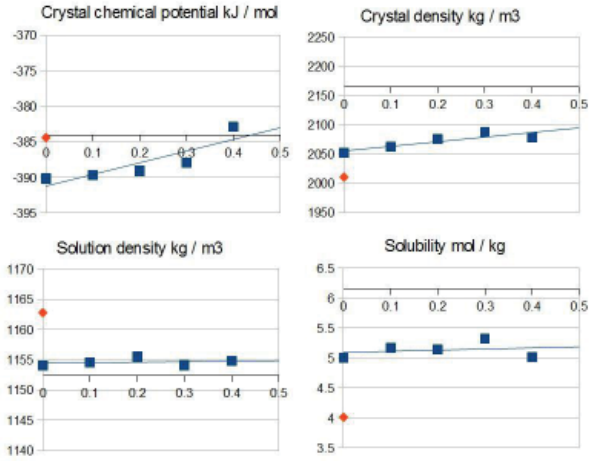

Figure: NaCl crystal and solution properties as functions of a model parameter after one iteration of the force-field adjustment strategy. Blue: our results; Orange:results using the force field of Joung and Cheatham[4]; Horizontal lines: experiment.

Insights into the 2300Ma magmatic shutdown

R.G. SMITS[1*], M.HAND[1], W.J. COLLINS[2]

[1]Centre for Tectonics, Resources and Exploration, University of Adelaide, S.A. 5005, Australia, russell.smits@adelaide.edu.au (* presenting author)

[2]School of Environmental and Life Sciences, University of Newcastle, NSW 2308, Australia,

Zircon geochronology and isotope geochemistry allows insights into the temporal and geodynamic controls on tectonic events. The global record of magmatic events reflected from zircon spectra is episodic, with large widespread events in zircon geochronology occurring periodically and related to supercontinent amalgamation. Conversely large troughs in the zircon spectra have been inferred to tectonic shutdown and magmatic hiatus. A large trough in the global zircon record around 2300Ma is interpreted to reflect this phenomenon, with widespread reduction in magmatic activity beginning at 2.45Ga to 2.2Ga (Condie *et al.* 2009). Whilst no direct outcrop of 2.3Ga magmatic lithologies has been sampled, a number of detrital samples record distinct populations at 2.3Ga allowing for interrogation of this geodynamically distinct time in the Earths evolution. The detrital zircon spectra in the Warumpi Province sediment samples display peaks at 1.8Ga, 2.5Ga with minor 2.3Ga comparable to the North China Craton and to a lesser extent Antarctica. Coupled U-Pb geochronology and Hf isotopic data from detrital samples in the central Australian Warumpi Province reveals distinct populations of 2300Ma zircons and the source mantle composition. The similarities in the age distributions raise the possibilities of co-evolution between these cratons and the links to the Nuna Supercontinent formation in the Paleoproterozoic. The coupled Hf isotope and U-Pb age analysis for zircons between 2.45-2.2Ga display variable arrays and large distribution between juvenile mantle to evolved sources, with distinct clusters observed. The variable spread of the Hf isotopic data indicates there are varied geodynamic systems at large during a period of proposed tectonic quiescence.

The U-Th-Pb allanite petrochronometer: a combined ID-TIMS and LA-ICP-MS study

A.J. SMYE [1*], N.M.W. ROBERTS[1], D.J. CONDON[1], M.S.A. HORSTWOOD[1], R.R. PARRISH[1,2]

Abstract

Allanite ($(Ce,Ca,Y,La)_2(Al,Fe^{+3})_3(SiO^4)_3(OH)$) is important as a U-Th-Pb petrochronometer of metamorphic and igneous crustal processes. Largely, this is because of its extended *P—T—X* stability field over other U-Th-Pb mineral chronometers [1], its ubiquity in felsic to aluminous melts [2] and its ability to retain radiogenic Pb at temperatures > 650ºC [3]. Furthermore, allanite plays a key role in the transport of LREE, U, Sr and Th in subducted crust [4].

Weight % concentrations of U and Th mean that both U-Pb and Th-Pb systems can potentially be used to constrain the age of radiogenic Pb in-growth. Th/U values up to 1000 mean that the Th-Pb system is preferentially targeted. However, successful U-Th-Pb allanite geochornology is hampered by: (**i**) the propensity of allanite to sequester high levels of non-radiogenic Pb (up to 95%); (**ii**) the presence of excess-^{206}Pb arising from incorporation of ^{230}Th; (**iii**) its common lack of crystallographic integrity, and (**iv**) compositional solid-solution with the epidote group minerals. Therefore, as the use of allanite U-Th-Pb data becomes more widespread, it is vitally important to understand the limitations and strengths of allanite as a petrochronometer.

Available allanite reference materials are poorly characterised; notably, there is a dearth of accurate U-Pb, and particularly, Th-Pb ID-TIMS data. Given that allanite is most commonly dated by LA-ICP-MS and SIMS, this means that many published datasets likely conceal considerable uncertainty in the accuracy of calculated age estimates.

This contribution presents the results of a combined ID-TIMS and LA-ICP-MS U-Th-Pb study on a suite of allanite reference materials, including two of the most commonly used allanite standards: the SISS and Tara allanites [5], in addition to a new potential allanite reference material. Both ID-TIMS and LA-ICP-MS analyses have been performed on the same allanite grain fractions so as to minimise normalisation-induced uncertainty. The high spatial resolution of the LA-ICP-MS technique, together with WDS-SEM imaging and powder XRD shows that allanite retains closed-system U-Th-Pb isotope systematics despite its pervasively metamict state. Open-system behaviour is restricted to clearly-identifiable zones of fluid-mediated alteration.

Redox conditions of Hadean magmas: Insight from Ce-in-zircon oxygen barometry

DUANE J. SMYTHE[1*] AND JAMES M. BRENAN[1]

[1]University of Toronto, Department of Geology, Toronto, Canada, smythe@geology.utoronto.ca (* presenting author), j.brenan@utoronto.ca

Positive Ce anomalies on chondrite normalized REE abundance diagrams are a nearly ubiquitous feature of zircon. This is the result of the presence of trace amounts of Ce^{4+} in natural systems and the higher compatibility of Ce^{4+} over Ce^{3+} in zircon. Using experimental determinations of the Ce^{4+}/Ce^{3+} in the melt as a function of fO_2 and melt composition, we have calibrated a Ce-in-zircon oxygen barometer independent from that of Trail et al. [1]. Our method takes the approach of Ballard et al. [2], applying the lattice strain model to measured D(zircon/melt) trace element distribution coefficients for both the REEs and a suite of 4+ cations (Zr, Hf, Th, U) which allows the estimation of the end-member D values for Ce^{3+} and Ce^{4+}. Measured "bulk" D_{Ce} values, which plot on a mixing curve between these end members, can then be related to the fraction of Ce as 4+ in the melt. Our calibration then allows for this to be linked directly to fO_2.

Evaluation of this technique has been carried out on zircons from three different lithologies whose fO_2 (expressed as Δ FMQ) has been estimated independently: rhyolite from the Bishop tuff, California (FMQ +1.1 ± 0.6), dacite from the Toba tuff, Indonesia (FMQ +0.9 ± 0.6), and monzodiorite from the Umiakovik pluton, Nain plutonic suit, Labrador (FMQ -2.4 ± 1.4). Trace element concentrations of zircon and host glass were measured by LA-ICP-MS. Values of Δ FMQ calculated by our method are +1.6 ± 0.4 (Bishop tuff), +0.8 ± 0.7 (Toba tuff) and -3.9 ± 0.5 (Umiakovik pluton), which are within error of the independent estimates.

Using D(zircon/melt) values for the REEs from Sano et al. [3] and empirical estimates for the 4+ cations, we have applied our oxygen barometer to Hadean zircons from the Jack Hills, Australia. Calculated values of Δ FMQ for zircons whose $\delta^{18}O$ is in the mantle range yield a bimodal distribution with peaks at –2.4 (n = 4) and +2.0 (n = 7). This appears to be connected to the crystal chemistry as light REE enriched samples consistently give lower estimations of fO_2. In addition to fO_2 we have also observed considerable dependence in Ce^{4+}/Ce^{3+} on melt composition. For the likely range in composition of zircon crystallizing melts this would affect the calculated fO_2 by at most 1 Δ FMQ unit. Therefore, the range in fO_2 observed is beyond that which can be explained by melt composition alone. This suggests that heterogeneities in fO_2 persisted in the source region for the zircon-producing magmas during the Hadean.

Atomic scale imaging of U, Th and radiogenic Pb in zircon

DAVID R. SNOEYENBOS[1*], DAVID REINHARD[1], AND DAVID P. OLSON[1]

[1]Cameca Instruments Inc., Madison, WI, USA David.Snoeyenbos@ametek.com (* presenting author)

Radiometric dating of a mineral depends on the assumption that the parent radionuclides and daughter radiogenic Pb have remained together within the analyzed volume. Isotopic dating techniques continue to evolve from bulk methods towards *in situ* techniques with ever smaller analyzed volumes such as afforded by LA-ICPMS and SIMS. The use of small sample volumes in zircon minimizes common Pb from microinclusions, but increases the importance of knowing if there has been any spatial redistribution of the radiogenic Pb relative to its parents.

In Atom Probe Tomography (APT) a specimen with dimensions of a few hundreds of nanometers is evaporated atomic layer by atomic layer. The original position of each atom is identified, along with its atomic species, and in most cases its isotope. The result is a reconstruction allowing quantitative three-dimensional study of the specimen at the atomic scale, with very low detection limits and high mass resolution.

A zircon specimen in garnet from recently identified possible UHP rocks from the Taconian of Western Massachusetts, USA [1] was selected for study by APT. WDS mapping and quantitative analysis by FE-EPMA had revealed high concentrations of Th and U in a submicron envelope between a resorbed zircon core, and a subsequent metamorphic overgrowth.

Guided by FE-EPMA trace-element mapping, a sample of this envelope was extracted by FIB and milled into 200nmX100nm conical tips appropriate for APT. A dataset of ~11 million atoms was obtained, revealing a 25nm wide band of zircon between core and overgrowth containing >0.25 at% each of U and Th.

Sufficient radiogenic Pb had accumulated within the specimen to be detectable by APT, consistent with the high concentrations of radionuclides and the expected 4-500my age of the specimen,. Strong spatial covariance was observed between U and 206Pb, without apparent migration or agglomeration of the radiogenic Pb atoms.

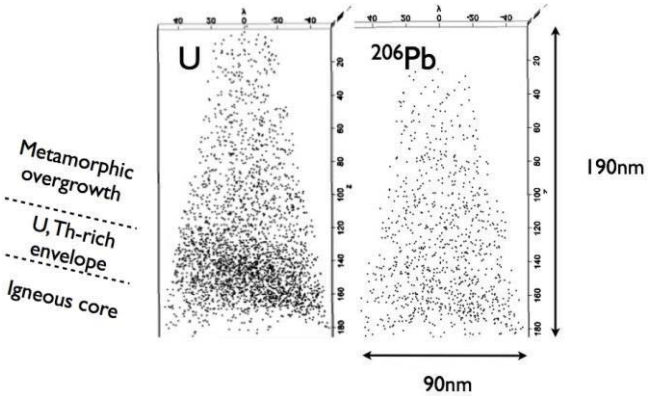

Figure 1: Ion image of U(total) and 206Pb atoms detected by APT.

Sr, Nd, Pb and Hf isotopic constraints on mantle sources in the Payenia backarc basalts (Mendoza, Argentina)

NINA SØAGER[1*], PAUL MARTIN HOLM[1], MATTHEW F. THIRLWALL[2]

[1]University of Copenhagen, Copenhagen, Denmark, ns@geo.ku.dk (*presenting author)
[2]Royal Holloway University of London, London, UK, M.Thirlwall@rhul.ac.uk

The mainly alkaline basalts and trachybasalts from the Payenia volcanic province of southern Mendoza show a great variation in geochemistry ranging from intraplate to arc-backarc compositions. In Pb-Sr-Nd-isotopic space the retroarc and Nevado volcanic field samples form a common trend from the isotopic composition of the Andes transitional southern volcanic zone arc (TSVZ) towards a component with higher Sr and lower Nd-isotopes. This is interpreted as contamination by lithospheric mantle melts due to a sharp decrease in La/Sm, Tb/Yb and incompatible element contents (except Ti) along this trend, making upper crustal contamination unlikely.

The intraplate basalts from the Río Colorado area have lower Pb and Sr and slightly higher Nd-isotopic composition than the Nevado samples and apparently reveal the composition of an astenospheric mantle end-member. The very low Th/Nb, high U/Pb and Ce/Pb of the Río Colorado basalts precludes any significant input from the subduction zone. In Nd-Hf isotopic space they plot at negative ΔεHf along with FOZO and HIMU-type basalts but the Sr-isotopic values are slightly higher (~0.70355) than these. The Pb-isotopes and trace element patterns are comparable to EM1-type ocean island basalts (OIB) which could suggest that the Río Colorado mantle source is a mixture of FOZO and EM1 material. Even though the trace element patterns are very similar to some Somuncura basalts (another Patagonian hotspot [1, 2]), the Somuncura EM1 end-member is dissimilar in Pb-isotopic space [2]. The presence of recycled crust in the mantle source is supported by the indication that some of the Río Colorado and Payún Matrú basalts are pyroxenite melts as judged by their low Ca, Sc, Mn and MgO and high FeO_T, Ni and SiO_2 compared to peridotite melts.

The high $^{143}Nd/^{144}Nd$ Nevado and retroarc samples have similar εNd to Río Colorado samples but higher εHf and possibly trend towards South Atlantic N-MORB compositions. Furthermore, the major element composition of these lavas is akin to peridotite melts. This suggests that there are two asthenospheric mantle sources beneath the Payenia province: a South Atlantic normal upper mantle and an OIB-type mantle which dominates in the Río Colorado and Payún Matrú regions. The normal upper mantle peridotite is apparently only melted when fluids are added from the subduction zone whereas the OIB mantle melts due to a higher mantle temperature or/and a lower solidus temperature of the pyroxenite components.

Melt inclusions as a source of principal geochemical information

ALEXANDER V. SOBOLEV[1,2,3]

[1] University J. Fourier, ISTerre, Grenoble, France. alexander.sobolev@ujf-grenoble.fr
[2] Max Planck Institute for Chemistry, Mainz, Germany.
[3] Vernadsky Institute of Geochemistry, RAS, Moscow, Russia.

Recent papers [1-5] on the in-situ radiogenic isotope composition of melt inclusions report controversial conclusions on the scale and origin of isotope heterogeneities. In this paper I will review these results focusing mostly on the question: whether melt inclusions can provide the new geochemical information on the origin, composition and scale of mantle heterogeneity?

The study of some 140 olivine hosted melt inclusions from a single lava of Mauna Loa volcano (Hawaii) reveals incredible Sr isotope source heterogeneity: at least 87Sr/86Sr=0.7027-0.7074 (Fig 1) [5]. Based on the 2-sigma criterion we found that 21% of inclusions fall out of the isotopic range of Mauna Loa lavas and 8% fall out of the isotopic range of all Hawaiian Lavas (Fig 1). Most compositionally distinct melts were trapped in high Mg olivine (Fo>86). We show that melt fractions with different compositions were mixed up during olivine crystallization producing typical Mauna Loa lavas. This result indicates unprecedented Sr isotope anomaly in Hawaiian mantle source caused by entrainment of Phanerozoic oceanic crust altered by seawater [5]. It also shows that bulk rocks could easily mask original source heterogeneity, which can be often deciphered ONLY by melt inclusions study.

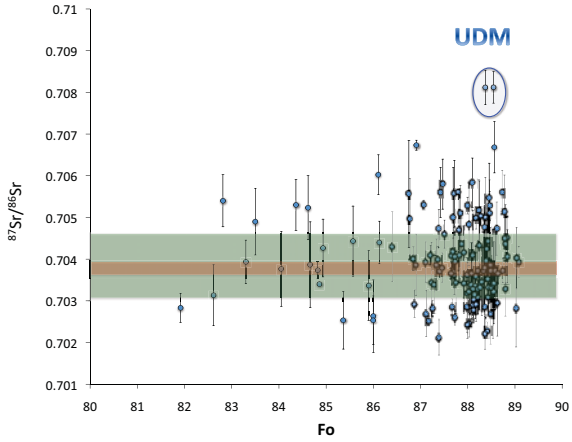

Figure 1: Isotope compositions of melt inclusions in olivine phenocrysts from a single lava sample of Mauna Loa volcano, Hawaii versus composition of host olivine [5]. Narrow (brown) and wider (green) fields manifest composition of all Mauna Loa lavas and all Hawaiian lavas respectively. Error bars: one standard error. Outlined are ultra-depleted melt inclusions (UDM).

The way to destroy thick cratonic lithosphere

STEPHAN V. SOBOLEV [1]* AND ALEXANDER V. SOBOLEV[2,3]

[1]GFZ, Geodynamic Modelling, Potsdam, Germany, stephan@gfz-potsdam.de (* presenting author)
[2]University J. Fourier, ISTerre, Grenoble, France, alexander.sobolev@ugf-grenoble.fr
[3] Vernadsky Inst. of Geochemistry, RAS, Moscow, Russia

Thick and chemically distinct cratonic lithosphere is known to be tectonically stable. However there are natural examples when large areas of such lithosphere are flooded by huge volumes of basalts comprising Large Igneous Provinces (LIPs). The examples of LIPs that were at least partially extruded at Archean or Proterozoic lithosphere since 250 Ma are numerous, i.e. Siberian Traps, Central Atlantic Province, Karoo, Parana, North-Atlantic Province etc. The outstanding example of the older (2 Ga) LIP is Bushveld Complex located at Archean craton. Thinning of lithosphere is required by any model of origin of such LIPs because only when the source ascends to shallow level can normal mantle peridotite produce a large amount of melt.

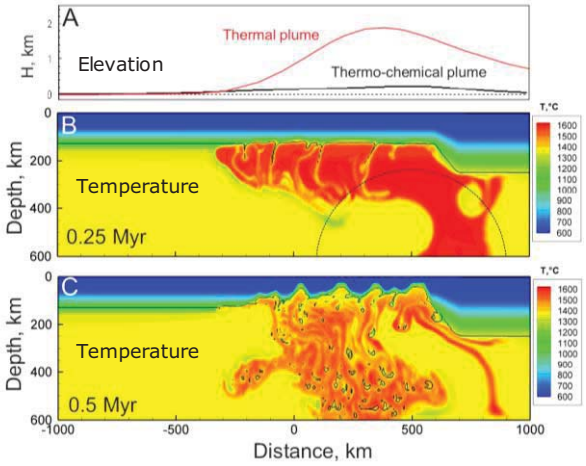

Figure 1: Model of rapid destruction of thick cratonic lithosphere by thermochemical plume without pre-magmatic surface uplift [1].

Recently, a numeric model of LIPs formation focused at Siberian LIP [1] explained rapid destruction of the cratonic lithosphere by the thermo-chemical mantle plume having potential temperature of 1600°C and containing large amount (15 Wt%) of recycled oceanic crust. The huge amount of melt generated from this plume intruded into the lithosphere and caused its delamination/foundering in less than 1 mln years (Figure 1).

In this study we explore limitations of this process. We demonstrate that realistic mantle plume with potential temperature up to 1650 °C, carrying as much recycled oceanic crust as it can remaining positively buoyant in the mantle, can significantly damage lithospheric root up to 200km thick.

The Qaidam Basin (QB)(32°-35°N/90°-100°E), located in the northern edge of the Qinghai-Tibet Plateau (China), is a high-altitude desert (aridity index ~0.04). Located at ~3000 m above sea-level, the basin features numerous dissicated evaporative lakes. Fig. 1 displays a partially eroded anticlinal structure (Xiao Liangshan (XL)) within the remains of a former lake in the Da Langtan (DL) playa region of the QB. The evaporation of the lake occurred in parallel with the rise of the anticline, thus producing the spectacular sequence of light and dark-toned rings shown in Fig. 1. This sequence depicts the multiple stages in the evolution of the lake. In-situ IR reflectance spectra were recorded along a traverse across XL, and samples were collected for subsequent laboratory analysis using Vis-NIR reflectance spectroscopy, Raman spectroscopy, and laser-induced breakdown spectroscopy (LIBS). XL was also imaged by Hyperion onboard NASA's EO-1 satellite to extract spectral endmembers from the scene and generate a mineral facies classification map. The surface mineralogy includes carbonates, gypsum, halides, hydrated Mg- and Na-sulfates, and chlorites. This mineral sequence resembles that observed at various locations on Mars, particularly at Gale crater. We have built a lake evaporation model that constrains the physico-chemistry of the DL lake's water (T, pH ...), and can help understand the occurrence of water-related mineral deposits and elucidate the geochemistry of putative former aqueous systems on Mars that resemble those we are investigating at Da Langtan.

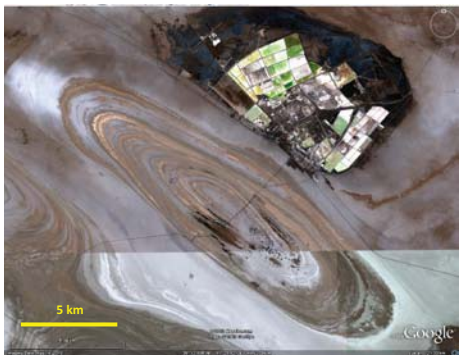

Figure 1: Xiao Liangshan image. Note the ring structure of the deposits across the anticline. Older deposits are on top.

Soil water vapor isotopes as a tool for understanding ecohydrological processes

K. SODERBERG*[1], S. P. GOOD[1], L. WANG[2], AND K. K. CAYLOR[1]

[1]Department of Civil and Environmental Engineering, Princeton University, Princeton, NJ, USA, soderbrg@princeton.edu (* presenting author)

[2]School of Civil and Environmental Engineering, University of New South Wales, Australia

Abstract

Soil evaporation can represent a significant loss of moisture from an ecosystem. As part of our research into evapotranspiration (ET) dynamics [1], we utilize continuous (1 Hz) measurements of water vapor isotopes to help partition ET into transpiration (T) from plants and evaporation (E) from the soil. This type of measurement is made possible through the recent development of portable, laser-based water vapor isotope analyzers. Defining the necessary isotopic endmembers is relatively straightforward in the case of δ_T using a chamber attached to leaves [2]. The δ_E isotopic signal is more difficult to characterize given that it involves both equilibrium and kinetic isotope fractionation. The liquid soil water isotope composition that gives rise to the δ_E signal can also be very heterogeneous in time and space. We have utilized both a modified Craig-Gordon (CG) modelling approach [3,4] as well as *in situ* measurement of soil water vapor isotopic composition. The CG model was designed to describe the evolution of isotopic composition during evaporation from open water, but is commonly applied to soil evaporation. We propose that soil water potential be used to adjust the normalized humidity parameter in this model, just as the activity of water is used to model evaporating brines. We present results from field measurements at our eddy covariance flux tower in central Kenya, as well as some laboratory data. The effect of this modification is variable, but appears to become significant with soil water potentials drier than around -10 MPa. The *in situ* measurements indicate that even shallow (5-10 cm) soil water vapor appears to be in isotopic equilibrium with adjacent liquid soil water. However, we are currently looking into the effects that soil matric forces can have on equilibrium isotope fractionation factors.

Stoichiometry of dissolved bioactive trace metals in the Indian Ocean

HUONG THI DIEU VU[1] AND YOSHIKI SOHRIN[2]*

[1]Institute for Chemical Research, Kyoto University, Uji, Japan, huong@inter3.kuicr.kyoto-u.ac.jp

[2] Institute for Chemical Research, Kyoto University, Uji, Japan, sohrin@scl.kyoto-u.ac.jp (* presenting author)

Introduction

GEOTRACES JAPAN has conducted a section study in the Indian Ocean during the KH-09-5 cruise of R/V Hakuho Maru from November 2009 to January 2010 (Fig. 1). Here we report the results on dissolved bioacitive trace metals (Al, Mn, Fe, Co, Ni, Cu, Zn, Cd and Pb) in seawater. This is the first simultaneous distribution of the nine metals in the Indian Ocean.

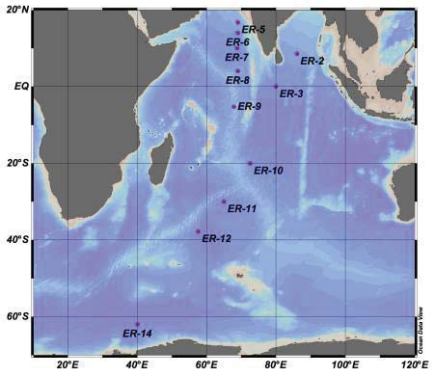

Figure 1: Sampling locations in the Indian Ocean

Methods

Seawater samples were collected using clean technique in accordance with the GEOTRACES protocol. The bioactive trace metals were preconcentrated by solid extraction using the NOBIAS CHELATE-PA1chelating resin [1] and determined by HR-ICP-MS.

Results and Conclusion

The dissolved bioactive trace metals are divided into 3 groups: (1) scavenged-type for Al, Mn, Co and Pb, (2) nutrient-type for Ni, Cu, Zn and Cd, and (3) recycled and scavenged-type for Fe. The atmospheric dust deposition and horizontal advection cause elevated concentrations of DAl, DMn, DCo, DCu and DPb in the upper water column in the Arabian Sea and the Bay of Bengal. Manganese reduction and iron reduction occur in the Oxygen Minimum Zone resulting the increase of DMn, DCo and DFe. Mid-depth enrichment of DMn and DFe above the Central Indian Ridge is influenced by hydrothermal plumes. The distribution of DNi, DCu, DZn and DCd is controlled by the biogeochemical cycle. Although DFe does not show a linear correlation with macronutrients and nutrient-type DMs, iron will be a co-limiting factor for phytoplankton production in most of the study area. The stoichiometry of DMs is generally comparable between deep waters in the northern Indian Ocean and the North Pacific Ocean, suggesting consistence of the mechanism controlling the behaviors of DMs between the Indian and Pacific Oceans.

Iberian paleogeography traced by U-Pb zircon ages of Ediacaran-Cambrian rocks

RITA SOLÁ[1*], FRANCISCO PEREIRA[2, 5], MARTIM CHICHORRO[3], LUÍS LOPES[2], AXEL GERDES[4] AND J.BRANDÃO SILVA[5]

[1] Laboratório Nacional de Energia e Geologia and Centro de Geociências, Portugal, rita.sola@lneg.pt (* presenting author)
[2] Dep. de Geociências, Universidade de Évora, Portugal
[3] Dep. de Ciências da Terra, Universidade Nova de Lisboa, Portugal

[5] Instituto Dom Luiz, Universidade de Lisboa, Portugal

The stratigraphic sequence of the Estremoz Anticline in the Ossa-Morena Zone (SW Iberia) includes: 1) an Neoproterozoic basement in the core - Série Negra Succession with greywackes, pelites and black cherts - unconformably overlain by 2) a lower Cambrian Dolomitic Formation, with arkosic sandstones and dolomitic limestones followed by 3) a Volcanic-Sedimentary Complex (VSC) with rhyolites and basalts interbedded with pelites and marbles.

The age of the VSC of the Estremoz Anticline has been a matter of debate, either due to the scarcity of fossils or to the complexity of the regional Variscan deformation. It was firstly attributed to the lower Cambrian, latter reported to the Ordovician or even to the Silurian [1]. Recently, a new interpretation attributed an upper Silurian to Devonian age to the VSC based on a lithological correlation with fossiliferous detritic carbonate rocks that outcrop in the vicinity of the Estremoz Anticline [2].

In this study we present new U-Pb ages of zircons from the Estremoz Anticline stratigraphic sequence.

The spectra of detrital zircon ages of the Ediacaran greywackes (Série Negra Succession) and lower Cambrian arkosic sandstones (Dolomitic Formation) indicates a predominance of Neoproterozoic ages (69-86%) and few Paleoproterozoic (10-16%) and Archean (2-12%) ages. The spectra of Proterozoic detrital zircon ages (with a typical gap in Mesoproterozoic ages) are similar to other peri-Gondwana correlatives with West African Craton provenance [3]. The source area is characterized by an important population of zircon ages in the range c. 850-545Ma. These Cryogenian and Ediacaran ages correspond to zircon crystallization events related to North Gondwana assembly during Pan-African/Cadomian orogenic processes.

The metarhyolites that are interbedded in the marbles of the VSC yielded a magmatic zircon crystallization age of 499.4 ± 3.3 Ma (MSWD=1.16; n=15/16; upper Cambrian). The result obtained indicates that carbonate production was episodic and occurred during lower and upper Cambrian in SW Iberia, related to North-Gondwana break-up. This new evidence should be taken into account in the reshaping of paleogeographic reconstruction models that have erroneously insisted on placing Iberia at southerly cold water higher latitudes (>60ºS) during the Furongian [4].

The importance of a conceptual framework for interpreting tracer data

D. K. SOLOMON[1*], S. D. SMITH[1], B. J. STOLP[1], A. MASSOUDIEH[2]

[1]University of Utah, SLC, USA, kip.solomon@utah.edu (* presenting author)
[2]The Catholic University of America, Washington D.C., USA

Introduction

The interpretation of tracer data are highly dependent on the conceptual framework of the system being investigated. We describe several of our field and laboratory investigations in which the time scale of the tracer was poorly matched to the equilibration time of the system being invesitaged. Numerical modeling has been used to evaluate the extent to which a suite of tracer data can be used to uniquely characterize groundwater flow systems.

Results and Conclusions

A stream tracer test was performed by injecting NaBr for a period of about three times the the in-stream transit time, but steady was still not obtained due to long hyporheic flow paths. This led to estimates of groundwater discharge into the stream that were inflated by a factor of five. A combination of groundwater age data and major ion chemistry in both the stream and groundwater were required to develop a conceptual model that is more consistent with the injected tracer data.

At a geologic time scale we have evaluated the equilibration of helium in pore fluids with quartz grains in an attempt to use the helium content of quartz as a proxy for pore fluids [1]. While pore fluid and quartz helium values agree to within an order of magnitude, we have found differences that are best explained by transients in the groundwater flow systems that are less than the quartz equilibration time (0.01 to 2 MA). A realization of the non-steady effects resulted by applying multiple methods, each with their own time scale.

We have employed multiple tracers/techniques in an attempt to help define the conceptual framework of systems including the residence time distributions with some limited success; however, the introduction of transients as additional unknowns severly complicates obtaining a unique model from even a large suite of tracer data. Such complexities are likely to require large amounts of distributed data within a system, as well as tracer data at discharge points, to even narrow the possible range of conceptual models.

Investigations of Fe(II) sorption onto montmorillonite. A wet chemistry and XAS study

D. SOLTERMANN[1*], M. MARQUES FERNANDES[1], R. DÄHN[1], B. BAEYENS[1], AND M.H. BRADBURY[1]

[1]Laboratory for Waste Management, Paul Scherrer Institut, Villigen PSI, Switzerland, (*daniela.soltermann@psi.ch)

For some important radionuclides (RN) redox processes in high-level waste repositories play an important role in their retention. Virtually all deep underground repository concepts contain large amounts of iron, and reducing conditions will prevail in the long-term. The presence of high ferrous iron (Fe(II)) concentrations in the interstitial porewaters in the near- and far-fields could have a significant influence on the sorption behaviour of certain RNs through sorption competition effects. The best suited approach to investigate the sorption of Fe(II) on clay minerals and the influence of high aqueous Fe(II) concentrations on the RN retention is a multi-disciplinary one, consisting of macroscopic sorption experiments and advanced microscopic techniques, such as X-ray absorption spectroscopy (XAS).

Fe(II) sorption isotherms were measured on native iron containing montmorillonites (SWy with 3.4 wt.% structural Fe and STx with 0.7 wt.% Fe [1]), on a partially reduced SWy (structural Fe(III) reduced by sodium dithionite [2]) and on a synthetic iron-free montmorillonite (IFM) at pH 6.2 in 0.1 M $NaClO_4$ under anoxic conditions (O_2 < 0.1 ppm). The iron sorption on a reduced SWy and on IFM is significantly lower than that measured on native SWy and STx montmorillonites and agrees well with a calculated Fe(II) isotherm using the 2 Site Protolysis Non Electrostatic Surface Complexation and Cation Exchange (2SPNE SC/CE) sorption model [3]. The high sorption values on native iron bearing montmorillonites suggest that the sorbed Fe(II) is oxidised at the clay mineral surface to Fe(III).

XAS was employed to determine the oxidation state and the local structural environment of Fe sorbed on IFM. The results indicate that iron is predominantly present as Fe(II). Furthermore, the XAS analysis showed that Fe(II) is forming inner-sphere complexes at the IFM surface.

These findings support the hypothesis that oxidation of sorbed ferrous iron on the clay mineral surface might occur through an electron transfer to the structural ferric iron. The results of this study will help to better understand the role of Fe(II) in retention processes in radioactive waste repositories and contribute to an improved molecular interpretation of the Fe(II)-clay interaction at the solid-liquid interface under anoxic conditions.

Identification of Cu-Mo anomalous zones using the Thermo Scientific Niton portable XRF analyzer in the Eaglehead Cu-Mo porphyry deposit, British Columbia, Canada

ALIREZA SOMARIN[1*], AND DAVID CLIFFORD[1]

[1]Thermo Fisher Scientific, Billerica, MA 01824
alireza.somarin@thermofisher.com (* presenting author)

Introduction

The Eaglehead Cu-Mo deposit is a classic porphyry style mineralization hosted by a granite-granodiorite intrusion and felsic volcanic wall rocks in northern British Columbia, Canada. The mineralization varies from disseminated to sporadic veins and veinlets of quartz±chalcopyrite±bornite±molybdenite. To identify Cu-Mo anomalous zones and compare assay data from the Thermo Scientific Niton portable XRF analyzer with the lab data, three sets of analyses were carried out on samples from drill hole DDH-106. These assays include direct shot on the core with the analyzer, and analyses of powder samples obtained from portable mill and grinder.

Results and Conclusion

The comparative studies show that Cu correlation (R^2) increases from 0.81 in direct shot assays to 0.84 and 0.86 in powder samples from mill and grinder, respectively (Table 1). Mo correlation increases from 0.87 in direct shot analyses to 0.95 in samples obtained by grinder. Zn correlation also increases by using powder samples from mill and grinder.

Thermo Scientific Niton XRF Analyzer Method	Lab (ICP-MS)		
	Cu	Mo	Zn
Direct Shot	0.81	0.87	0.66
Grinder	0.86	0.95	0.82
Mill	0.84	NA*	0.88
* Mill material contains Mo.			

Table 1: Correlation (R^2) between Thermo Scientific Niton XRF analyzer and lab assays.

In addition, depth-metal diagrams (Figure 1) show that Cu and Mo anomalous zones can be identified by using the Thermo Scientific Niton analyzer in the field.

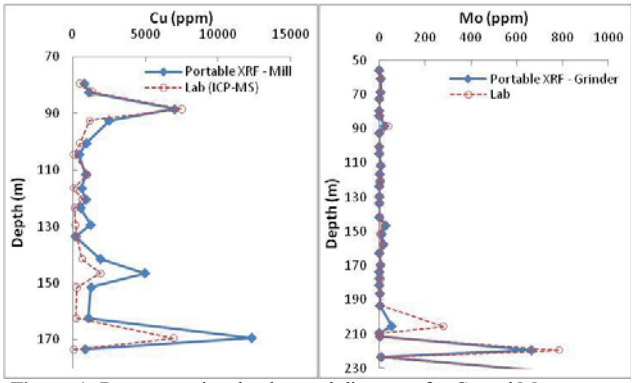

Figure 1: Representtaive depth-metal diagrams for Cu and Mo.

Characterization of re-suspended ash from the Eyjafjallajökull

FRANK SOMMER[1*], VOLKER DIETZE[2], BERNARD GROBÉTY[3], AND RETO GIERÉ[1]

[1] Universität Freiburg, Geowissenschaften, 79104 Freiburg, Germany (FrankSommer@t-online.de) (* presenting author)
[2] Deutscher Wetterdienst, Research Centre Human Biometeorology, Air Quality Department, 79104 Freiburg, Germany
[3] Université de Fribourg, Geosciences, 1700 Fribourg, Switzerland

The 2010 eruption of the Eyjafjalla volcano had a great impact on international air traffic as well as on the local population and illustrated the potential risks of active volcanism. The explosive reaction between magma and glacier ice produced an ash plume of up to 20 km in height in the atmosphere. The present study is focussed on re-suspended ash in ambient air samples collected near the volcano and aims to develop automated analysis techniques for airborne particles in volcanic environments.

Ambient air samples of airborne re-suspended ash were collected in winter 2010/11 with a passive sampler (Sigma-2, Deutscher Wetterdienst), positioned 12 km south of the eruption zone. In a first step, approximately 200 particles were characterized individually using an optical microscope under transmitted, polarized and cross-polarized light and an electron microprobe with BSE and EDX analysis. Subsequently, the light optical images from the same sample were processed with an automated image analysis program, which allowed for classification of the individual particles as glass, mineral, composite or agglutinated particles. Chemical compositions of individual particles were determined from EDX spectra. To gain a statistically relevant dataset for the sample and to maximize the efficiency of the analytic work, a larger area of the same sample, including the area studied manually, was examined using automatic single-particle SEM analysis (EDAX Genesis program), which resulted in characterisation of approximately 1600 particles. The results of both methods were compared against each other to evaluate the advantages and disadvantages of the different approaches and to advance this combined analytical approach. Additionally, one sample of re-suspended ash was examined using X-ray diffraction supplemented by Rietveld-refinement to determine its mineral content.

The examined particles range from 2.5-80 µm in size (equivalent diameters), and their size distribution is typical of ambient aerosol, particles, i.e., decreasing number of particles with increasing diameter. Only ~10% (surface area) of the particles consist of glassy material, i.e. most particles are crystalline. With a surface-area fraction of 63%, feldspar is the predominant mineral (plagioclase 43%, K-feldspar 20%), followed by pyroxene (18%), and quartz (12%). Minor quantities (≤1%) of olivine, ilmenite and titanite are found as well. The sample is also contaminated with salt of oceanic and/or volcanic origin. These results are consistent with the data obtained from the Rietveld-refinement.

Our study shows that a combination of automated and manual analysis is required to obtain best results. Only an automated method allows for examination of a large number of particles, but the manual control is necessary to collect more detailed information about the composition and the crystallinity of the individual particles.

Geochemical evaluation of the karstified Bangestan reservoirs in the Dezful Embayment, SW Iran

HOSSEIN RAHIMPOUR-BONAB[1], AMIN NAVIDTALAB[1], HAMZEH MEHRABI[1], ROSHANAK SONEI[1,2*]

[1]Department of Geology, College of Science, University of Tehran, Iran rahimpor@khayam.ut.ac.ir
[2]Department of Earth Sciences, University of Ottawa, Canada rsone092@uottawa.ca (* presenting author)

Geochemical composition of carbonate sediments are in equilibrium with the contemporaneous sea-water composition in absence of considerable biotic fractionation. However, in carbonate sediments, diagenetic imprints may have considerable effects on primary sediments textures, mineralogy, reservoir quality and finally geochemical characters. Depending on some factors including primary (depositional) sediments characteristics, governing climate and diagenetic history, geochemical composition of carbonates has been altered by post-depositional overprints. Stable isotopes and trace elements analyses can be used as a good tool to measure the extent of these alterations[1,2]. Coupled imprints of tropical climate and recurring emersions had considerable effects on Middle-Upper Cretaceous carbonate reservoirs of the SW Iran (Dezful Embayment) and Middle East region[3]. Petrographic studies (from core to thin section scales) and geochemical analyses (stable isotopes and trace elements) were carried out on 478 samples from five giant and supergiant oilfields in these embayment to reveal the main diagenetic alterations of these karstified carbonate sequences (Fig. 1). Variations in $\delta^{18}O$ and $\delta^{13}C$ compositions and trace elements (Mn, Fe and Sr) concentrations are useful diagenetic indicators that resulted in classification of studied intervals into four diagenetic classes according to their meteoric diagenetic features, intensities and developments.

Silicate polymerization on crystalline and amorphous TiO_2: an ATR-IR and synchrotron XPS investigation

YANTAO SONG[1*], PETER JAMES SWEDLUND[1], JAMES METSON[1], GEOFFREY I.N. WATERHOUSE[1] AND BRUCE COWIE[2]

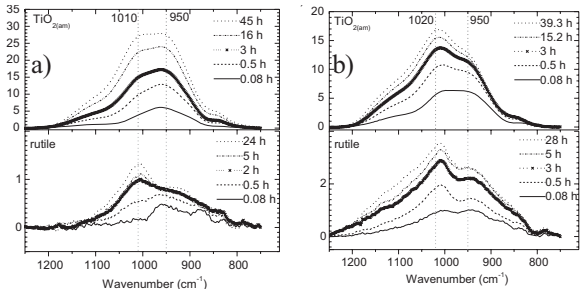
[1]School of Chemical Sciences, the University of Auckland, y.song@auckland.ac.nz (* presenting author)
[2]Australian Synchrotron, SoftXRay@synchrotron.org.au

Introduction

The presence of silicate at metal oxide-aqueous interfaces influences many oxide properties. Understanding the chemistry of silicate at these interfaces is important to describe the geochemistry of these metal oxides and elements associated with the oxides [1-2]. This work compares silicate sorption and polymerization on the disordered surface of an amorphous TiO_2 ($TiO_{2(am)}$) with silicate chemistry on the well defined faces of rutile TiO_2. The work used *in situ* attenuated total reflectance-infrared spectroscopy (ATR-IR) and *ex situ* synchrotron based X-ray photoelectron spectroscopy (XPS).

Results and Conclusion

The ATR-IR results show that a monomeric silicate species with a Si-O stretching mode at ≈ 950 cm^{-1} formed on all TiO_2 surfaces at low surface coverage. Linear oligomeric silicates with a Si-O IR adsorbance at ≈ 1020 cm^{-1} form when the surface coverage reaches a threshold value (Figure 1). The process of silicate oligomerization was favoured on the crystalline rutile surface compared to the amorphous TiO_2. This agrees with the XPS results and the proposed model of heterogeneous silicate polymerization which would be favoured by the arrangement of TiO_2 octahedra on the rutile (110) face (Figure 2).



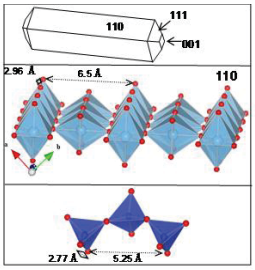


Figure 1 (above): ATR-IR spectra of H_4SiO_4 adsorbed on the surface of $TiO_{2(am)}$ and rutile at pH 9 and 0.1 M NaCl measured over time. Final concentrations of H_4SiO_4 are (a) 0.2 mM and (b) 1.5 mM.

Figure 2 (left): Rutile morphology and enclosing faces. Bottom panel shows a section of ferrosilite, a linear silicate.

Cr(VI) Reduction and Isotopic Fractionation In Bacteria: Cytoplasmic/Extracellular Reduction Rate and Diffusion Controls

ERIC SONNENTHAL[1*], JOHN N. CHRISTENSEN[1], AND RUYANG HAN[1]

[1]Earth Sciences Division, Lawrence Berkeley National Lab, Berkeley, CA, USA, elsonnenthal@lbl.gov (* presenting author)

Reduction of Cr(VI) to Cr(III) by bacteria is well documented and leads to significant Cr isotopic fractionation ($^{53}Cr/^{52}Cr$), with experimental values in abiotic systems of ~3.4‰[1] to 5‰[2], and theoretical equilibrium values of 6-7‰[3]. Biologically-mediated Cr isotopic fractionation of ~4.2‰[4] has been attributed to kinetic fractionation, with possible controls by metabolic pathways, transport, or reduction sites. In lactate-amended cell suspension experiments with *Pseudomonas stutzeri* strain RCH2, Cr isotopic fractionation was less under denitrifying vs. aerobic conditions[5], and attributed to Cr(VI) transport limitation. In this work, a reactive-transport model was developed to evaluate effects of cytoplasmic/extracellular reduction rates and transport in bacteria on Cr isotopic fractionation with comparison to experimental data.

The multicontinuum reactive-transport model is based on a simplified structure of bacterium *Pseudomonas stutzeri*, of average dimension of 2 x 0.5μm, a cell membrane thickness of 15nm, and an average bacterium spacing derived from the suspension cell density. Cr reduction in the cytoplasm is dependent on chromate diffusive transport through the outer membrane (via sulfate channels), the periplasmic space, and to reduction sites. Cell wall diffusivities were estimated from published cell wall permeabilities. Cr reduction was assumed to be thermodynamically and kinetically-controlled by $Cr(OH)_3$ precipitation using a solid solution model of $^{53}Cr(OH)_3$ and $^{52}Cr(OH)_3$. Simulations considered an aerobic case with lactate oxidation to pyruvate, and a denitrifying case forming pyruvate, as well as conditions of the experiments described in [4].

Simulations with differing cell densities using Toughreact [7] showed that it is necessary to limit diffusive transport through the cell wall by ~4 orders of magnitude to match the change in Cr isotopic fractionation from ~2‰ (aerobic) to ~0.4‰ (denitrifying). By severely limiting diffusive transport, Cr reduction rates decrease significantly, inconsistent with experimental data. In contrast, by increasing the Cr reduction rate in the cytoplasm, a large decrease in the fractionation factor is observed, without inhibiting the Cr reduction rate, capturing the observed $^{53}Cr/^{52}Cr$ and Cr reduction rates over a range of cell densities. Although it is not known where Cr reduction was localized in the cell suspension experiments[5], simulations show that Cr reduction in the extracellular medium also leads to higher Cr reduction rates and Cr isotopic ratios close to the maximum value for the reduction reaction.

[5]Dept of Geology, University of Toronto, Toronto, Canada

Summary:

The behaviour of soda aluminosilicate glasses and melts under pressure and temperature is of interest in both the materials and Earth Sciences, especially for understanding magmatic processes. Although these systems have been well studied at room pressure by several workers, their structural modifications at high pressure (HP) are less well known. Several studies have been carried out on glasses quenched from HP using both NMR and XANES. The latter have also been performed on glasses and melts at HP. All these studies revealed structural changes occurring in the glasses and/or melts with increasing pressure.

We synthesized glasses along the NS3/Albite glass join extended into the peralumimous domain. The glasses were permanently densified in a Belt press at the Lyon Plateform of High Pressure Experimentation (PLECE) (5GPa, 600°C) and in a Multi Anvil press at the University of Toronto (7GPa, 600°C). The densified samples were studied with various methods in order to follow the pressure induced structural modifications. Short range order (SRO) was investigated using ^{23}Na, ^{27}Al NMR and Si L-edge XANES. The intermediate range order (IRO) was studied by Raman spectroscopy and long range order (LRO) with Brillouin spectroscopy.

^{27}Al NMR spectra show, with increasing pressure, an increase in the Al coordination, with large amounts of ^{V}Al and ^{VI}Al appearing in glasses with low Al_2O_3 contents. Contrary to this, ^{V}Al and ^{VI}Al increase more slowly for albite and peraluminous glasses. ^{23}Na NMR spectra exhibit a decrease in the Na-O bond length with pressure.

For glasses between NS3 and albite composition, Raman experiments show an increase in Q^2 and Q^4 species with pressure and a symmetrical decrease of the Q^3 species. A strong shift of the vibrational band around 500 cm^{-1} toward higher wavenumbers is observed for albite and peraluminus glass.

The pressure induced structural modifications noted in these glasses are dependent upon composition. For compositions characteristic of depolymerized glasses Al coordination increases and further depolymerization are primarily responsible of the densification process. For compositions indicative of fully polymerized glasses densification mainly occurs as a decrease in the intertetrahedral angle T-O-T. Al *L*- edge XANES and O, Na, Al, and Si *K*-edge XANES along with *in situ* (DAC) experiments will be performed soon to complete this preliminary study.

Heterogeneous hydrous mantle in arc settings: Constraints on the genesis of silica-undersaturated arc magmas

F. SORBADERE[1,2*], E. MEDARD[1,2], D. LAPORTE[1,2], P. SCHIANO[1,2]

(*F.Sorbadere@opgc.univ-bpclermont.fr)

Partial melting of a hydrous lherzolite mixed with variable amounts of amphibole-bearing clinopyroxenite (OCA2) [1] has been experimentally investigated at 1 GPa between 1150 and 1300°C (piston-cylinder, $Au_{80}Pd_{20}$ capsules) under oxidized condition (FMQ+2). Our new capsule configuration [2] allows efficient melt extraction, with melt layers more than 50 µm wide in the capsule traps.

Peridotite derived melts are hypersthene-normative while amphibole-clinopyroxenite melts are strongly Si-undersaturated (~7 % normative nepheline). Melts derived from lherzolite-clinopyroxenite mixtures containing less than 50% clinopyroxenite have identical major element compositions than melts derived from pure peridotite. Above 50% pyroxenite, the CaO content in melt increases and the SiO_2 content decreases with increasing fraction of pyroxenite in the starting mixture. The transition between Hy-normative and Ne-normative melts occurs for mixtures containing between 50 and 75 % clinopyroxenite, when orthopyroxene disappears from the residue. In contrast, minor elements (K_2O, Na_2O, TiO_2 and H_2O) show a more linear behaviour with continuous mixing trends between the two lithologies, thus highlighting the source heterogeneity. Thus the signature of mantle heterogeneities is preserved in the minor/trace elements composition of the magmas, whereas the major elements are buffered by the dominant peridotitic lithology. Forsterite content of olivines in equilibrium with the melts reaches 91.3 for peridotite and 91.8 for clinopyroxenite and/or mixed lithologies at 1300°C. High-Mg olivines can thus crystallize from non-peridotitic magmas under relatively oxidized conditions at high temperatures.

Most primitive magmas found in arc environments and preserved as melt inclusions in high-Mg olivine (Fo ≥ 88) show Si-undersaturated compositions. The involvement of a heterogeneous source containing amphibole-bearing clinopyroxenites in addition to peridotites is often mentioned to account for the Si-undersaturated character of these melt inclusions [1; 3-5]. Our experiments give further support for this hypothesis, but indicate that either the source is almost exclusively made of amphibole-bearing clinopyroxenites, or the Si-undersaturated melts issued from the clinopyroxenites do not reequilibrate with the peridotites.

Transition metal stable isotopes in komatiites

PAOLO A. SOSSI[1], OLIVER NEBEL[1], HUGH ST. C. O'NEILL[1], STEPHEN M. EGGINS[1], MARTIN VAN KRANENDONK[2]

[1] Research School of Earth Sciences, Australian National University, Canberra, 0200, Australia
[2] Geological Survey of Western Australia, 100 Plain St, East Perth, WA 6004, Australia

Komatiites represent large degree partial melts of the mantle (30-50%), which segregated from their sources at high temperatures (>1500°C) and pressures (>5GPa), and are thus largely restricted to the Archaean. As the magnitude of stable isotope fractionation decays according to $1/T^2$, the difference in the stable isotope composition between komatiites and their mantle source is negligible (Dauphas et al., 2009). This permits the characterisation of the stable isotopic composition of the mantle source, provided the effects of alteration and fractional crystallisation can be accounted for.

We present high precision Cu, Zn and Fe isotope analyses for a suite of Early Archaean komatiites (3.5-3.2Ga) from the Pilbara craton, separated from a single dissolution. Fe isotopes bracket a range of compositions from δ^{57}Fe (vs. IRMM-014) of -0.17‰ to +0.17‰. Zn isotopes show a more restricted range of compositions, with δ^{66}Zn varying from -0.1‰ to -0.16‰ (vs. IRMM-3702), consistent with the smaller range hitherto observed in igneous rocks (Albarède, 2004). A well defined increase in both δ^{57}Fe and δ^{66}Zn with decreasing Cr and MgO is attributed to a strong olivine control on their stable isotope composition. Cu isotopes scatter around 0‰ (vs. SRM-976), lacking any systematic trend with indices of differentiation. Nevertheless, confirmation of δ^{65}Cu values near 0‰ in other igneous rocks (Li et al., 2009) indicates no discernible change in the Cu isotope composition of the Earth over time.

While δ^{66}Zn and δ^{65}Cu values are representative of current-day mantle, the komatiite array has δ^{57}Fe that extends to ≈-0.15‰ lighter than the contemporary mantle value. At a given stage in their differentiation, the Pilbara komatiites are also 0.1‰ lighter than komatiites from Alexo (Dauphas et al., 2010).

Compared to carbonaceous chondrites, the Zn composition of the Earth lies at the volatile-poor end of a volatile-depletion trend, where δ^{66}Zn becomes lighter with decreasing Zn/Mg. This is the opposite trend to that expected if Zn were being lost by vaporisation.

Use of MC-ICPMS for laser ablation U/Pb geochronology of baddeleyite

SOUDERS A.K[1*] AND SYLVESTER P.J.[1]

[1]Department of Earth Sciences, Memorial University of Newfoundland, St. John's, NL, Canada (*kate.souders@mun.ca, psylvester@mun.ca)

Microbeam analyses by laser ablation inductively coupled plasma mass spectrometry (LA-ICPMS) are increasingly used for U-Pb geochronology of zircon. LA-ICPMS is a powerful method for U-Pb geochronology because grains can be dated directly in thin section, avoiding time-consuming laboratory procedures involving heavy liquid separations and ion exchange chromatography. In many silica-poor terrestrial rocks such as mafic dikes, anorthosites, gabbros and carbonatites as well as lunar rocks and Martian meteorites, baddeleyite (ZrO_2) rather than zircon is present. Unlike zircon, the baddeleyite tends to form very small elongate grains, typically no more than 30-50 μm in the longest dimension and less than 20 μm in the smallest dimension. This makes U-Pb analyses of baddeleyite by LA-ICPMS more challenging than for zircon because smaller laser spot sizes (<20 μm) and shorter ablation times (<30 sec) are required, reducing analytical precision significantly compared to zircon analyses.

High-precision thermal ionization mass spectrometry (TIMS) is commonly used for U-Pb baddeleyite geochronology of Large Igneous Provinces (LIPs), particularly where mafic magmatic events need to be determined with a precision better than 5 Ma. In cases where ages with uncertainties of approximately 20 Ma provide useful data for LIPs, however, it would be desirable however to apply LA-ICPMS to U-Pb baddeleyite geochronology.

We report a U-Pb dating method for baddeleyite by LA-multi-collector-ICPMS using a Thermo Scientific NEPTUNE MC-ICPMS. The collector array consists of six Channeltron ion counters allowing for the simultaneous collection of ^{202}Hg, ^{204}Pb, ^{206}Pb, ^{207}Pb, ^{208}Pb and ^{235}U isotopes. The use of a collector array consisting only of ion counters eliminates the need of cross-calibration between ion counters and Faraday detectors. Standard – sample – standard bracketing is employed to correct for instrumental mass bias using Forest Center baddeleyite (FC-4b; TIMS age = 1095.42 ± 0.16 Ma) as a standard. A slow line scan ablation is used where a 4μm laser beam with an energy density of 9 J/cm^2 and a repetition rate of 5 Hz scans across the sample surface at a rate of 1 μm/sec. Using the method described, after 30 sec (150 pulses) of ablation, the ^{207}Pb/^{206}Pb age determined for the ca. 2060 Ma Phalaborwa baddeleyite is 2058.9 ± 18 Ma (2σ, n = 6) with an external precision of 0.9 % (2RSD). While this result is comparable to U-Pb zircon and analyses by single-collector LA-ICPMS, the smaller volume of material consumed and the shorter ablation time required to achieve such precision during multi-collector analyses is more suitable for, typically smaller, baddeleyites. The described method can be used as a reconnaissance tool to screen baddeleyite grains prior to physical separation for further high precision TIMS analyses, in order to identify critical samples that can be used for paleocontinental reconstruction in LIPs.

AMS studies in "Foz do Douro metamorphic complex" (N Portugal): preliminary insight

MÓNICA SOUSA[1*], HELENA SANT'OVAIA[1] AND FERNANDO NORONHA[1]

[1]Porto University, DGAOT, CGUP, Porto, Portugal, monica.sousa@fc.up.pt (* presenting author) hsantov@fc.up.pt fmnoronh@fc.up.pt

Introduction

The "Foz do Douro Metamorphic Complex" (FDMC) is situated on the shoreline of Porto extending along a series of small beaches between the Douro river mouth and the "S. Francisco Xavier" Fort. The geology of this zone is marked by the presence of Porto-Tomar-Fereira do Alentjo, NNW-SSE dextral, shear zone and by magnificent outcrops of a thin band of Precambrian metamorphic rocks intruded by Variscan granites [1,2]. The metamorphic band is represented by outcrops of metasedimentary rocks, spatially associated to orthogneisses of different types and ages (606±17 to 567± 6 Ma) and amphibolites that constitute the FDMC [3]. The granites belong to a late-Variscan granite group (298±11Ma) [4].

A Anisotropy of magnetic susceptibility (AMS) study is being carried out in these several types of orthogneisses. In this work we present the first data obtained with 49 samples of leucocratic gneisses, some with garnet, and augen gneisses (Group 1) and with 15 samples of biotite-rich orthogneisses (Group 2).

Results and Discussion

Magnetic susceptibility (K) ranges between 20.0 and 72.3 x 10^{-6} SI in Group 1 orthogneisses which indicates a paramagnetic behaviour of this lithology, due to ferromagnesian minerals, such as biotite. However in Group 2 orthogneisses, K presents values > 10^{-3} SI (0.12 x 10-3 SI, in average) which enhance the presence of magnetite. These two distinct behaviours indicate two different types of Precambrian magmatism: a oxidized type (magnetite type) (Group 2) and a reduced type (Group 1).

Magnetic anisotropy, expressed by the ratio Kmax/Kmin, ranges from 1.052 to 1.144 in Group 1 orthogneiss and is higher (1.204) in the Group 2 gneisses. These values are typical of deformed rocks but the high anisotropy of the Group 2 orthogneisses also reflects the presence of magnetite. In both lithologies, magnetic fabric is characterised by subvertical magnetic lineations associated to subvertical E-W to ESE-WNW and NW-SE trending magnetic foliations, related to a shear deformation.

The association of carbon with mineral phases has been increasingly recognized as a major stabilizing mechanism for protecting organic matter against microbial degradation in soils. Iron (Fe) and manganese (Mn) oxides are of particular importance because of their abundance in soils and high reactive surface area. Both Fe and Mn are susceptible to redox variability along landscape gradients. Reductive dissolution and transformation of Fe and Mn minerals governs the amount, form and transport of sequestered C. We have investigated Fe speciation as well as the composition of organic matter and its molecular interaction with soil minerals across hillslope transects within the Christina River Basin Critical Zone Observatory (CRB-CZO) to link iron-redox coupling processes with soil C cycling. Selective chemical extractions, X-ray absorption spectroscopy (XAS), micro-XAS techniques, and Mossbauer spectroscopy were employed to characterize soil Fe speciation. Applying scanning transmission X-ray microscopy (STXM) and carbon near edge X-ray absorption fine structure (CNEXAFS) spectroscopy, we mapped the spatial distribution of carbon and carbon forms, and imaged the association of organic functional groups with specific minerals in the soils. Ferrihydrite, because of its ubiquitous occurrence in the environment and its high surface area, contributes significantly to the sorption of organic matter and protects it against microbial degradation in soils and sediments. In addition, ferrihydrite often forms in the presence of dissolved organic matter in the natural environment, which leads to coprecipitation of organic matter with ferrihydrite. However, the extent and mechanisms of organic matter adsorption to or coprecipitation with ferrihydrite, and the consequences of such reactions for the properties of sorbed versus coprecipitated organic matter remain largely unknown. In this presentation, we compare adsorption and coprecipitation with dissolved organic matter from a forest litter layer. To examine the chemical fractionation of the organic matter and the mechanisms of organo-ferrihydrite complex formation associated with these two processes CNEXAFS and Fourier transform infrared (FTIR) spectroscopic techniques were employed. To study spatial distribution, macromolecular structure, and chemical composition of sorbed and coprecipitated OM at the nanometer-scale we used STXM. Data on the role of Mn in C cycling will also be presented. Such studies will enhance our understanding of OM stabilization mechanisms on soil mineral surfaces and will provide new insights on the metal-redox coupling processes affecting carbon cycling at soil/sediment-water interfaces.

Tectonic implications of short metamorphic episodes

FRANK S. SPEAR[1]*, KYLE T. ASHLEY[2], LAURA E. WEBB[3], AND J. B. THOMAS[1]

[1]Renssaelaer Polytechnic Institute, Troy, USA, spearf@rpi.edu (*presenting author), thomaj2@rpi.edu
[2]Virginia Tech, Blacksburg, USA, ktashley@vt.edu
[3]University of Vermont, Burlington, USA, lewebb@uvm.edu

Quartz inclusions in garnet undergo exchange of Ti with the host garnet resulting in diffusion of Ti into the quartz. Modeling of this diffusion in samples from the Barrovian terrane of eastern Vermont reveals that the entire metamorphic episode (heating from 450 C to metamorphic peak and cooling back to 450 C) has occurred in less than 1 m.y. and perhaps in as little as a few hundred thousand years, depending on the presumed peak metamorphic temperature. This terrane does not contain volumetrically significant plutons, so the only possible cause must be tectonic.

Two-dimensional thermal modeling has been used to constrain the rates of thrusting required to achieve such short-lived metamorphic episodes. Rocks heat rapidly when overthrust by hot rocks and cool rapidly when they are thrust onto cooler rocks, a process that has been modeled as a simple, mid-crustal duplex structure. A typical model involves the first thrust sheet moving up a 20 degree ramp at a rate of 10 cm/year (0.1 m/year) for 0.1-0.5 m.y. then the fault stepping out (in sequence) and a second thrust sheet moving up a similar ramp for a similar time interval. The rocks of interest are those in the horse between the two thrusts which are initially loaded quickly and subsequently heated by thermal conduction from the overlying hotter rock mass. The second thrust places these hot rocks onto cooler substrate which initiates cooling of the mass but not necessarily a change in pressure. Exhumation was likely to have been rapid following the metamorphic peak, consistent with the rapid post-peak cooling history inferred from the diffusion studies. The near isothermal loading exhibited by P-T paths of rocks from eastern Vermont also supports the hypothesis of crustal loading at rates of 5-10 cm/year.

The rate of heating and cooling depends on the thermal difference between the overthrust sheet and the rocks of interest, and the proximity of the rocks to the thrust. Models with different thrust sheet dimensions reveal that it is impossible to rapidly heat and cool the same rock if the sheet is thicker than ca 5 km. This fact raises the interesting possibility that metamorphic terranes that have experienced such rapid heating and cooling are comprised of thin thrust sheets bounded by ductile shear zones stacked together in duplex-like geometries with significant internal deformation. Such geometries might be very difficult to decipher with the limited outcrop exposure in Vermont. It is also interesting to speculate that the two major “deformations” that produce the two dominant fabrics in these rocks were caused by the initial loading and subsequent ramping of the thrust sheet, respectively. Thrust ramps also produce ramp anticlines that, in ductile terranes, will have the geometries of domes as are seen in eastern Vermont.

Such rapid tectonic juxtaposition is unresolvable by current geochronologic techniques, and is only revealed through diffusion modeling of systems with diffusivities appropriate for the metamorphic conditions.

Timing and mechanism for intratest Mg/Ca variability in living planktic foraminifera

HOWARD J. SPERO[1*], STEPHEN M. EGGINS[2], ANN D. RUSSELL[1], LAEL VETTER[1], BÄRBEL HÖNISCH[3]

[1]University of California Davis, Dept. Geology, Davis CA., USA; hjspero@ucdavis.edu (* presenting author)
[2]The Australian National University, Research School of Earth Sciences, Canberra, Australia; Stephen.Eggins@anu.edu.au
[3] Columbia University, Lamont-Doherty Earth Observatory, Palisades, NY, USA, hoenisch@ldeo.columbia.edu

Problem and Results

Recent microscale data indicate that Mg/Ca in foraminifera tests is distributed heterogeneously, thereby challenging its use as a robust tool for paleotemperature reconstructions. We present Mg/Ca and Ba/Ca data collected by laser ablation (LA) ICPMS from living *Orbulina universa*, that were grown in controlled laboratory experiments. Test calcite was labeled with Ba-spiked seawater for 12h periods during either day or night calcification, to quantify the timing of intratest Mg-banding across diurnal cycles. Results demonstrate high Mg bands are precipitated during the night, whereas low Mg bands are precipitated during the day. Similarly, the amplitude of the Mg/Ca ratios in Mg-rich bands decreases in experiments with elevated pH (and $[CO_3^{2-}]$). These results suggest that symbiont photosynthesis influences but does not fully control Mg/Ca banding. We hypothesize that mitochondrial uptake of Mg^{2+} may explain Mg-depleted calcite layers. Symbiont photosynthesis and foraminifera respiration may exert a secondary influence on shell Mg/Ca via their effect on $[H^+]$ in the microenvironment around the calcifying shell. Data obtained from specimens growing at 20º and 25ºC show that intrashell Mg/Ca ratios increase with temperature in both high and low Mg bands, such that average test Mg/Ca ratios are in excellent agreement with temperature calibrations based on bulk solution ICPMS analyses.

Conclusion

Results presented here demonstrate that Mg banding is an inherent component of the biomineralization process. However, despite intratest Mg/Ca variability, the Mg/Ca paleothermometer as measured on whole tests remains a robust tool for reconstructing past ocean temperatures from the fossil foraminifera record.

Ab initio vibrational properties of silica species in aqueous fluids

G. SPIEKERMANN[1*], M. STEELE-MACINNIS[2], C. SCHMIDT[1], P. M. KOWALSKI[1] AND S. JAHN[1]

[1]GFZ German Research Centre for Geosciences, Section 3.3, Telegrafenberg, 14473 Potsdam, Germany, spiek@gfz-potsdam.de (* presenting author)

[2]Department of Geosciences, Virginia Tech, Blacksburg VA 24061, USA, mjmaci@vt.edu

The solubility of minerals in aqueous fluids is an important property to understand the chemical transport of elements. On the atomic-scale the solubility is related to the solute speciation in the fluid. Vibrational spectroscopy is especially useful for probing solute speciation in aqueous fluids because vibrational frequencies depend on molecular structure. Assignment of spectroscopic features to specific structural units can be challenging, but atomic-scale modeling may provide support [1, 2].

We investigate the vibrational properties of silica species in aqueous solution at high pressures and temperatures. The investigated species include H_4SiO_4 and $H_3SiO_4^-$ monomers, $H_6Si_2O_7$ and $H_5Si_2O_7^-$ dimers, three and fourfold silica rings and higher polymers [3]. Simulations are performed at the level of density-functional theory with the PBE exchange-correlation functional. We use periodic boundary conditions and a system of 25-27 H_2O molecules at 300 K and 1000 K, at a fluid density around 1 g/cm^3.

In our approach to analyze the vibrational properties, we exploit the two facts that (1) observed Raman frequencies are equal to the real vibrational frequencies, and (2) the spectroscopically important silica vibrations are quasi-localized normal-mode-like vibrations. The concept of mode-projected velocity autocorrelation (VACF) and its Fourier transform [4] is applied to yield normal-mode-like vibrational subspectra of the vibrational density of states, e.g. from tetrahedral subunits (T_d), Si-O-Si units of bridging oxygens (C_{2v}), the dimer (C_{3d}/C_{3h}), the SiOH bending, and "breathing" of silica rings.

Our results give a comprehensive picture of the vibrational behaviour of small silica species such as monomers and dimers. New insight is given into the polymerization-driven frequency shift. Our studies help to clarify vibrational contributions of Q^1 tetrahedra, the silica dimer, Q^2 tetrahedra, and the SiOH bending motions. We demonstrate that the mode-projection technique is a powerful tool for investigation of vibrational properties of isolated and network-forming species in their environment at elevated temperatures and pressures.

Lunar Lu-Hf and Sm-Nd systematics – effects of neutron capture reactions

P. SPRUNG[1*], T. KLEINE[2], AND E.E. SCHERER[3]

[1]Institute for Geochemistry and Petrology, ETH Zürich, Switzerland, sprung@erdw.ethz.ch (* presenting author)

[2]Institut für Planetologie, Westfälische Wilhelms-Universität Münster, Germany, thorsten.kleine@uni-muenster.de

[3]Institut für Mineralogie, Westfälische Wilhelms-Universität Münster, Germany, escherer@uni-muenster.de

The silicate differentiation history of planetary objects including the Moon can be constrained by combined Lu-Hf and Sm-Nd studies [1]. Previous Lu-Hf studies on lunar basalts [2-6] yielded results broadly consistent with a magma ocean history for the Moon as constrained by Sm-Nd systematics, but some inconsistencies persist: Most KREEP-rich bulk rocks have initial $^{176}Hf/^{177}Hf$ that are too radiogenic, overlapping the composition of chondrites at the same time, and are inconsistent with the unradiogenic initial $^{143}Nd/^{144}Nd$ of KREEP. This disparity in the Lu-Hf and Sm-Nd systems may reflect a non-chondritic composition of the Moon [7] but could also be due to capture of (epi)thermal neutrons (NC) during cosmic-ray exposure of the lunar surface [8]. NC reactions can induce positive shifts in measured $^{176}Hf/^{177}Hf$ [8] and negative shifts in measured $^{143}Nd/^{144}Nd$ [9]. However, none of the previous Lu-Hf studies of lunar samples accounted for NC effects. To assess the significance of NC effects on the lunar Lu-Hf and Sm-Nd systematics we obtained Lu-Hf, Sm-Nd, and Hf and Sm isotope data for a suite of lunar samples (KREEP-rich rocks and mare basalts).

The KREEP-rich samples display no NC-induced Hf or Sm anomalies and yield the lowest initial $^{176}Hf/^{177}Hf$ yet reported for any KREEP-rich rock. In contrast, most mare basalts exhibit well-resolved, NC-induced anomalies in Hf and Sm. Low-Ti mare basalts show the strongest NC effects, with $^{180}Hf/^{177}Hf$ and $^{149}Sm/^{152}Sm$ as low as ≈820 ppm and ≈72 ε-units below those of terrestrial samples, respectively. NC-induced ^{180}Hf and ^{149}Sm anomalies are well correlated, yielding distinct slopes for low- and high-Ti mare basalts. The errors in measured $^{176}Hf/^{177}Hf$ and $^{143}Nd/^{144}Nd$ induced by NC reactions are up to +12 and -0.7 ε-units, respectively.

The well-defined, distinct correlations between ^{149}Sm and ^{180}Hf anomalies in low- and high-Ti mare basalts imply almost constant neutron energy spectra for chemically similar samples. Using the respective neutron energy spectra and published ^{149}Sm data [e.g., 9], we estimate that the $^{176}Hf/^{177}Hf_{now}$ previously reported for low- and high-Ti mare basalts are too high by up to 7 and 1.7 ε-units, respectively. Published ^{149}Sm data suggest that previously reported data for KREEP-rich rocks are biased by NC reactions too, thus yielding more radiogenic initial $^{176}Hf/^{177}Hf$ values than expected for KREEP. Interpreting lunar Lu-Hf and Sm-Nd systematics without accounting for NC effects may thus yield erroneous conclusions.

Integrating geochemical, reactive transport, and facies-based modeling approaches at the contaminated Savannah River F-Area

NICOLAS SPYCHER[1*], SERGIO BEA[1], HARUKO WAINWRIGHT[1], SUMIT MUKHOPADHYAY[1], JOHN N. CHRISTENSEN[1], WENMING DONG[1], SUSAN S. HUBBARD[1], JIM A. DAVIS[1], AND MILES DENHAM[2]

[1]Lawrence Berkeley National Lab., Berkeley, CA 94720, USA, nspycher@lbl.gov (* presenting author)
[2]Savannah River National Laboratory, Aiken, SC 29808, USA

Objective

This study aims at understanding key hydrogeochemical processes dictating pH behavior and U transport at the Savannah River F-Area in South Carolina, USA. A nearly 1 km long acidic plume has developed under this site from the disposal of low-level acidic radioactive waste solutions into seepage basins overlying relatively permeable, mostly sandy sediments. The impact of chemical and physical heterogeneities on contaminant mobility is of particular interest.

Approach and Results

Various geochemical, horizontal 1D, and vertical 2D reactive transport simulations are conducted, that include the effects of mineral dissolution and precipitation, as well as H+ and U(VI) sorption using surface complexation models. Simulations consider the historical 35-year discharge of U-bearing nitric acid solutions, followed by a post-discharge period of 65 years. The concept of "reactive facies", integrating sediment chemical and hydrophysical properties with geophysical signatures, is explored to spatially distribute linked physical and chemical heterogeneities at local and field scales. Results of isotopic studies are also used to constrain the modeling effort. Simulations are conducted in a step-wise manner, first considering only the saturated zone then increasing complexity by including the vadose zone and a free water table.

Simulations indicate that H^+ sorption reactions on goethite and kaolinite (the main minerals at the site besides quartz), and the precipitation of Al minerals could delay the pH rebound for decades. Such slow rebound is likely to be exacerbated by residual saturation of the plume below the discharge basins. U concentrations potentially could decrease faster than pH from dilution with clean recharge water.

Two reactive facies are identified in the main formation at the site, each with distinct effects on predicted plume migration. Heterogeneous reactive properties (i.e., surface areas) within each facies, however, do not appear to affect the simulated historical pattern of the plume, because sorption sites become quickly saturated by the massive H^+ and U influx during the discharge period. Consequently, intra-facies heterogeneities mostly affect the predicted pH and U transport at early times and at the plume edges, and are expected to become relevant over the long term only once contaminant concentrations have decreased below sorption saturation levels. Rigorous uncertainty quantification studies are underway to further evaluate the effect of key model input parameters on model predictions.

Calcite Growth from the Molecular Scale.

ANDREW G. STACK[1*], JACQUELYN N. BRACCO[2], PAOLO RAITERI[3], JULIAN D. GALE[3], MEG C. GRANTHAM[2]

[1] Chemical Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN, U.S.A., stackag@ornl.gov * presenting author
[2] School of Earth and Atmospheric Sciences, Georgia Institute of Technology, Atlanta, GA, U.S.A.
[3] Nanochemistry Research Institute, Dept. of Chemistry, Curtin University, Perth, WA, Australia

Calcite ($CaCO_3$) growth and dissolution play important roles in determining ocean and subsurface geochemistry, such as buffering pH and serving as a biomineral for a large number of organisms. An understanding of the molecular-level mechanisms by which calcite grows and dissolves may enhance our ability to understand and predict the response of calcite to changes in these environments.

While abundant measures of calcite growth and dissolution rates exist, these are often made by measuring the solution composition over time, a method which convolutes the multiple reactions that occur on the mineral surface itself and these studies therefore have limited value in understanding reaction mechanisms. Historically, most surface sensitive techniques applied to this problem have probed calcite reactivity under stoichiometric solution compositions, which also cannot distinguish between the independent reactivities of calcium and carbonate. Using *in situ* atomic force microscopy, Stack and Grantham[1] and others[2] have recently shown that the ratio of calcium-to-carbonate plays an important role in determining overall reaction rate.

Here, we will evaluate the efficacy of analytical crystal growth models applied to the advance of monomolecular steps on the calcite surface. In particular we will focus on how well they capture the response of step velocity under varying saturation index as well as aqueous calcium-to-carbonate ratio. We will use strontium and its inhibitio of growth as an indicator of how well these models are capturing the salient aspects of reactions such as the nucleation and propagation of kinks on steps. At the time of writing, no single model yet derived captures the entirety of the richness of reactivity observed.

As an alternative to pre-defined analytical models fit to experimental data, we also will show the results of rare event theory molecular dynamics simulations applied to the same kink site reactions on the calcite surface. This method was recently successfully applied to the barite ($BaSO_4$) {120} steps[3]. These have the potential to give accurate reaction rates and mechanisms independent of a crystal growth model.

This research was sponsored by the Division of Chemical Sciences, Geosciences, and Biosciences, Office of Basic Energy Sciences, U.S. Department of Energy.

Arsenic transport from former mine sites: an empirical modeling approach

DAVID H. STACK[1*], CHRISTOPHER S. KIM[2], JAMES J. RYTUBA[3]

[1]Chapman University, School of Earth and Environmental Sciences, Orange, USA, stack104@mail.chapman.edu (* presenting author)
[2]Chapman University, School of Earth and Environmental Sciences, Orange, USA, cskim@chapman.edu
[3]U.S. Geological Survey, Menlo Park, USA, jrytuba@usgs.gov

As a result of extensive gold and silver mining in California, elevated levels of naturally-occurring arsenic and other trace metals are exposed in mine wastes located in semi-arid regions (e.g. the western Mojave Desert). With extended periods of weathering and erosion, these potentially toxic elements can become mobilized and contaminate surrounding communities. Concerns over the health of individuals living in and visiting these communities have increased due to the greater awareness of this issue [1, 2]. In the past, other studies on this topic have focused on the chemical characteristics of wash sediments [3], the spatial distribution around mine sites [4], and the sources of the heavy metals [5]. While there has been some work in other semi-arid environments examining wash sediments [6], an empirical model used to reconstruct the concentration patterns observed in mining regions has not been developed.

This study sought to examine the role infrequent rain events have on the transport of mine tailings down washes and conduct a quantitative analysis of the empirical observations at multiple mine sites. Soil and sediment samples were collected from multiple mine sites in the Mojave Desert and analyzed for a suite of 49 elements. Distances between points were calculated and plotted against arsenic concentration. An empirical model was then developed and fitted to the data to explain the fluvial migration of mine wastes down washes.

The field data indicated that arsenic concentrations are highest closest to the main waste pile. Generally, as the distance from the pile increases, the arsenic concentration decreases. However, due to the complex patterns of each wash resulting from multiple source inputs and episodic movements of mine wastes, multiple power law trends were used to model the variations, and apparent pulses, of arsenic concentration. These pulses can be representative of infrequent, but intense, rainfall events occurring in the past that are characteristic to semi-arid environments. This has implications for future modeling efforts in similar environments as a potentially predictive tool for the nature of mine waste fate and transport.

Strontium-, Magnesium- , Sulfur- and Bromine-isotopes as indicators for brine origin and migration

SUSANNE STADLER[1]*, FRIEDHELM HENJES-KUNST[1], ORFAN SHOUKAR-STASH[2], DIETER BUHL[3]

[1]BGR-Federal Institute for Geosciences and Natural Resources, susanne.stadler@bgr.de (* presenting author)

[3]Ruhr-University Bochum, Germany

Introduction

Causes and extents of subrosion processes following potash mining activities are still under debate for the city of Stassfurt, Germany. In our study, we investigate the role of groundwater in this context, and examined a set of environmental tracers to identify the water's origin from different aquifers (Quaternary, Triassic, caprock and the saline Zechstein formation (including flooded former mining shafts). Groundwater flow in strata covering the salt dome is well constrained: Stadler et al. [1] showed that the sampled groundwater could be related to multi-component mixing processes having occurred under three time scales: young groundwater ages were locally found (0-50 a), an old (< 40 ka) component was identified by radiocarbon data, and contact between meteoric water and Zechstein salts (naturally or anthropogenically induced) could be identified by the presence or absence of Permian crystallization water from the dissolution of e.g. Carnallite and/or Kieserite. Interactions between these components could be idenfied for the studied site. However, the origin and fate of highly saline water sampled from both the salt dome and the mining shalts remained unclear. A non-traditional isotope ($^{87}Sr/^{86}Sr$, $\delta^{26}Mg$, $\delta^{81}Br$, $\delta^{34}S$-SO_4 and $\delta^{18}O$-SO_4) study was initiated to gain insight into the brine history.

Results and Conclusion

$^{87}Sr/^{86}Sr$ of saline water samples range 0.70713 to 0.71014 with Sr concentrations varying between 0.2 and 52.3 mg/L. $\delta^{81}Br_{SMOB}$ values were found to range between 0.16‰ and 1.01‰ with Br concentrations of 6 to 3336 mg/L. $\delta^{34}S_{VCDT}$ and $\delta^{18}O_{VSMOW}$ (of SO_4) range from 0.5‰ to 15.4‰ and from 4.5‰ to 11.7‰, respectively, with SO_4 concentrations varying between 0.2 and 33 g/L. $\delta^{26}Mg_{DSM3}$ values range from -0.794‰ to 0.291‰ with Mg concentrations up to 84 g/L. Rocks from the various aquifers were also examined. Combining the isotopic results with geochemical data indicate that saline water samples from the Zechstein formation are largely unmodified residual brines formed during evaporation. The brines could be identified according to their origin (potash salt z(K2) or anhydrite z(A3) (and in few cases Leine salt residuals z(Na3)). For instance, potash salts and related brines could be linked by in part highly radiogenic $^{87}Sr/^{86}Sr$. $\delta^{26}Mg$ could not differentiate betweeen z(K2) and z(A3). Both sets of isotopes can however, clearly identify evaporitic components in fluids of cover layers.

The stability of carbon and carbonate within eclogites

V. STAGNO[1]*, Y. FEI[1], C.A. MCCAMMON[2] AND D. J. FROST[2]

[1] Geophysical Laboratory, Carnegie Institution of Washington, Washington, DC, USA. (* presenting author)
vstagno@ciw.edu
[2] Bayerisches Geoinstitut, Universität Bayreuth, D-95440, Germany

The redox conditions at which carbon and carbonate are stable in eclogitic settings are still relatively uncertain with respect to temperature and pressure of stability for these rocks. A comparison between the oxygen fugacity defined by carbon/carbonate equilibria in peridotite [1] and eclogite assemblages [2] indicates that diamond-bearing eclogites might be stable at conditions where only carbonates would be stable in peridotite rocks. However, these conclusions are suggested by thermodynamic predictions involving possible equilibria in eclogitic rocks, while an experimentally calibrated oxybarometer is still not available.

We conducted experiments to determine the oxygen fugacity at which elemental carbon coexists with carbonate minerals and melts in synthetic eclogites representative of natural assemblages. We performed experiments at both above and below the solidus of a carbonated eclogite in the Na-Ca-Mg-Al-Si-Fe-O-C system at pressures between 3 and 25 GPa and temperature of 800-1600 °C. Iridium powder was added to the starting mixture to act as redox sensor. Experiments were run in piston cylinder and multi anvil devices. Further, we were able to measure the ferric iron of omphacite and garnet equilibrated with graphite (or diamond) and carbonate (solid or melt) in the eclogitic assemblages using Mössbauer spectroscopy. Experimental results of the oxygen fugacity at which graphite/diamond and carbonate are equilibrated within an eclogitic assemblage, were parameterized as a function of pressure and temperature.

Results from this study improve our knowledge regarding the origin of diamonds in eclogitic rocks as well as the fate of carbon when subducted back into the mantle. Further, the results allow us to determine the ferric iron contents of eclogitic minerals, such as garnet and omphacite, as a function of pressure and temperature in presence of carbon-bearing phases, and they are used to develop an oxygen thermo barometer for eclogitic rocks.

Carbon cycling in oil sands tailings ponds mature fine tailings under sulphate - reducing and methanogenic conditions: A microcosm study

SEBASTIAN STASIK[1]* AND KATRIN WENDT-POTTHOFF[1],

[1]UFZ Helmholtz Centre for Environmental Research,Magdeburg, Germany, sebastian.stasik@ufz.de (* presenting author)

Oil sands tailings ponds are considered as a permanent storage and remediation approach for the extraction waste of the oil sands industry in the Athabasca Basin in northeastern Alberta (Canada). The anaerobic biodegradation of organic contaminants as well as the microbially mediated methane production, which can enhance the densification of the fine tailings, have been studied for many years. Thereby the anaerobic degradation of hydrocarbons is proposed to be accomplished by a complex microbial consortium, including syntrophic and methanogenic microorganisms as well as microbes of the iron,- nitrogen- and sulphur cycle.

Using selective cultivation, we detected heterotrophic and autotrophic sulphate reducers, thiosulphate oxidisers, and iron reducers in frequencies similar to those of natural lakes. To understand the interactions of indigenous methanogenic and sulphate-reducing communities, we conducted a 6 month microcosm experiment with mature fine tailings (MFT) supplemented with different carbon sources as well as molybdate and/or BES as specific inhibitors for the processes of sulphate reduction and methanogenesis. The carbon sources comprised low molecular weight electron donors (e.g. acetate, lactate, ethanol) that are and typically generated during hydrocarbon degradation and serve as easily available carbon sources[1].

We found that sulphate reduction was more limited by the presence of sulphate than by the availability of extra carbon sources, since considerable sulphate reduction occurred in microcosms without additional organic carbon, when sulphate was available. Methanogenesis increased when microcosms were supplemented with extra carbon sources, but was completely inhibited by the addition of BES. Molybdate not only inhibited sulphate reduction, but also methanogenesis, indicating a positive relation between the two processes. The turnover of the extra carbon sources differed between microcosms treated with molybdate and BES. Acetate and propionic acid were not consumed in microcosms amended with molybdate, indicating that sulphate–reducing communities were most responsible for the metabolization of these carbon sources, and that methane was rather produced by hydrogenotrophic instead of acetoclastic methanogens. In microcosms without molybdate, concentrations of lactate, ethanol and propionic acid decreased, while acetate accumulated during the first weeks and was consumed afterwards, indicating the occurrence of both, incomplete and complete oxidizing sulphate reducers. Ethanol and lactate were consumed in microcosms even when treated with BES and molybdate together, demonstrating that other processes than methanogenesis and sulphate reduction are involved in carbon cycling in the MFT.

Interactions between network cation coordination and oxygen speciation in oxide glasses

JONATHAN F. STEBBINS[1*], LINDA M. THOMPSON[1], JINGSHI WU[1]

[1]Dept. of Geological and Environmental Sciences, Stanford University, Stanford CA 94305 USA, stebbins@stanford.edu (* presenting author)

Recent experimental studies of aluminosilicate glasses and melts have greatly enhanced our information on the details of network structure that supersede conventional approximations, notably the presence of non-bridging oxygens (NBO) in metaluminous and even peraluminous compositions, and the widespread presence of significant concentrations of five-coordinated Al even in highly peralkaline (and peralkaline-earth) regions. Especially as Al, Si, (and B) coordination increase at high pressures, the interactions of these species become important for melt properties (e.g. density, viscosity, configurational entropy) and component activities. This interplay can sometimes be more apparent in borosilicate and germanate analog systems, even at ambient pressure, as composition and temperature have now well-known, large effects on structure. For example, the sizes and charges of the network modifier cations can have strong effects, as smaller and/or higher-charged cations often favor the formation of NBO and/or BO such as Al-O-Al linkages, both of which serve as relatively concentrated negative charge that can more effectively coordinate the modifier cations. We will compare results on such speciation reactions for a variety of oxide melt systems, note similarities and differences, and suggest important areas for future investigation.

Diffusion versus surface reaction control of mineral precipitation and dissolution kinetics at the pore scale

CARL I. STEEFEL*, DAVID TREBOTICH, SERGI MOLINS, LI YANG, CHAOPENG SHEN

Lawrence Berkeley National Laboratory, Berkeley, USA, CISteefel@lbl.gov (* presenting author)

Introduction

The rates of mineral precipitation are important as a subsurface carbon sequestration mechanism in the case of carbonates, while mineral dissolution is important as a source of both metal cations and alkalinity for precipitation. Pore scale flow and transport processes within the complex pore structure of the subsurface can lead in some cases to a complete or partial control of reaction rates by molecular diffusion. The extent to which a diffusion control develops depends on the rates of local surface reaction, but also on the pore geometry and the rate of flow, since these effects influence the width of diffusion boundary layers that develop adjacent to reactive mineral surfaces.

Approach and Results

In this study, we use Direct Numerical Simulation of pore scale reactive transport processes to investigate the effect of a complete or partial limitation of rates by molecular diffusion through a hydrodynamic boundary layer (Figure 1). We focus here on the dissolution and precipitation of carbonate phases, with rates at the mineral surface taken from experimental studies in which a complete surface reaction control can be demonstrated. The partial control of rates by molecular diffusion, which is particularly pronounced for larger grain sizes within porous subsurface materials, is investigated as a function of the saturation state of the bulk solution with respect to the carbonates, as well as temperature and pH, since these can influence both the rate of surface reaction and multicomponent diffusion. The simulations are combined with selected microfluidic reactor experiments in which hydrodynamic boundary layers and surface reaction can be rigorously quantified. The simulations demonstrate that a partial diffusion control of reaction rates in medium to coarse grained materials is much more prevalent than is commonly thought.

Quartz precipitation and fluid-inclusion characteristics in submarine hydrothermal systems

M. STEELE-MACINNIS[1*], L. HAN[1], R.P. LOWELL[1], J.D. RIMSTIDT[1] AND R.J. BODNAR[1]

[1]Department of Geosciences, Virginia Tech, Blacksburg VA 24061 USA, mjmaci@vt.edu (* presenting author)

Numerical modeling of quartz dissolution and precipitation in a sub-seafloor hydrothermal system was used to predict where in the system quartz could deposit and trap fluid inclusions. The spatial distribution of zones of quartz dissolution and precipitation is complex, owing to the many inter-related factors controlling quartz solubility, including temperature, fluid salinity and fluid immiscibility, and quartz may exhibit either prograde or retrograde solubility, depending on the *PTX* conditions [1]. Using the *PVTX* properties of H_2O-NaCl, the petrographic and microthermometric properties of fluid inclusions trapped at various locations within the hydrothermal system are predicted. Vapor-rich inclusions are trapped as a result of the retrograde temperature-dependence of quartz solubility as deep convecting fluid is heated in the vicinity of the magmatic heat source. Coexisting liquid-rich and vapor-rich inclusions are also trapped in this deep region when quartz precipitates as the convecting fluid enters the region of fluid immiscibility. Vapor generated as a result of fluid immiscibility migrates upward, entraining variable amounts of brine and/or heated seawater. During ascent, vapor condenses and mixes with seawater entrained in the upwelling plume. Fluid inclusions trapped along the upflow path in the shallower subsurface near the seafloor vents and in the underlying stockwork are liquid-rich and homogenize at 200-400 °C. Salinities of these inclusions are similar (but generally not equal) to that of seawater. Volcanogenic massive sulfide (VMS) deposits represent fossil submarine hydrothermal systems, in which mineralization commonly forms a stockwork zone beneath seafloor vents. Because the spatial variation of fluid-inclusion properties in this portion of the submarine hydrothermal system can be predicted, relationships between fluid-inclusion properties and location within the hydrothermal system can be inferred. Fluid inclusion properties can thus be used as an exploration tool for VMS deposits. Importantly, fluid inclusions can define vectors to infer the direction towards potential massive sulfide ore within fossil submarine hydrothermal systems, and can be used to determine the "up" direction within a deformed or tilted volcanic pile.

Climate forcing of ice sheet dynamics in West Antarctica

ERIC J. STEIG[1]*

[1]University of Washington, Seattle, WA, USA, steig@uw.edu (* presenting author)

Recent West Antarctic Climate and Ice Sheet Change

Ice shelves and glaciers along the margin of the Antarctic ice sheet are thinning rapidly. The greatest thinning rates are in West Antarctica, where warm Circumpolar Deep Water (CDW) floods the continental shelf and melts the ice shelves from below. This region has also experienced significant climate changes in the last 30 years or more, including rising temperatures over most of continental West Antarctica and the Antarctic Peninsula, and declines in sea ice in the Amundsen-Bellingshausen Seas [1].

Climate and glaciological changes in West Antarctica are linked by changes in the regional atmospheric circulation which have caused increased poleward warm-air advection, sea ice convergence, and wind-driven inflow of CDW onto the shelf. These changes in regional atmospheric circulation are largely a response to forcing from the tropical Pacific (Figure 1). Particularly in the 1990s, strong sea surface temperature anomalies and anomalous deep convection in the central tropical Pacific caused enhanced Rossby wave activity, resulting in anomalous westerlies along the Amundsen Sea coast of West Antarctica [2].

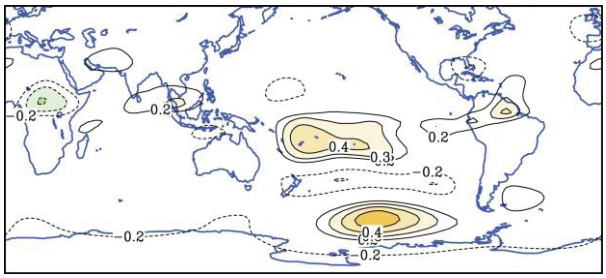

Figure 1: Correlation between the global 200 hPa stream function and the westerly wind stress over the West Antarctic shelf edge [2].

Attribution

These results imply that recent glaciological changes in West Antarctica can be attributed to anthropogenic forcing only to the extent that recent changes in the tropical Pacific can be so attributed. Paleoclimate record from corals shows that the anomalous conditions in the tropics in the last ~30 years are very likely exceptional in the last millennium. Similarly, the ice core record from West Antarctica shows that the 1990s are the most anomalous decade in at least the last 300 years. Nevertheless, attribution of tropical Pacific climate changes to anthropogenic forcing remains equivocal, largely because there is significant uncertainty in the response of the El Niño-Southern Oscillation. Uncertainty in projections of the future behavior of the West Antarctic ice sheet is further complicated by uncertainty in projections of tropical climate.

What is source rock?

H.J. STEIN[1,2] AND J.L. HANNAH[1,2]

[1] AIRIE Program, Colorado State University, Fort Collins, CO, USA
[2] Physics of Geological Processes, University of Oslo, Norway

From the perspective of a commodities expert, the likely answer will be organic-rich shales with hydrocarbon potential, or metal-bearing magmatic or sedimentary systems. You're either a petroleum geologist or an ore geologist, and the two professions typically stay on their own side of the fence. Has anyone seen a petroleum geologist regularly gobbling-up science at ore geology meetings or, even more unheard of, the reverse? And up the middle, are those studying "fluids in the crust", knowing the economic potential of their efforts but feeling uncertain how to access it – how to break into the terminology and be embraced as an outsider in resource-driven clubs. These are the statements that give us pause and discomfort.

The futures of research in both resource fields, hydrocarbons and metals, are co-dependent. The big leaps in commodity-driven science will be made by those who move unabashed between these two fields. Too many ore geologists fall back on the same tired models, never stepping outside their own sandbox to explore different ways to play. Ore deposits are formed by "deep-seated mantle-derived fluids" or by "granite-derived fluids", we are told. Who stops to consider the importance of organic complexes, or the chemical and physical consequences of hydrocarbon maturation? Similarly, how many petroleum geologists ponder the metal porphyrins that populate hydrocarbon systems, and what becomes of those metals as the organic molecules are cracked?

Modeling the mobility and concentration of both metals and hydrocarbons requires a keen understanding of fluids and volatiles in all kinds of rocks. Source rock is any rock that experiences breakdown of kerogen or undergoes oxidation thereby liberating metal from sulfide, silicate, or organic-rich material. Neither process is very interesting in the absence of water and CO_2, a pressure gradient, and space to move.

It is the fluid and volatile phases in rocks that move natural resources into place. The processes involved may be incremental to catastropic. The time scales may be instantaneous to hundreds of millions of years depending on one's perspective. But the notion that an ore deposit in the crust had a direct pipeline to the mantle should be put to rest. Rather, large scale mantle events stimulate processes in the crust over long time-scales. Source rock can be any rock implicated in the process with volatile, fluid, metal, or hydrocarbon to contribute.

Field-based examples that capture these processes are explored in this contribution. Processes that "upgrade metals" and "downgrade kerogen" are constrained in absolute time through precise Re-Os dating of sulfides and hydrocarbon.

Mantle plume chemical asymmetry - implications from geodynamic models

BERNHARD STEINBERGER[1,2*], RENÉ GASSMÖLLER[1] AND ELVIRA MULYUKOVA[1]

[1]GeoForschungsZentrum Potsdam, Potsdam, Germany, bstein@gfz-potsdam.de (* presenting author)
[2]Physics of Geological Processes, Univ. of Oslo, Oslo, Norway

Introduction

Recent results indicate that mantle plume composition systematically varies with position relative to the plume center, and that this heterogeneity could correspond to different regions where the plume material came from before rising through the plume conduit [1,2]. Here we present results of a numerical model regarding the relation of source region and location in the plume.

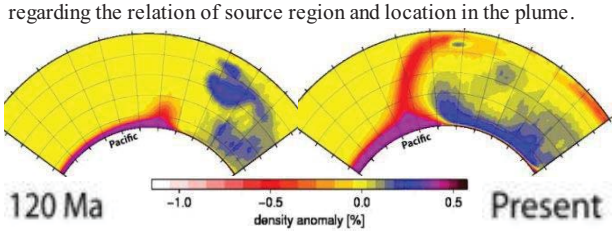

Figure 1: Cross sections for a mantle model [3]. Subducted slabs (blue) sink to the base of the mantle, and push hot material from the thermal boundary layer (red) towards the edges of thermo-chemical piles (violet) where it rises in the form of mantle plumes.

Observations and Models

Almost all Large Igneous Provinces, when reconstructed to their eruption locations, fall above the margins of either of the two Large Low Shear Velocity Provinces beneath the Pacific and Africa [4], often viewed as chemically distinct. Based on plate reconstructions since 250-300 Ma, we model a pattern of several plumes each at the edges of two thermo-chemical piles in the lowermost mantle, both with a numerical code based on spherical harmonics [5] and the finite element code CitcomS [6,7]. We develop a 2-D finite element code that allows us to accurately model entrainment of chemically distinct material in plumes.

Results and Conclusions

Model plumes often occur at locations similar to observed hotspots with conduit shapes similar to [8] where flow is based on tomography-based density models. By tracking along flow lines, both for subduction- and tomography-based flow superposed with plume influx, we map source regions onto predicted location in the plume. The mapping allows insights into the element distribution in the source region by comparing the properties of plume-related magmas. Furthermore, comparing the created models allows us to constrain under which conditions plumes entrain chemically distinct material in their source region and whether these are likely to occur on earth. Based on high-resolution 2-D results we assess entrainment and where inside the conduit chemically distinct material is expected to occur.

Compositional heterogeneity within the Yellowstone magma reservoir: Insight from zircon age, trace-element, and Hf-isotopic analyses

MARK E. STELTEN[1*], KARI M. COOPER[1], JORGE A. VAZQUEZ[2], JOSH WIMPENNY[1], GRY H. BARFOD[1], QING-ZHU YIN[1]

[1]University of California – Davis, Davis, CA, USA, mestelten@ucdavis.edu (* presenting author)
[2]U.S. Geological Survey, Menlo Park, CA, USA

Introduction

The Yellowstone Plateau (USA) hosts one of the largest Quaternary magmatic systems in the world, with caldera forming eruptions at 2.059 ± 0.004 Ma, 1.285 ± 0.004 Ma, and 0.639 ± 0.002 Ma, as well as numerous intracaldera and extracaldera eruptions between caldera-forming events [1]. The most recent eruptive episode at Yellowstone caldera produced the Central Plateau Member (CPM) of the Plateau Rhyolite, which erupted intermittently between ~170-70ka with a cumulative volume ≥600km^3, thereby approaching the ≥1000km^3 (dense rock equivalent) of rhyolite erupted during the preceding caldera forming eruption of the Lava Creek Tuff [1]. Thus, the CPM rhyolites provide snapshots of an evolving large silicic magma reservoir though time.

In this study we examine the degree of compositional heterogeneity ca. 100ka in the Yellowstone magma reservoir by comparing sub-crystal-scale SIMS age, SIMS trace-element, and LA-MC-ICPMS Hf-isotopic data from zircons hosted in three CPM rhyolites erupted at different locations within the caldera during the 100-120ka time period, as well as an ~118ka extracaldera rhyolite. Linking the age, trace-element, and Hf-isotopic compositions of zones within individual zircons provides a robust method for recognizing distinct crystal populations and magma compositions within the CPM reservoir, and monitoring the evolution of the magma reservoir over time using crystal zoning patterns. Comparing crystal populations in coeval rhyolites erupted from different parts of the caldera furthermore allows for assessment of whether the rhyolites have similar crystal populations and provides insight into the degree of compositional heterogeneity within the magma reservoir at ~100ka.

Results and Conclusions

Age, trace-element, and Hf-isotopic data for zircons from the intracaldera West Yellowstone flow, Solfatara Plateau flow, and Hayden Valley flow as well as from the extracaldera Gibbon River flow document the presence of multiple zircon populations within the CPM magma reservoir. Hf-isotopic compositions of zircons in the CPM rhyolites vary from -8.5 εHf to 1.2 εHf, with individual grains displaying large (>4 εHf) Hf-isotopic variations. These data document that the CPM reservoir experienced mixing and crystal exchange with multiple magmas prior to eruption, and place constraints on the degree of compositional heterogeneity in the Yellowstone magma reservoir ca. 100ka.

Temporal variation of sulfur and iron metabolisms within composite tailings and overlying sand cap at Syncrude's Mildred Lake property

KATE STEPHENSON[1*], KATHRYN KENDRA[1], TARA COLENBRANDER-NELSON[1], RODERICK AMORES[1], STEVEN HOLLAND[1], TARA PENNER[2], AND LESLEY WARREN[1]

[1]McMaster University, School of Geography and Earth Sciences, Hamilton, Canada, stephk2@mcmaster.ca (* presenting author)
[2]Syncrude Environmental Research, Edmonton, Canada, penner.tara@syncrude.com

In accordance with provincial regulations, the Alberta oil sand companies must reclaim mined areas and composite tailings (CT) deposits produced as a by-product of bitumen extraction. Syncrude, the largest operator in the Alberta oil sands is currently building the first pilot fen reclamation project overtop of CT. Dewatering of CT associated with reclamation activities at Syncrude's Mildred Lake property (Fort McMurray, AB), has resulted in unexpected incidents of H_2S gas release from CT dewatering wells, identifying the need for in depth biogeochemical characterization of these materials and identification of the potential roles of microbial activity in H_2S generation. The objectives of this field and experimental research are to establish the existence of Fe- and S- respiring bacteria within CT porewaters and their potential linkages to H_2S release over seasonal and spatial scales within the CT deposit. An operationally defined sequential extraction procedure was used to quantify biologically accessible pools of amorphous Fe and S substrates within the sand cap overlying the CT, an important interface between the CT pore-water brine and the developing fen. Results show high concentrations of bioavailable Fe (124 µmol/g) and S (48 µmol/g) in the reducible ("amorphous and crystalline oxyhydroxides") and the oxidizable ("organic/sulfide") sediment fractions respectively. Porewater wells within CT and the overlying 10 m sandcap on which the fen is currently being constructed were sampled 4 times from June 2010 to October 2011. H_2S was detected in all wells and at all sampling dates, the highest concentration detected was for a well within the sandcap of 183 µmol/L. Enrichments for S and Fe oxidizing and reducing bacteria from samples collected in June and September 2010 and July 2011, have shown positive growth for S- and Fe- oxidizing and reducing bacteria in well water from the location of reported H_2S_g release, consistent with the involvement of these microbes in S- cycling and H_2S production in CT. Experimental mesocosms with targeted Fe and S metabolisms are currently being assessed for H_2S generation to identify key metabolic pathways involved. Select field and laboratory results, including 16S rRNA sequencing of environmental enrichments and the bulk well water community, along with the results of experimental mesocosms will be discussed.

The role of subduction erosion in the recycling of continental crust

CHARLES R STERN[1]

[1]University of Colorado, Department of Geological Sciences, Boulder, CO 80309-0399 USA, Charles.Stern@colorado.edu

Subduction erosion occurs at all convergent plate boundaries, even if they are also accretionary margins. Frontal subduction erosion results from a combination of erosion and structural collapse of the forearc wedge into the trench, and basal subduction erosion by abrasion and hydrofracturing above the subduction channel. High rates of subduction erosion are associated with relatively high convergence rates (>60 mm/yr) and low rates of sediment supply to the trench (<40 km^2/yr), implying a narrow and topographically rough subduction channel which is neither smoothed out nor lubricated by fine-grained water-rich turbidites such as are transported into the mantle below accreting plate boundaries. Rates of subduction erosion, which range up to >440 km^3/km/my, vary temporally as a function of these same factors, as well as the subduction of buoyant features such as seamount chains, submarine volcanic plateaus, island arcs and oceanic spreading ridge, due to weakening of the forearc wedge. Globally, subduction erosion is responsible for >1.7 Armstrong Units (1 AU = 1 km^3/yr) of crustal loss [1], a significant proportion of the yearly total crustal loss caused by sediment subduction, continental lower crustal delamination, crustal subduction during continental collision, and/or subduction of rock-weathering generated chemical solute that is dissolved in oceanic crust. The paucity of pre-Neoproterozoic blueschists suggests that global rates of subduction erosion were probably greater in the remote past, perhaps due to higher plate convergence rates. Subducted sediments and crust removed from the over-riding forearc wedge by subduction erosion may remain in the crust by being underplated below the wedge, or these crustal debris may be carried deeper into the source region of arc magmatism and incorporated into arc magmas by either dehydration of the subducted slab and the transport of their soluble components into the overlying mantle wedge source of arc basalts, and/or bulk melting of the subducted crust to produce adakites. In selected locations such as in Chile [2,3], Costa Rica, Japan and SW USA, strong cases can be made for the temporal and spatial correlation of distinctive crustal isotopic characteristics of arc magmas and episodes or areas of enhanced subduction erosion. Nevertheless, overall most subducted crust and sediment, >90% (>3.0 AU), is transported deeper into the mantle and neither underplated below the forearc wedge nor incorporated in arc magmas. The total current rate of return of continental crust into the deeper mantle is equal to or greater than the estimates of the rate at which the crust is being replaced by arc and plume magmatic activity, indicating that currently the continental crust is probably slowly shrinking [4,5]. However, rates of crustal growth may have been episodically more rapid in the past, most likely at times of supercontinent breakup, and conversely, rates of crustal destruction may have also been higher during times of supercontinent amalgamation. Thus the supercontinent cycle controls the relative rates of growth and/or destruction of the continental crust. Subduction erosion plays an important role in producing and maintaining this cycle by transporting radioactive elements from the crust into the mantle, perhaps as deep as the core-mantle boundary.

Stable strontium isotope behaviour in Himalayan river catchments

EMILY I. STEVENSON[1]*, KEVIN W. BURTON[2], IAN J. PARKINSON[3], CHRISTOPHER R. PEARCE[3] FATIMA. MOKADEM[1], AND RACHAEL JAMES[4]

[1]Department of Earth Sciences, Oxford University, South Parks Road, Oxford, OX1 3AN, UK. emilys@earth.ox.ac.uk (* presenting author)
[2]Department of Earth Sciences, Durham University, Durham, DH1 3LE, UK
[3]Department of Environment, Earth and Ecosystems, The Open University, Milton Keynes, MK7 6AA, UK
[4]National Oceanography Centre, European Way, Southampton, SO14 3ZH, UK

The radiogenic strontium ratio ($^{87}Sr/^{86}Sr$) is commonly used as a weathering tracer of continental sources in seawater, with carbonate and silicate based lithologies having different $^{87}Sr/^{86}Sr$ ratios. However, $^{87}Sr/^{86}Sr$ interpretations can be hindered by the difficulty of distinguishing changes in riverine flux from changes in composition. This is a particular problem for Himalayan rivers as those draining both silicate and carbonate catchments have elevated $^{87}Sr/^{86}Sr$ ratios, and there is debate as to how much of the ^{87}Sr flux is actually derived from silicate weathering [1].

Recent stable strontium isotope data suggested that carbonate weathering yields a $\delta^{88/86}Sr$ value distinct from those of both silicate weathering and seawater [2]. This difference in isotopic ratio could resolve whether inputs into rivers, and eventually the oceans, are truly dominated by either silicate or carbonate lithologies and may also be used to distinguish between flux and source.

This study presents high-precision $\delta^{88/86}Sr$ data and $^{87}Sr/^{86}Sr$ data obtained from river waters draining both silicate and carbonate dominated terrains in the Himayala. Rivers draining carbonate based terrains have an average $\delta^{88/86}Sr$ value of 0.28±0.08‰ and increase to heavier values downstream (heading towards those of the Ganges, 0.38±0.01‰ [3]), possibly because of continued carbonate precipitation through the catchment. The $\delta^{88/86}Sr$ of carbonate rivers also correlates with [Si], and other major divalent cations as well as sulphate concentration. [4] Silicate rivers are generally heavier (0.34±0.07‰), but show little systematic behaviour with other elements. These results indicate that the carbonate rivers are generally lighter than those draining silicate terrains, and also suggest that continued secondary mineral precipitation (primarily carbonates) is occuring with within those catchments.

Owing to ecosystem and human health consequences, understanding uranium's potential for mobility in environmental settings is important. In anaerobic soils and sediments, oxidized U(VI) may be reduced through biological or chemical pathways to U(IV), forming sparingly soluble solids. However, formation of uranyl-calcium-carbonato complexes may limit reduction and authogenic UO_2 is susceptible to reoxidation. Determining reaction pathways of uranium that promote solids stable under aerobic and anaerobic conditions is critical for limiting dissolved concentrations and migration of uranium. This is of particular concern in settings near or at redox boundaries where surface and subsurface environments may be subjected to fluctuating redox conditions. We examined the nature and association of solid-phase uranium in both oxidized and reduced sediments from a hillside surface seep in Rifle, Colorado where uranium appears to be naturally attenuated in the solid phase. Visibly reduced sediments occur at the surface of the seep adjacent to (< 100cm from) pockets of freshly precipitated iron (III) phases, indicative of a redox boundary. Uranium release and solid-phase association were measured in systems containing sediment and 3 mM Fe(II) that were maintained under reducing conditions for 15 d followed by 5d of oxidation to simulate a redox cycle. Aqueous and solid-phase results show that >75% of uranium present in the sediments remains associated with the solid phase throughout the oxidation portion of the experiments.

Predicting the speciation and transport behaviour of contaminants in a wet discard dam

The burning of pulverised coal in coal-fired boilers to generate heat causes the production of fly ash. In addition water used in the process of cooling and turbine propulsion results in the production of high saline effluents. The high saline streams (ca. 20% ash) are used for the hydraulic transport of ash to the dumping sites, which results in ash dams that can act as salt sinks. The slurry that is pumped onto the wet dump area is allowed to settle. The water that has separated from the ash is skimmed off and re-circulated to transport more fly ash to the site. However a certain fraction of the water infiltrates the dam resulting in geochemical transformations.

Due to the presence of high saline water during the operational phase an extensive salt loading is observed onto the ash particles. During the decommisioning phase of the ash dam certain physical and chemical processes need to be considered to manage the produced water from the system. In particular the mechanism of leachate production needs to be considered in conjunction with the temporal and spatial extent.

The results presented will focus on the effect that disposal methods of the fly ash has on the transport of chemical species within the ash dam (Figure 1). In addition the rate of release of chemical species will also be presented as this influences the measures required to manage these facilities over an extended time period.

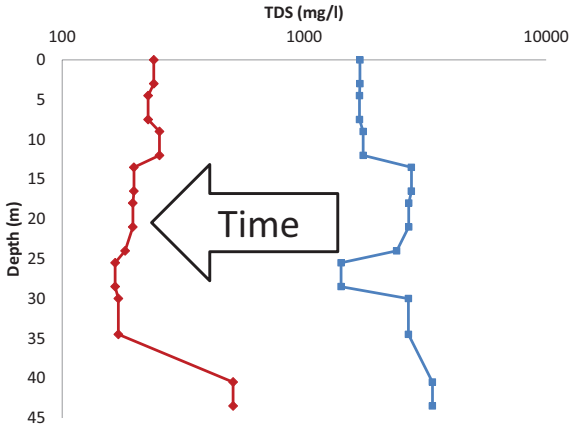

Figure 1: Diagram depicting the change in TDS values over time from a leachate analysis. The build-up of initially higher TDS values can be observed in two distinct areas (15 – 24 and 30 – 45 m).

When the surface is not what you think it is

STIPP S.L.S.[1], HASSENKAM T.[1], YANG M.[1], SKOVBJERG L. L.[1], SAND K.K.[1], PASARÍN I.[1], BOHR J.[2]

[1]Nano-Science Center, Department of Chemistry, University of Copenhagen, stipp@nano.ku.dk
[2]DTU Nanotech, Danish Technical University, Denmark.

More than a century ago, chemists began to explore the thermodynamic and kinetic relationships between solids and fluids in nature. Goldschmidt attempted to classsify them and Garrels, Christ, Krauskopf, Stumm, Schindler, Helgeson, Sposito and many others taught us to use thermodynamic relationships to predict natural system behaviour. When it has failed, we have often blamed kinetics.

About two decades ago, surface sensitive techniques first demonstrated that a calcite surface is not simply a termination of the bulk atomic structure. Surface atoms shift position, water delocalises charge on dangling bonds, adventitious carbon is ubiquitous and even on surfaces that appear dry, an adsorbed water film promotes recrystallisation[1]. New instruments allow us to see ever closer, giving new insights into the properties and behaviour of nano-particles and mineral-fluid interfaces so there is now little doubt. Surfaces are not simply where the bulk terminates.

Still, however, there are many cases where natural surfaces do not behave as we assume they ought to[2]. Molecular modelling, atomic force microscopy (AFM) and X-ray reflectivity show that water, structured at calcite surfaces, is displaced by ethanol and the alcohol orders itself, almost like a lipid layer. Adhesion properties change in response to ionic strength but reproducibility is elusive on ideal surfaces, whereas mineral grains plucked from sandstone, with their natural adventitious carbon, behave consistently. It is this organic "contamination" on these mineral surfaces that determines their hydrophillic properties, not the mineral beneath. Recent AFM studies have also revealed that sediment grain surfaces are frequently covered by nanocrystals of clay. These are far too thin for detection by X-ray diffraction so they have previously gone unnoticed but in some cases they cover significant portions mineral surfaces, meaning they can control water-rock properties. Finally, sea creatures produce aragonite and calcite in crystal forms tailored to their needs but these biogenic materials behave differently than inorganically produced minerals, even when organic components that remain associated with the biominerals are present only in the parts per billion range.

Materials adsorbed on mineral surfaces change properties in unexpected ways. By understanding surfaces better, we are likely to discover why large scale geological systems do not always behave as thermodynamics leads us to expect. We can hope that our new insight brings us to a point where we might have less need of the excuse "kinetically hindered".

Mechanisms controlling $^{238}U/^{235}U$ isotopic fractionation in low- and high-temperature environments

C.H. STIRLING[1*], A. KALTENBACH[1] AND Y. AMELIN[2]

[1]Department of Chemistry, University of Otago, Dunedin, New Zealand, cstirling@chemistry.otago.ac.nz (* presenting author), akaltenbach@chemistry.otago.ac.nz
[2]Research School of Earth Sciences, Australian National University, Canberra ACT, Australia, yuri.amelin@anu.edu.au

Recent studies have documented sizeable, permil-level isotopic fractionation between ^{238}U and ^{235}U in low-temperature environments, facilitated by analytical advancements in multiple-collector ICP-MS (MC-ICPMS) [1,2]. Variability in $^{238}U/^{235}U$ has a direct impact on the accuracy of the U decay series chronometers, requiring the $^{238}U/^{235}U$ of every sample to be characterized, and the revision of important cosmo- and geo-chronological models. Further efforts have focussed on investigating the processes controlling $^{238}U/^{235}U$ isotope fractionation, especially during U reduction. To this end, the ^{238}U-^{235}U isotope system offers significant potential as a monitor of redox conditions in U bioremediation studies [3], and as a paleo-redox tracer of the extent of anoxia in the historic oceans [4] to complement the growing inventory of other redox-sensitive metal isotope tracers (e.g. Mo and Fe) which each have differing redox potentials and respond to anoxia at different rates. However, additional studies are required to gain an improved understanding of the mechanisms controlling ^{238}U-^{235}U isotope fractionation before these applications can be fully explored, as the available datasets show some contrasting U isotopic behaviour during U reduction.

Using MC-ICPMS, we report $^{238}U/^{235}U$ observations for samples collected from a range of low- and high-temperature environments. A ^{233}U-^{236}U double spike was employed to monitor instrumental mass fractionation, allowing variations in $^{238}U/^{235}U$ to be resolved at the 0.005 % level (2σ) on 50 ng U sample sizes, and at the 0.003 % level (2σ) on larger sample sizes by pooling the data of replicate analyses. In all of the low-temperature environments we have investigated, the magnitude and direction of the $^{238}U/^{235}U$ isotopic fractionation is consistent with the 'nuclear field shift effect' [5] as the dominant fractionation mechanism, favouring enriched $^{238}U/^{235}U$ compositions in the reduced reaction product where the electron density near the nucleus is lower. Our results for a wide range of meteorites [6,7] and volcanic terrestrial samples reveal small (0.01 % level) but resolvable variations in $^{238}U/^{235}U$ in high-temperature environments. Further efforts should focus on identifying U fractionation mechanisms in high-temperature systems by linking $^{238}U/^{235}U$ to U concentration and oxidation state. Bulk samples and mineral aggregate sub-samples spanning the primitive to differentiated meteorite classes should also be be investigated to determine the extent to which $^{238}U/^{235}U$ variations are controlled by U isotope heterogeneity or extant ^{247}Cm effects in the early solar system versus U 'stable' isotope fractionation during subsequent chemical and thermal processing.

Deep water in the Upper Rhine Rift Valley, central Europe

INGRID STOBER

Institute of Geosciences. University of Freiburg. Albertstr. 23b. D-79102 Freiburg. Germany. ingrid.stober@minpet.uni-freiburg.de

Section 9f: Innovative geochemical approaches to understanding geothermal systems

Hydrochemical data from deep wells in the Upper Rhine Graben area in France and Germany were collected und examined. Primary targets were the potential geothermal reservoirs: Hauptrogenstein (Dogger). Upper Muschelkalk (middle Triassic) and Buntsandstein (lower Triasic). The data (table) were used to characterize the fluids found in the hydrogeothermal reservoirs [1. 2]. Waters at < 500 m depth are weakly mineralized. Water composition is controled by the rock. With increasing depth also TDS increases and the distinct waters of the three different aquifers all evolve to Na-Cl brines independent of the reservoir rock. Water from 3000 m depth is of very similar composition. All waters are saturated with respect to calcite and some other minerals. When thermal water is pumped to the surface and cooled, they become oversaturated with respect to a series of predictable solids including calcite, barite, celestite and others.

Within the underlain Variscan crystalline basement the fracture porosity is filled with saline thermal water[3]. Its composition forms a continuum with the waters from the deep sedimentary aquifers. The crystalline basement in the Upper Rhine Graben is used for enhanced geothermal systems (EGS). TDS at 5000 m depth is about 100 g/kg.

Magnetite (U-Th)/He dating– Attractive Dates in Mafic and Ultramafic Rocks

DANIEL F. STOCKLI[1], JORDAN L. TAYLOR[2*], EUGENE SZYMANSKI[2], RICHARD A. KETCHAM[1]

[1]University of Texas, Austin, USA, stockli@jsg.utexas.edu (*presenting author), ketcham@jsg.utexas.edu
[2]University of Kansas, Lawrence, USA, jordanleightaylor@gmail.com, eugene.szymanski@gmail.com

Magnetite is a common mineral phase in felsic, mafic, hydrated ultramafic igneous and metamorphic rocks. Magnetite (U-Th)/He (MHe) dating has been shown to be a reliable and powerful alternative method for obtaining absolute age constraints from mafic volcanic rocks in light of inherent difficulties in $^{40}Ar/^{39}Ar$ dating due to excess ^{40}Ar and/or recoil, susceptibility to alteration, or lack of datable mineral phases [1]. More recently, we have explored MHe as a novel and exciting geo- and thermochronometric technique for constraining the formation and thermal processes related to serpentinization and exhumation of sub-lithospheric mantle during continental break-up. While ultramafic rocks (e.g., sub-lithospheric mantle) do not commonly contain mineral phases that are datable by traditionally for geo- and thermochronometric, magnetite occurs ubiquitously as an alteration phase in serpentinized peridotites as a result of olivine breakdown. MHe Tc of ~250°C [1] can be exploited to elucidate the thermal history of exhumed mantle and formation of serpentinites. Application of MHe ages should provide critical temporal insights into continental rifting and serpentinization during break-up along magma-poor continental margins. As attractive and powerful as MHe dating is, not all magnetite samples are suitable for MHe dating due to its texture, grain size, and [U] making it prone to matrix He implantation. Detailed petrographic characterization of basaltic and ultramafic magnetite is required to determine the suitability of magnetite size and textures for MHe dating. The biggest hurdles in reliable magnetite dating, however, are grain morphology and He implantation, as matrix [U] commonly is one order of magnitude greater than magnetite (~100 ppb). While air-abrasion tends to alleviate this in large magnetite [1], irregular and complexly intergrown magnetite require careful pre-analysis screening. We have the developed the routine use of non-destructive microCT scanning for imaging of magnetite, identification of suitable magnetite, and monitoring of air-abrasion progress and high-U matrix removal. Understanding petrologic context and screening prior and during analysis are critical for deriving reliable and meaningful MHe dates.

Calcite nucleation and growth on basaltic glass and silicate minerals

Mineral substrates and their effect on calcite nucleation and growth

Calcite was precipitated in flow-through experiments at 25 ºC from supersaturated aqueous solutions in the presence of seeds of calcite and six different silicates: augite, basaltic glass, enstatite, labradorite, olivine, and peridotite. The aim of the experiments was to determine how calcite nucleation and growth depends on the identity and structure of the growth substrate. Calcite saturation was achieved mixing a $CaCl_2$-rich solution with a $NaHCO_3$-Na_2CO_3 buffer in a mixed-flow reactor containing 0.5-2 grams of mineral grains. This led to a calcite saturation index of 0.6 and pH 9.1 for the reactive solution inside the reactor.

Although chemical conditions, flow rate and temperature were identical for all experiments, the onset of calcite nucleation and the amount of calcite being precipitated depended on the identity of the mineral substrate. With calcite as the growth substrate, new calcite crystals formed instantaneously. Calcite nucleated relatively rapidly on olivine, enstatite, and peridotite (mainly composed of Mg-olivine). Scanning Electron Microscope images showed silicate crystals to be almost completed covered with calcite coatings at the end of the experiments. Less calcite growth was found on labradorite and augite, and least on basaltic glass. In all cases, calcite precipitation occurs on the mineral substrate and not adjacent to them.

Results and Conclusion

These findings indicate that calcite nucleation and its subsequent growth depends on the crystal structure of the silicate substrate. Orthorhombic silicate minerals (olivine and enstatite) are the easiest for trigonal calcite to nucleate on. Monoclinic augite and triclinic labradorite show intermediate behavior, whereas basaltic glass with its non-ordered crystal structure is the least favorable platform for calcite growth. The results have implications for CO_2 mineralization in ultramafic and basaltic rocks [1,2] indicating that trigonal carbonates easier precipitate on crystalline rather than glassy rocks, but even glass surfaces can serve as a substrate for calcite nucleation.

Smart K_d-concept based on Surface Complexation Modeling

M. STOCKMANN[1]*, V. BRENDLER[1], J. SCHIKORA[1], S. BRITZ[2], J. FLÜGGE[2], AND U. NOSECK[2]

[1]Helmholtz-Zentrum Dresden-Rossendorf, D-01328 Dresden, Germany, m.stockmann@hzdr.de (*presenting author)
[2]GRS Braunschweig, D-38122 Braunschweig, Germany

Methodology

Sorption on mineral surfaces of sediments is one important retardation process for radionuclides to be considered in long-term safety assessments for radioactive waste repositories. Previously, the K_d-concept with temporally constant values was applied to describe the radionuclide retardation in the far field of a repository.

In this study, pre-calculated distribution coefficients (K_ds) based on surface complexation models (SCM) are implemented in the existing 3D transport program r³t [1]. The so-called smart K_d-values are calculated as a function of important environmental parameters to reflect changing geochemical conditions. Respective multi-dimensional K_d-matrices are generated and stored a-priori to any r³t run. The calculations follow a bottom-up approach, i.e. the sorption of an element on each single mineral phase contributes to the distribution coefficient for a sediment.

Results

As an exemplary proof-of-concept, the Gorleben site (a potential repository site in Germany) was selected. Figure 1 shows the 3D plot for the $\log K_d$-matrix of UO_2^{2+} in the upper aquifer (UAF) at the Gorleben site as a function of pH, [Ca], and [DIC] (logarithmic scale).

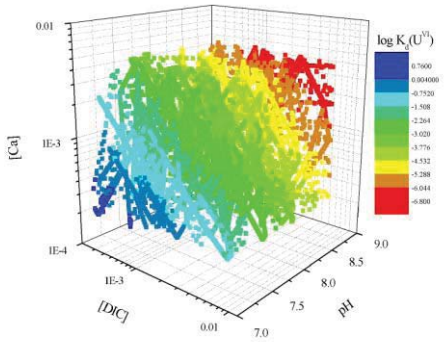

Figure 1: Multidimensional K_d-matrix for UO_2^{2+} in UAF as a function of pH, [Ca], and [DIC] (K_d in m³/kg, logarithmic scale).

These pre-calculated $\log K_d$-values vary between -6.8 and 0.75. Comparing to the temporally constant conservative $\log K_d$ of -2.7 from [2], which was previously used in r³t for the retention of UO_2^{2+} in fresh water in the upper aquifer at the Gorleben site, the resulting mean $\log K_d$ of -2.74 shows a good general agreement, but account now for geochemical variations.

Measurement of intact methane isotopologues, including $^{13}CH_3D$

DANIEL A STOLPER[1], ALEX L SESSIONS[1], JOHN M EILER[1]

[1]California Institute of Technology, dstolper@caltech.edu

Methane (CH_4) is both a significant greenhouse gas and resource. Its present and past cycling can be studied through measurements of concentration and/or bulk isotopic ratios ($^{13}C/^{12}C$, D/H, and $^{14}C/^{12}C$). Currently, isotope ratios are measured by mass spectrometric analysis of H_2 and CO_2 produced from CH_4, or by spectroscopy of CH_4. However, the interpretation of bulk isotopic variations of CH_4 are often equivocal, necessitating additional tracers.

We have developed a technique for mass spectrometric analysis of several isotopologues of intact CH_4, including $^{12}CH_4$, $^{13}CH_4$, $^{12}CH_3D$, and $^{13}CH_3D$ (and the method can be extended to others). Our most novel capability is the analysis of the multiply substituted isotopologue $^{13}CH_3D$, which is expected to differ relative to a random isotopic distribution due to kinetic isotope effects, mixing processes, and as a function of temperature at equilibrium. Measurements of $^{13}CH_3D$ concentrations (along with the singly substituted species) could elucidate the formation temperatures of thermally generated CH_4, discriminate between sources of CH_4 to the atmosphere (e.g., microbial vs thermogenic gas), and help to characterize CH_4 chemistry in the atmosphere where potentially large enrichments are expected (e.g., [1], [2], [3]).

Measurement of intact CH_4 requires a mass spectrometer capable of separating CH_4 species both from water and from internal isobars (CH_4 adducts, fragments, and isotopologues). We show here the initial results and capabilities of such measurements using the MAT 253 Ultra prototype high-resolution gas-source mass spectrometer. We reproduced δD values of known samples to within 0.2 ‰ (1 s.e. = 0.1‰). In addition to demonstrating accuracy, this result reveals that the method may result in improved precision for δD measurements of CH_4 relative to conventional techniques. We have measured ratios of $^{13}CH_3D$ to mass 17 species ($^{13}CH_4$, $^{12}CDH_4$, and $^{12}CH_5$) to better than ±0.4 ‰ (1 s.e.); this value reflects counting statstics and should be improved with longer counting times. The critical enabling feature of our mass spectrometer is the ability to cleanly separate a portion of the $^{13}CH_3D^+$ peak from that of $^{13}CH_5^+$ (shown in Figure 1.)

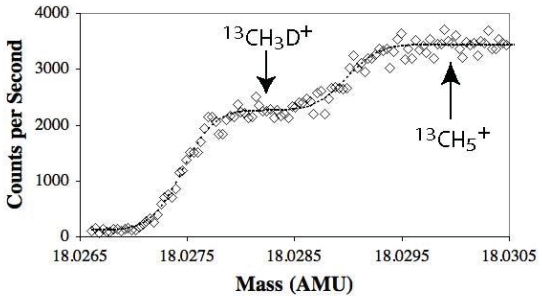

Figure 1: Peak scan of mass 18 CH_4 with a model fit through the data. Water is sufficiently resolved as to not appear at this scale.

The Unsaturated (Vadose) Zone—the Where of Weathering

DAVID A. STONESTROM[1*], MARJORIE S. SCHULZ[2], AND ARTHUR F. WHITE[3]

[1]US Geological Survey, Menlo Park, CA, USA, dastones@usgs.gov (*presenting author)
[2]US Geological Survey, Menlo Park, CA, USA, mschulz@usgs.gov
[3]US Geological Survey, Menlo Park, CA, USA, afwhite@usgs.gov (emeritus)

The unsaturated zone (UZ), that portion of the Earth's crust between land surface and the regional water table—the latter being defined as the surface below which pore-water pressure is persistently above atmospheric—is the vital bio-geochemical reactor that sustains the planetary critical zone. Weathering reactions in the UZ sustain life by releasing bioessential elements such as potassium, calcium, and magnesium that are mostly locked up in solid mineral phases during the bioaccessible parts of the rock cycle. The UZ sits at the intersection of the lithosphere, atmosphere, and terrestrial biosphere, acting as a highly non-linear regulator of water, carbon, and nutrient dynamics. It is the key interface controlling hydrospheric influences on land based life. UZ water is the mobile solvent that delivers aqueous reactants and removes aqueous products from the sites of weathering reactions. It also partitions the pore space within the evolving geometry of soil structure, thereby controlling crucial pore-geometric relations including proximal and long-range connectedness (topology) of gas and liquid phases. The resulting dynamics mediate residence times, redox states, complexation, and chemical activity, along with fluid permeabilities and solute dispersivities. Hysteresis in the relations between water content θ and matric pressure ψ acts to partially constrain fluxes of water (and heat) to the uppermost UZ. This provides plant-root microcosms more opportunity for water and nutrient extraction and moderates weathering reactions by controlling equilibrium versus kinetic control of chemical processes. UZs may be classified according to water-table depth, water balance, and water-flux variability in time and space. These determine whether UZs act as (1) rapid, disequilibrium pass-through conduits with little opportunity for weathering reactions, (2) equilibrium controlled static reservoirs of water and solutes where not much is happening, or (3) totally happening places essential for oxygen-intensive life.

The ideas herein stem from many fruitful discussions and collaborations with Art White, Jorie Schulz, Alex Blum, Jennifer Harden, Sue Brantley, Kate Maher, Michelle Walvood, Bridget Scanlon, Jim Constantz, John Nimmo, Dave Prudic, Amanda Garcia, Brian Andraski, Jacob Rubin, Laurie Flint, Alan Flint, and others.

Vive la Weathering. Vive l'UZ Science. Vive l'Art!

The Fingerprint of Geologic Carbon on Glacial/Interglacial Marine Carbonate Chemistry and Atmospheric CO_2

LOWELL STOTT[1*]

[1] University of Southern California, Earth Sciences, stott@usc.edu (* presenting author)

The rise in atmospheric pCO_2 during the last glacial termination was accompanied by a 190‰ decrease in surface ocean $\Delta^{14}C$ between 17 to 10 kyB.P., which cannot be explained without calling upon an input of ^{14}C-depleted carbon from either a formally isolated deep ocean reservoir or input of geologic carbon. There are now enough marine $\Delta^{14}C$ records spanning the deglaciation to make clear that Pacific deep water $\Delta^{14}C$ did not track the atmosphere whereas the $\Delta^{14}C$ of intermediate waters did, except in the eastern equatorial Pacific (EEP) where there were large negative excursions in $\Delta^{14}C$. To explain the contrasting deep and upper ocean deglacial $\Delta^{14}C$ histories a new hypothesis calls upon a release of ^{14}C-depleted CO_2-rich hydrothermal fluids at intermediate water depths as the ocean warmed during the deglaciation. Here we use an Earth System model of intermediate complexity (cGENIE) with new geochemical records from the tropical Pacific to test this hypothesis. We show that a total release of 1400Gt of ^{14}C-dead DIC into intermediate waters of the EEP (700Gt) and Arabian Sea (700Gt) causes $\Delta^{14}C$ changes throughout the ocean that agree with observations. The injection also causes a ~40μmol/kg drop in $[CO_3^{=}]$ of tropical surface waters. Trace metal proxies of $[CO_3^{=}]$ and carbonate preservation data are presented for the EEP that document a transient decrease in $[CO_3^{=}]$ in association with the deglacial $\Delta^{14}C$ excursions. This carbonate preservation event is associated with elevated V/Ca, Zn/Ca and Cu/Ca in planktonic foraminifera from the EEP.

Taken together, the model and geochemical data provide strong support for the hypothesis that there was a release of geologic carbon during the deglaciation that contributed as much as 60ppm to the rise in atmospheric pCO_2. If the geochemical signatures documented across glacial Termination 1 are found to occur at earlier glacial terminations as well, these findings will have profound implications for our understanding of glacial/interglacial CO_2 variability. Hydrothermal systems in the oceans may act as a CO_2 capacitor, regulating storage and release of carbon, and in doing so, affect the radiative balance that determines Earth's climate on orbital time scales.

Inter-mineral Mg isotope fractionation in mantle xenoliths

ANDREAS STRACKE[1,2*], EDWARD T. TIPPER[3,2], MICHAEL BIZIMIS[4]

[1]Westfälische Wilhelms Universität, Münster, Germany, stracke.andreas@uni-muenster.de (* presenting author)
[2]ETH Zürich, Zürich, Switzerland
[3]University of St. Andrews, St Andrews, U.K., ett@st-andrews.ac.uk
[4]University of South Carolina, Columbia, SC, U.S., mbizimis@geol.sc.edu

The bulk Mg isotope composition of the silicate Earth is homogeneous and identical within analytical error to that of chondritic meteorites [1-7]. Systematic fractionations among minerals in mantle peridotites [1,2,4,8-10] are resolvable, however, and are broadly consistent with theoretical predictions for high-T equilibrium Mg isotope fractionation [10]. Theory predicts that tetrahedral crystallographic sites have higher $^{26}Mg/^{24}Mg$ than octahedral sites; up to 0.5 – 0.8‰ for spinel – silicate pairs at 1000K [10], which is in agreement with recent data from two spinel peridotites [9].

Here we investigate the inter-mineral Mg isotope fractionation in 5 spinel peridotite and 5 garnet pyroxenite xenoliths from Salt Lake Crater, Hawaii. Calculated whole rock $\delta^{26}Mg$ compositions of both rock types are within error of those of bulk silicate Earth, suggesting that inter-mineral differences are due to equilibrium isotope fractionation. In the spinel peridotites, the $\delta^{26}Mg$ of olivine (ol), orthopyroxene (opx) and clinopyroxene (cpx) are indistinguishable. In the three measured olivine-spinel pairs, the spinels (sp) have consistently higher $\delta^{26}Mg$ values than the olivines, by 0.21 - 0.28‰. The sp-ol difference in $\delta^{26}Mg$ suggests an equilibration temperature of ca. 1700°C, considerably higher than the calculated opx-cpx mineral equilibration temperature of ca. 1100°C. The $\delta^{26}Mg$ of garnet in the garnet pyroxenites is consistently lower by 0.38 - 0.45‰ than in the coexisting cpx. Hence, the $\delta^{26}Mg$ values increase from garnet with a Mg coordination number of 8, to the octahedrally coordinated silicates (ol ≤ opx ≤ cpx) and the tetrahedrally coordinated spinels, consistent with coordination number exerting a first-order control on inter-mineral high-T equilibrium Mg isotope fractionation [10].

However, a strong positive correlation of $\delta^{26}Mg_{spinel}$ with the spinel Cr (Al) content or spinel Cr# shows that composition also influences the $\delta^{26}Mg$ values of individual minerals. The latter observation may explain the discrepancy between calculated equilibration temperatures based on mineral equilibria (opx-cpx) and Mg isotope fractionation ($\delta^{26}Mg_{ol-sp}$), and may hamper the use of spinel-silicate Mg isotope fractionation as a reliable geothermometer in magmatic rocks.

Tracing subduction erosion through arc chemistry in the central Mexican Volcanic Belt

SUSANNE M. STRAUB[1*], GEORG F. ZELLMER [2], ARTURO GÓMEZ-TUENA[3], YUE CAI[1], FINLAY M. STUART[4], CHARLES H. LANGMUIR[5]

Continental crust recycled via subduction erosion has been suggested to be a quantitatively important component that may overshadow the crustal contributions from subducted trench sediment to arc magmas at erosional convergent margins [1]. However, unlike the trench sediment that can be measured directly and linked to arc chemistry [2], the composition of eroded lower continental crust is essentially unknown. Hence, its identification in arc magmas poses a real challenge as signals of the eroded crust must be distinguished from those of the trench sediment and also from contamination by the overlying crust.

Here we present results of a comprehensive geochemical study from two Holocene high-Nb monogenetic arc volcanoes (Texcal Flow and V. Chichinautzin) that were erupted within ~1100 year and within only 6 km from each other. Major and trace element and Sr-Nd-Hf-Pb-He isotope systematics demonstrate that the basaltic and basaltic-andesitic magmas are mixtures of mantle and crustal materials. High $^{3}He/^{4}He$ of 6-7 R_a in equilibrium olivines, however, and high and increasing melt Nb (from 17 to 36 ppm) and Nb/Ta (from 16 to 19) with increasing melt SiO_2 preclude substantial assimiliation of the overlying crust. Combined Sr-Nd-Hf isotope data and trace elements argue against the trench sediment as an isotopic end member as this would require an unreasonably large loss of Nd (~50%) relative to Hf in the trench sediment. Alternatively, we propose that Sr-Nd-Hf-Pb isotope and trace element systematics may best be explained through melting of a subarc mantle that was infiltrated with crustal components recycled via subduction erosion from the lower Mexican forearc crust. The data suggest for this region a model in which the recycled eroded crust may dominate arc chemistry together with fluids released from the subducted igenous oceanic crust while the signals of the subducted trench sediment are largely eclipsed. This may be explained by the low volumeric flux of sediment in this region owing to the young age of the subducting plate.

The diagenetic history of marine sediments as revealed by C-S-Fe systematics

HARALD STRAUSS

Westfälische Wilhelms-Universität, Münster, Germany, hstrauss@uni-muenster.de

Marine sediments archive the products of primary productivity, subsequent mineralization of the sedimentary organic matter through microbial and/or inorganic processes, the input of detrital components, and the authigenic mineral formation within the sedimentary column. The C-S-Fe system constrains respective depositional as well as diagenetic aspects within marine sediments, frequently occurring under changing redox conditions. A diverse set of petrographic, geochemical, and isotopic proxy signals has evolved during the past fifty years with an ever increasing specificity. These proxy signals allow distinguishing between local/regional phenomena and perturbations of global geochemical cycles, both in modern sediments as well as for sedimentary rocks in the geologic record. Hartmann and Nielsen [1] were among the very early researchers applying some of these proxy signals in their study of marine coastal sediments from the Kiel Bight, Baltic Sea, northern Germany.

Abundances of carbon, sulfur, and iron, organic and inorganic carbon isotopes, multiple sulfur isotopes of sulfides and sulfates, and oxygen isotopes for sulfate were measured in pore waters and sediments collected during a revisit of these Baltic Sea sediments some 45 years after the original study. Respective proxy signals reveal a complex diagenetic evolution that is largely governed by bacterial sulfate reduction. Key features include a sizeable sulfur isotopic fractionation of up to 64‰ between sulfate and sulfide. The downcore evolution towards ^{34}S-enriched sulfur isotope values for both sulfur species in the pore waters suggest the development of sulfate limiting conditions. Disproportionation of sulfur intermediates cannot be excluded and would be consistent with the observed large fractionations in $\delta^{34}S$ as well as from a combination of $\delta^{34}S$ and $\Delta^{33}S$. Conclusions derived here overall confirm interpretations made by [1]. At the same time, an expanded analytical approach allows for more detailed information about microbially driven processes in the pore water realm and the sediments.

Microbial characterization of groundwater from boreholes at CRL

SIMCHA STROES-GASCOYNE[1*], DANIELLE BEATON[2], MARILYNE AUDETTE-STUART[2], KAREN KING-SHARP[2], AMY FESTARINI[2], CONNIE HAMON[1], STEVE ROSE[2] AND LEE BELLAN[2]

[1]Atomic Energy of Canada Limited, Whiteshell Laboratories (WL), Pinawa, MB, Canada, stroesgs@aecl.ca (* presenting author)

[2]Atomic Energy of Canada Limited, Chalk River Laboratories (CRL), Chalk River , ON, Canada

Purpose of study and methods

A microbiological characterization study was carried out on groundwater samples from various depths in older (CR9, CR18) and recently drilled boreholes (CRG-1, CRG-2, CRG-4A) at Chalk River Laboratories (CRL). This work was carried out as part of a technical feasibility study assessing the suitability of the CRL site to host a proposed Geologic Waste Management Facility for CRL's radioactive non-fuel waste.

A multi-analysis approach was used to characterize the water samples for microbial content. Analyses included: (1) Geochemical analysis for major cations, anions, pH, Eh and DOC. (2) Total (live + dead) and viable (live) cell counts using a number of different dyes and probes. (3) Phospholipid fatty acid (PLFA) analysis for viable cells and community structure. (4) Classic culturing for heterotrophic aerobic and anaerobic bacteria, nitrate-utilizing and -reducing bacteria and sulphate-reducing bacteria. (5) Identification of isolates using BIOLOG GEN III. (6) Identification of microbes using DNA extraction and (pyro-) sequencing.

Result and Conclusions

The water samples contained a total population of 10^4 to 10^5 cells/mL of which generally only < 1% could be cultured. However, a large percentage of the total population was viable and showed some signs of metabolic activity. Identification results for isolates showed a dominance of *Pseudomonas*, *Sphingomonas* and *Acidovorax* species. Identification based on DNA sequencing showed a dominance of different species. The combined microbial and geochemical results suggest an oligotrophic biogeochemical system in the CRL groundwater. The presence of a population of viable but not culturable cells implies that, given an increased source of electron donors (e.g., DOC) and electron acceptors (e.g., metals) leached from the waste, microbial activity could increase significantly in a potential GWMF. This could have both positive effects (e.g., lower Eh and radionuclide (RN) solubility) and negative effects (e.g., increased RN mobility, ^{14}C-containing gas production). Ultimately the biogeochemical system is expected to return to its original oligotrophic conditions but the rate at which this would occur is uncertain because waste leach rates and *in situ* microbial metabolic activity rates are unknown. This study illustrates that microbial effects need to be considered in the safety assessment of a deep geologic nuclear waste repository.

Biogeochemical Characterization of a Late Archean Sub-Seafloor Hydrothermal System, Dome Mine, Timmins, Ontario, Canada

Much of our understanding of early life on Earth is dependant on the characterization of habitable environments preserved in Archean terrains. One such example can be found in the Tisdale mafic volcanics and hydrothermally altered metasediments of the Abitibi greenstone belt in Northern Ontario [1]. These late Archean volcanics host greenstone quartz-carbonate vein gold desposits, which are characterized by iron-carbonate alteration from low-salinity, CO_2-rich hydrothermal fluids, resulting in the precipitation of carbonates such as dolomite and ankerite.

Previous work has identified endogenous molecular fossils within the 2,770-2,685 Ma Tisdale assemblage, suggesting the presence of a subsurface hydrothermal biosphere [1]. This study is focused on a unique set of 2,690-2679 Ma crustiform banded ankerite veins within the Tisdale mafic volcanics at the Dome mine, in Timmins. This ankerite horizon provides an opportunity for the characterization of an ancient sub-seafloor hydrothermal system and its potential biosphere. We are using multiple biogeochemical techniques to characterize the system, to elucidate its environmental conditions, genesis and evolution, as well as biomarkers, and any associations with gold mineralization.

XRD and IR-spectroscopy have identified compositional variations in the carbonate speciation and minerology of the ankerite horizon. These datasets in combination with SEM and stable C- and O- isotope analysis are being used to determine the degree of hydrothermal alteration, the fluid composition and genesis, and provide environmental constraints for the system. Extracted biosignatures are being characterized by GC-MS, stable C-isotope, and ToF-SIMS analysis.

An understanding of early earth habitable environments, the developement of methods for their characterization, and the identification of biosignatures is a key aspect in furthering the search for evidence of habitable environments and extant life on Mars [2]. In particular, given the detection of Fe-Mg carbonates on the Martian surface [3,4]. As well, this research has potential implications for the development of paleobiological vectors for mineral exploration.

Photochemistry of arsenite on ferrihydrite and goethite

NARAYAN BHANDARI[1], RICHARD J. REEDER[2], AND DANIEL R. STRONGIN[1,*]

[1]Department of Chemistry, Temple University, Philadelphia, PA 19122, USA (dstrongi@temple.edu)

[2]Department of Geosciences, Stony Brook University, Stony Brook, NY 11794, USA

The photochemistry of arsenite (As(III)) in the presence of the iron oxyhydroxides, ferrihydrite and goethite, has been investigated. Attenuated total reflection Fourier transform infrared spectroscopy (ATR-FTIR), X-ray absorption near edge structure (XANES), and solution phase analysis have been used to characterize the surface bound and aqueous phase species. Both ATR-FTIR and XANES show that the exposure of ferrihydrite or goethite to As(III) for up to 24 h in the dark leads to no change in the oxidation state of the adsorbed or aqeuous phase As species. Exposure of either the As(III)/ferrihydrite or As(III)/goethite system to simulated solar radiation results in the majority of the surface bound As(III) becoming oxidized to arsenate (As(V)). At a solution pH of 5, this conversion of As(III) to As(V) on ferrihydrite results in the partitioning of a stoichiometric amount of Fe(II) into the aqueous phase. The majority of the As(V) product remains bound to the ferrihdyrite surface. This chemistry on ferrihydrite is relatively similar in the absence or presence of dissolved oxygen. Also, in the ferrihydrite circumstance, the As(III) to As(V) conversion shows the characteristics of a self-terminating reaction in that there is a significant suppression of this redox chemistry before 10% of the total iron making up the ferrihydrite partitions into solution as ferrous iron. The self-terminating behavior exhibited by this photochemical As(III)/ferrihydrite system is likely due to the passivation of the ferrihydrite surface by the strongly bound As(V) product. In contrast, the As(III)/goethite system shows a different photochemical behavior in the absence or presence of dissolved oxygen. In the presence of dissolved oxygen at a solution pH of 5, results suggest that in contrast to ferrihydrite the majority of the As(V) product is in the aqueous phase and the relative amount of aqueous Fe(II) is significantly less than in the ferrihydrite circumstance. A possible reason for this experimental observation is that in the oxic environment Fe(II) on the goethite, which forms via the photoinduced oxidation of As(III), is oxidized to Fe(III) by dissolved oxygen resulting in the formation of reactive oxygen species that can lead to the further oxidation of As(III) in solution. Additional experiments suggest that this behavior is not observed on ferrihydrite at pH 5, due to the lower affinity of the surface for Fe(II), compared to goethite. Overall, the research has brought forward how differences in the surface properties of iron oxyhydroxides can result in changes in redox chemistry.

Characterisation of arsenic and trace metals in acid sulfate environments

JACQUELINE L. STROUD[1]* AND RICHARD N. COLLINS[1]

[1]School of Civil and Environmental Engineering, UNSW, Sydney, Australia, j.stroud@unsw.edu.au (* presenting author)

Contaminant mobilisation in acid sulfate environments

Disturbed acid sulfate environments pose a serious threat to water quality, ecosystem health and commercial activities. The interaction between hydro-biogeochemical factors leads to the discharge of sulfuric acid and toxic concentrations of dissolved contaminants including iron and aluminium to adjacent water bodies. Comparatively little is known about trace metals and arsenic mobilisation in these environments.

We evaluated the mobilisation of trace metals and arsenic in groundwater and adjacent drain waters during a 10-day rainfall event at our Tweed Valley field site, NSW, Australia. This site has previously been identified as a metal mobilisation hotspot. We used multi-piesometers, drain water autosamplers and Diffusive Gradients in Thin films (DGT) devices to monitor the temporal changes in contaminant mobilisation. Metal and metalloid concentrations were determined using ICP-MS, and arsenic speciation (As(III), As(V), DMA and MMA) was analysed using HPLC-ICP-MS. Changes in contaminant concentrations were compared to concomitant changes in redox potential, pH, anions and dissolved organic carbon concentrations in order to characterise mobilisation processes. Elevated concentrations of cadmium, zinc and arsenic (arsenate and arsenite) were detected, suggesting that trace metals and arsenic also contribute to the poor water quality in these environments. DGT devices were effective in metal and metalloid assessments, and we were able to measure the fluctuations in contaminant concentrations downstream from the metal mobilisation hotspot.

Outcomes

These results will help us to understand the mobilisation and transport processes of trace metals and metalloids in these environments and better predict their risk to water quality.

Uraninite (UO_2) is the most abundant uranium ore mineral, the product of proposed bioremediation strategies for uranium-contaminated soils and aquifers, and its synthetic analog is the primary constituent of most nuclear fuels (1-3). This material is known to incorporate interstitial oxygen up to a stoichiometry of $UO_{2.25}$ without disruption of the uranium lattice, but the structural details of the process are the subject of ongoing study and debate (e.g., 4-5). Because the solubility and dissolution kinetics of uraninite depend heavily on the oxidation state of uranium, understanding the mechanims of UO_2 surface oxidation and corrosion is essential to predicting its stability in the environment throughout the nuclear fuel cycle. To date, however, no study has addressed this process at the molecular scale at atmospheric pressure and room temperature.

We present results of a crystal truncation rod (CTR) x-ray diffraction study of the UO_2 (111) surface. This hard x-ray technique is ideally suited to such studies, because it can probe the structures of interfaces at atmospheric conditions and buried below liquids and solids. The single-crystal surface was prepared under anoxic conditions, measured under dry helium, then exposed to dry O_2 gas and measured at several time points over the course of two weeks. The pristine surface is characterized by minimal contraction of the uppermost atomic layers and the addition of an oxygen layer above the vacuum-terminated surface. Following exposure to dry O_2, an oxidation front proceeds into the crystal, intersitial oxygen atoms penetrate to depths of 30 Å or more, U-U layer distances contract (consistent with bulk uraninite oxidation), and an ordered superlattice, which is commensurate with the underlying bulk, forms. These results demonstrate that the solid state diffusion of oxygen into UO_2 and UO_{2+x} surfaces is facile and that ordering kinetics are relatively rapid, even at room temperature.

Ab initio thermodynamics, which combines density-functional theory calculations with macroscopic thermodynamics, provides insight into the energetics, bonding, and oxidation processes that occur as oxygen reacts with the surface and diffuses into the solid. Surface oxidation results in formation of a U^{+6} cation triply bonded to single oxygen adatoms. Subsurface oxidation is predicted to contract U-U layers consistent with experimental observations.

A COMPARISON OF GLASS AND MINERAL INCLUSIONS IN QUARTZ AND ZIRCONS FROM KEWEENAWAN RHYOLITE FLOWS

JAMES STUDENT[1*] AND ALEXANDRA MASSAD[2]

[1] Central Michigan University, Mount Pleasant, MI 48859, USA stude1jj@cmich.edu (* presenting author)

[2]Department of Geological Sciences, University of Texas at El Paso, El Paso, TX 79968, USA

Melt inclusions (MI) and a wide-variety of mineral inclusions are well preserved in quartz phenocrysts and zircons from porphyritic rhyolite flows of the Midcontinent Rift System. The inclusions and their host minerals have been examined using EPMA, cathodoluminescence microscopy (CL), SEM/EDS, and LA-ICP-MS. Rhyolite from the North Shore Volcanic Group, the Porcupine Mountains, the Portage Lake Volcanics, and the Michipicoten Island Formation were utilized in this study. Inclusions hosted by quartz and zircons were studied in thin sections and grain mounts, respectively.

The MI were categorized based on their phase assemblages and preservation style [1]. CL images of the host quartz phenocrysts reveal multiple stages of growth and dissolution. Ti contents (measured by EPMA and LA-ICP-MS) in the quartz vary widely and range from <15 to 280 ppm. Using a modified TitaniQ method [2], this corresponds to a temperature change of more than 250 °C in individual samples (using $aTiO_2$=1 and isobaric conditions). Presently there are still too many variables to constrain the absolute crystallization temperatures. The MI were analysed by LA-ICP-MS for major oxides and trace elements including Zr and Ti. The ranges in zircon saturation temperatures calculated using the model described by [3] agree with the TitaniQ temperature ranges. Unfortunately, it has been difficult to confidently constrain the Ti content (for TiO_2 activity calculations) in the MI using LA-ICP-MS analyses. This is due to the complex nature of the Ti distribution in the surrounding host quartz. The occurrence and distribution of zircon as inclusions in the quartz does suggest coeval crystallization of both phases.

An examination of SEM/EDS spectra of inclusions in zircon revealed at least 18 different minerals. They include K-spar, plagioclase, pyroxene, quartz, Fe-Ti oxides, apatite, monazite, and several different sulphides. Mineral inclusion assemblages in the zircons are distinct in each of the rhyolite samples that were studied. The mineral inclusions occur as isolated grains within zircon and inside glass bearing MI in zircon. While the majority of the inclusions appear to be primary and pristine, some of mineral and MI show evidence of modification by secondary processes. Utilization of the trace element chemistry of the mineral and MI trapped in zircon can potentially be used to better constrain the activity of TiO_2 in the melt during crystallization. This approach can lead to a more accurate estimate of quartz crystallization temperatures for Keweenawan rhyolite.

Enhanced nutrient consumption in the glacial Antarctic

A.S. STUDER[1*], A. MARTINEZ-GARCIA[1], M. STRAUB[1], D.M. SIGMAN[2], R. GERSONDE[3], G.H. HAUG[1]

[1]Department of Earth Sciences, ETH Zurich, Zurich, Switzerland ([*]anja.studer@erdw.ethz.ch, alfredo.martinez-garcia@erdw.ethz.ch, marietta.straub@erdw.ethz.ch, gerald.haug@erdw.ethz.ch) ([*] presenting author)
[2]Department of Geosciences, Princeton University, Princeton, NJ, USA (sigman@princeton.edu)
[3]Alfred Wegener Institute, Bremerhaven, Germany (Rainer.Gersonde@awi.de)

Productivity in surface waters leads to the sequestration of carbon dioxide (CO_2) in the deep ocean, a process known as the ocean's "biological pump." The Antarctic Zone of the Southern Ocean represents the major "leak" in this pump. Nutrient- and CO_2-rich waters are brought to the surface, allowing CO_2 to outgas. The scarcity of iron and/or light reduces phytoplankton productivity, leaving some of the major nutrients (nitrate, phosphate) unused. Those "preformed" nutrients are subducted into the subsurface without re-sequestering CO_2 into the deep ocean, introducing a degree of inefficiency to the global biological pump. To explain lower glacial atmospheric CO_2, it has been suggested that there was a decrease in the exchange between polar surface water and ocean interior, described as "polar ocean stratification." This physical change would have, in itself, reduced the outgassing of CO_2, and it may have increased the fraction of nutrients utilized in Antarctic surface ocean, rendering the region a more efficient part of the global biological pump. The first efforts to reconstruct nitrate utilization in the Antarctic measured nitrogen (N) isotopes on bulk sediment, but this can be biased by diagenesis and/or allochthonous N input. Subsequent studies measured the N isotopes encapsulated in diatom frustules ($\delta^{15}N_{db}$), which carry the pristine signal, but results have varied. Here, we report a consistent increase in $\delta^{15}N_{db}$ into the last two glacial periods, with abrupt decreases during the subsequent deglaciations. In contrast, the descent from interglacial to glacial conditions was more gradual/stepwise, reminiscent of the general atmospheric CO_2 pattern. The first major $\delta^{15}N_{db}$ increase into the last ice age occurred at the MIS 5e/5d transition, coincident with the major decline in Antarctic temperature and the first 40 ppm step in ice age CO_2 decline. In addition to our analysis of the total biogenic opal <100 µm, we analyzed the $\delta^{15}N_{db}$ of two distinct diatom species assemblages. Their $\delta^{15}N_{db}$ values are offset by roughly 1‰ but show the same trends through time. This rules out the possibility that the glacial-interglacial $\delta^{15}N_{db}$ changes measured on the total diatom community are caused by changing diatom species composition, a concern that had been raised previously.

Noble gas radionuclides in Yellowstone geothermal gases

We collected and analyzed noble gas radionuclides (^{39}Ar, half-life = 269 yr; ^{81}Kr, half-life = 229,000 yr; ^{85}Kr, half-life = 10.8 yr) in gases from four geothermal features at Yellowstone National Park (Beryl Spring, Frying Pan Spring, Ojo Caliente Spring, and Mud Volcano). In the field, condensation of water vapor and chemical stripping of CO_2 were done to reduce the samples to manageable volumes which were compressed into gas cylinders. Separations of Kr and Ar from gas samples were performed by existing methods [1,2]. Kr radionuclides were measured by atom-trap trace analysis at Argonne using ATTA-3 [3], and ^{39}Ar was measured by low-level counting at Bern [2].

Isotopic abundances of ^{39}Ar in all four samples were 4 to 6 times higher than atmospheric, indicating substantial contributions from subsurface nucleogenic production, as reported earlier [4]. ^{81}Kr isotopic abundances were not significantly different from atmospheric. ^{85}Kr isotopic abundances were 0.55 to 0.96 times atmospheric, possibly indicating contributions from recent groundwater recharge (≤ 10 yr) and/or contributions of both ^{39}Ar and ^{85}Kr from subsurface production at a ratio typical of that in granitic rock (see Figure).

Residence times of the upper low-arsenic aquifers in Bangladesh at the onset of increased abstraction

M. STUTE[1,2*]. I. MIHAJLOV[1], P. SCHLOSSER[1], K.M. AHMED[3] AND A. VAN GEEN[1]

[1]Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, USA, martins@ldeo.columbia.edu (*presenting author)

[2]Barnard College, New York, NY, USA

[3]Dhaka University, Dhaka, Bangladesh

Elevated levels of dissolved arsenic in shallow aquifers in the Bengal basin will result in increased use of deeper, currently low-arsenic aquifers. Compared to the shallow aquifers, relatively little is known about the flow dynamics of the deeper systems (>100 m depth).

Radiocarbon, ^{3}H, stable isotope, and noble gas data were obtained from both aquifer systems in our field area in Araihazar, 25 km east of Dhaka, Bangladesh. Noble gas temperatures of shallow groundwater generally reflect current water temperature at the water table despite elevated CO_2 (up to 12%) and depleted O_2 concentrations in the unsaturated zone. ^{3}H and $^{3}H/^{3}He$ data are consistent with recharge during the past 50 years. Most of the deeper groundwater (>100m depth) underlying the high-arsenic zone is ^{3}H free; and radiocarbon, stable isotope, and noble gas data indicate that recharge likely occurred at the transition between the late glacial period and the Holocene, a time of major changes in sea level, vegetation, and climate.

The relatively high residence time of water in the aquifer suggests a low recharge rate (cm's/year) until large-scale groundwater pumping for municipal supplies began in Dhaka in the 1960s.

Increased usage of this resource will result in higher recharge rates and might cause leakage from shallow high-arsenic aquifers and needs to be considered in management of water resources in Bangladesh.

Modulation of the product of U(VI) reduction by phosphate and calcium

MALGORZATA STYLO[1]*, DANIEL S. ALESSI[1], JUAN S. LEZAMA-PACHECO[2], JOHN R. BARGAR[2] AND RIZLAN BERNIER-LATMANI[1]

[1]Environmental Microbiology Laboratory, Ecole Polytechnique Federale de Lausanne, EPFL, Lausanne CH 1015, Switzerland, malgorzata.stylo@epfl.ch (*presenting author)

[2]Stanford Synchrotron Radiation Lightsource, Menlo Park, CA 94025, USA, bargar@slac.stanford.edu

One bioremediation strategy for uranium-contaminated aquifers involves the enzymatic reduction of soluble U(VI) to less mobile U(IV) species. The mineral uraninite, $UO_{2(s)}$, is considered to be the most desirable product of bioremediation due to its relative stability under reducing conditions. However, it has been shown repeatedly that uraninite is not the sole product of U(VI) reduction. Among these other U(IV) products are monomeric U(IV) species, believed to coordinate to bacterial biomass via phosphate and/or carboxylate groups and likely to be less stable than uraninite. For bioreduction to be a viable remediation strategy, it is crucial to pinpoint the factors promoting the formation of uraninite versus monomeric U(IV). Investigations to date have suggested that certain solutes, including PO_4^{3-} and Ca^{2+}, lead to preferential formation of monomeric U(IV). However, the mechanism of this process remains unknown.

In this study, we examine (1) the influence of PO_4^{3-} and Ca^{2+} on the product of U(VI) bioreduction and (2) the fate and behavior of those solutes during U(VI) reduction. Uranium L_{III} edge X-ray absorption spectroscopy and a wet chemical extraction technique were used to quantify the relative contribution of these two U(IV) species in systems in which the solute concentrations were systematically varied. We initially hypothesized that Ca^{2+} shields PO_4^{3-} from negatively charged groups and thus allows the binding of phosphate to the cell wall and the complexation of U(IV) by phosphate, leading to preferential monomeric U(IV) formation. To test this hypothesis, we measured the concentration of the two solutes during U(VI) reduction.

The results confirm that the U(IV) product of bioreduction is a mixture of uraninite and monomeric U(IV). The presence of calcium enhances the fraction of monomeric U(IV) produced. Moreover, even a low concentration of phosphate (1.9 mg/l) promotes greater formation of monomeric U(IV). However, the contribution of monomeric U(IV) does not change with increasing concentrations of this solute. The combination of calcium and phosphate results in a close to pure monomeric U(IV) product. Surprisingly, the aqueous concentrations of PO_4^{3-} or Ca^{2+} during U(VI) bioreduction are constant, suggesting little binding of these solutes to biomass. Hence, the direct association of these solutes with biomass cannot account for the observed effect. This suggests an indirect influence of phosphate and calcium on biological controls over the product of U(VI) reduction. For example, the production of bacterial extracellular polymeric substances could be limited by these solutes, restricting the number of nucleation sites for uraninite precipitation and promoting the formation of monomeric U(IV).

Our work provides a first glimpse into the complexity of the influence of geochemical factors on the biological controls of U(IV) product formation.

Solubility of Palladium (Pd) in Hydrocarbons: Application to Ore Genesis

ICHIKO SUGIYAMA[1]* and ANTHONY WILLIAMS-JONES[1]

[1]Department of Earth and Planetary Sciences, McGill University, Montreal, Quebec, ichiko.sugiyama@mail.mcgill.ca (*presenting author)

In natural systems, the platinum group elements (PGE) are commonly associated spatially with hydrocarbons. For example, pyrobitumen in the Kupferschiefer, Poland, has been shown to have high concentrations of Pd and Pt [1]. Black shales in South China likewise have been shown to contain elevated Pd and Pt (0.4 ppm Pd and 0.3 ppm Pt in the Zunyi deposit) [2]. These observations and preliminary experiments showing that crude oils can dissolve metals to potentially exploitable concentrations, suggest that liquid hydrocarbons could constitute important ore fluids [3]. The objective of this research is to experimentally determine the solubility of Pd in selected organic compounds known to be important constituents of natural liquid hydrocarbons, and thereby contribute to the body of knowledge on ore forming processes involving hydrocarbons. Approximately 40 to 50% of crude oil is composed of paraffins, including straight chain alkanes. In view of this and the fact that Pd is known to have a strong affinity for sulphur (some crude oils contain appreciable sulphur), we have investigated the solubility of Pd in dodecane and dodecanethiol.

Our experiments were performed in light-weight titanium autoclaves treated with nitric acid to produce an inert internal surface coated with TiO_2, and involved measuring the solubility of palladium metal in dodecane and dodecanethiol at 150 °C. The durations of the experiments ranged from 15 to 60 days. After completion of an experiment, the autoclave was quenched, and samples of the quenched solutions, and solutions used to wash the autoclaves (Pd commonly precipitated on the surface of the autoclave), were analyzed for Pd using NAA.

The concentration of Pd in dodecane was 0.33 ppm ± 0.18 ppm and in dodecanethiol was 0.90 ppm ± 0.45 ppm. These data show that that Pd is very soluble in these simple analogues of natural liquid hydrocarbons at temperatures commonly encountered in oil reservoirs, and that its solubility may be increased by complexation with thiol groups. We therefore conclude that liquid hydrocarbons could be very effective agents of Pd transport. This and the observed close spatial association of Pd with hydrocarbons in some PGE deposits suggest that liquid hydrocarbons could be important ore fluids for these deposits.

Exploration and enhancement of Sm/Nd carbonate geochronology

N.C. SULLIVAN[1], E.F. BAXTER[1], AND K. MAHER[2]

[1]Boston University, Boston, MA, norasull@bu.edu, efb@bu.edu
[2]Stanford University, Palo Alto, CA, kmaher@stanford.edu

Carbonate mineralization occurs across a broad spectrum of Earth's environment. Direct dating of carbonate minerals has become an important goal. Prior work has used the ^{14}C, U-series, and U/Pb isotope systems, but all have limtations. The Sm-Nd system has rarely been attmepted because most carbonate has very low $^{147}Sm/^{144}Nd$ ratios (<0.2), indicating limited geochronologic potential. A handful of published studies [e.g. 1,2,3] suggest that some high (0.2 to >1.0) $^{147}Sm/^{144}Nd$ carbonates do exist and that meaningful age information can potentially be extracted. These studies use mild acids to extract multiple carbonate separates from a single vein or deposit.

Our preliminary work has focused on three samples: a metamorphic calcite vein from Vermont, a hydrothermal dolomite from an ultramafic hosted talc deposit, also from Vermont, and a siderite from the Copper Chief Mine in Arizona. All three samples were put through an 8-step sequential extraction procedure (5.0, 4.2, 3.9, 3.5pH acetic, glacial acetic, 1.5N HCl, conc. HNO_3, HF) to isolate a high $^{147}Sm/^{144}Nd$ reservoir within the carbonates. All leachates were analyzed for Sm/Nd isotopes and major and trace element concentrations. Differences in Ca, Mg, Mn, Fe, and Sr between each leachate show that they represent different reservoirs. Electron microprobe data confirms there is subtle compositional zoning within the carbonate, at the micron scale, in all three samples.

As with previous studies, there is scatter in our "isochron" data. A 9-point isochron for the Vermont calcite vein shows a $^{147}Sm/^{144}Nd$ range of 0.09884-0.21180 yielding an age of 386 ± 34 Ma (MSWD 4.7). The high MSWD implies that some leached material did not form in isotopic equilibrium with the concordant carbonate fractions and therefore does not belong on the isochron. Assuming most of the carbonate is dissolved in the pH-controlled acetic leachates, and discarding the stronger acid extractions, we calculate a 4-point isochron age of 353 ± 27 Ma (MSWD 1.17). This age agrees with a published monazite age of 352.9 ± 8.9 Ma from the same outcrop [4]. The same effect is seen with the Vermont dolomite sample: when all leachates are considered the isochron yields an age of 508 ± 93 Ma (MSWD 41), but if we eliminate the stronger acid leachates the age becomes 657 ± 62 Ma (MSWD 1.05). The low MSWD implies this is a reliable "isochron", however the age is clearly older than Taconic or Acadian metamorphism expected for this sample. The siderite sample from Arizona shows a $^{147}Sm/^{144}Nd$ range of 0.21105-0.44711 and gives a reasonable Proterozoic age.

Our data shows that there are multiple chemical and isotopic domains present within each sample and our leaching procedure has begun to successfully isolate them. To refine sample selection and improve the reliability and precision of the carbonate ages, we are combining major and trace element data with electron microprobe images to identify the origin of the compositional variations and determine which acid extractions should be included in the isochron.

Halogens and noble gases subducted into the mantle: constraints from mantle wedge peridotites and olivines in arc lavas

HIROCHIKA SUMINO[1*], LISA ABBOTT[2], AYA SHIMIZU[3], RAY BURGESS[2] AND CHRIS J. BALLENTINE[2]

[1]GCRC, University of Tokyo, Tokyo, Japan, sumino@eqchem.s.u-tokyo.ac.jp
[2]SEAES, University of Manchester, Manchester, UK, lisa.abbott@postgrad.manchester.ac.uk, ray.burgess@manchester.ac.uk, Chris.Ballentine@manchester.ac.uk
[3]Tokyo Metropolitan Industrial Technology Research Institute, Tokyo, Japan, shimizu.aya@iri-tokyo.jp

Findings of subducted halogens and noble gases with seawater and sedimentary pore-fluid signatures in exhumed mantle wedge peridotites and eclogites from the Sanbagawa-metamorphic belt, southwest Japan [1, 2], as well as that of seawater-derived heavy noble gases (Ar, Kr, Xe) in the convecting mantle [3], challenge a popular concept that the water flux into the mantle wedge is controlled only by hydrous minerals in altered oceanic crust and sediment resulting in that subduction volcanism acts as a 'subduction barrier' which efficiently recycles volatile components contained in subducted slabs back to the Earth's surface. To verify whether and how such subduction fluids modify the composition of the mantle beneath subduction zones, we determined noble gas and halogen compositions of mantle wedge peridotites and olivines in arc lavas.

MORB-like $^{3}He/^{4}He$ and halogen ratios of olivines in lavas from the northern Izu-Ogasawara arc and a peridotite from the Horoman alpine-type peridotite complex in northern Japan indicate insignificant contribution to the mantle wedge of radiogenic ^{4}He and porefluid-like halogens both observed in the subduction fluids in the Sanbagawa samples to a depth ranging from 40 to 100 km [1, 2]. A hotter mantle wedge than those of mature subduction zones is proposed for the Sanbagawa subduction system [4], in contrast the Izu subducting slab is relatively cold and would therefore lose relatively little water at equivalent depths to other slabs [5]. This implies a relatively small amount of the pore water subduction fluids would be released from the Izu slab at a sub-arc depth (150-200 km) resulting in further subduction to great depths in the mantle.

The mechanism by which the seawater-like noble gases are delivered to the convecting mantle remains to be elucidated. Serpentinized lithosphere of subducting slab is probably the best candidate, because if the hydration of the lithosphere by pore fluids is operating in a closed system, subduction of the serpentinized lithosphere can transport pore-fluid derived noble gases and halogens into the deep mantle [1, 2]. This is supported by a recent observation of noble gases and halogens in exhumed serpentinites similar to that of seawater and sedimentary pore fluids [6].

Gold complexation within a halophilic cyanobacterium

KELLY L. SUMMERS*, JEREMIAH SHUSTER, MARTIN J. STILLMAN AND GORDON SOUTHAM

The University of Western Ontario, London, Canada
ksummer4@uwo.ca (* presenting author)

Introduction

Understanding the biogeochemical processes that transform gold are important in improving our ability to identify anomalies within dispersion halo environments, and potentially to recover trace amounts of gold [1]. Cyanobacteria have been implicated as potential gold nanofactories [2], and may contribute to gold nanoparticle formation in placer environments [3].

Octahedral platelet and nanoparticle gold precipitation has been observed after exposure of bacteria, e.g., *Plectonema boryanum* 485 [4], to $HAuCl_4$. The mechanism by which gold nanoparticles form within these cells is not well understood; however, adsorption of Au(I) to sulfur was reported following the addition of $HAuCl_4$.

Results and Discussion

X-ray analysis of near edge spectra (XANES), a synchrotron method, showed that the reaction of a halophilic *Plectonema sp*., with 0.5 mM $HAuCl_4$ reduced Au(III) to Au(I), which then formed complexes with sulfur. At higher gold concentrations (5 mM) Au(III) was reduced to elemental Au.

To investigate Au binding to known sulfur-containing proteins we probed glutathione (GSH), using Electrospray Ionization Mass Spectrometry (ESI-MS). GSH reduced Au(III) chloride to Au(I) and coordinated the Au through its cysteine residue (Figure 1). GSH binds Au as a monomer and as a dimer.

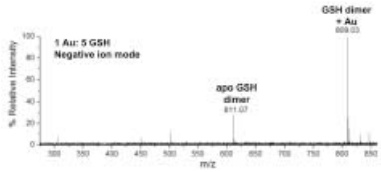

Figure 1. ESI-MS of a glutathione (GSH) complex with Au(I). $HAuCl_4$ added to 40 µM GSH for a final ratio of 1 Au: 5 GSH.

Cells reacted with 0.5 mM $HAuCl_4$ were lysed by liquid homogenization. Visualization of disrupted cells using phase contrast light microscopy revealed cell debris, and examination of whole mounts using TEM showed some cell envelope fragments. We recovered a soluble- and a cell envelope-fraction that bound Au. AAS and ESI-MS of the soluble fraction demonstrated the presence of low molecular weight Au-binding peptides. Occurrences of low molecular weight cysteine-rich metallothionein proteins in some species of marine cyanobacteria [5, 6] are targeted as possible gold-complexing organic compounds [7].

Microbial siderophore effects on Pb sorption and mineral nucleation

SARA SUMMERS[1]*, GELIANG SONG[2], BRUCE BUNKER[2], AND PATRICIA MAURICE[1]

[1]University of Notre Dame, Civil Engineering & Geological Sciences, Notre Dame, IN 46556, USA ssummer1@nd.edu (* presenting author), pmaurice@nd.edu

[2]University of Notre Dame, Physics, Notre Dame, IN 46556, USA gsong@nd.edu, bunker@nd.edu

Siderophores are low molecular weight organic ligands released by many aerobic microorganisms and plants to acquire Fe. These ligands may also bind other metals such as Pb, thus affecting Pb sorption and nucleation and growth of Pb-bearing minerals. In this study, a combination of batch experiments and XAS analysis was used to determine the effects of the trihydroxamate siderophore desferrioxamine B (DFOB) on Pb sorption to montmorillonite (mmt) clay. In the absence of DFOB, Pb sorption increased with increasing pH and decreased at higher background electrolyte ($NaClO_4$) concentrations. In some instances, Pb carbonates were detected in the sorption experiments, with nucleation perhaps enhanced by the presence of the clay. DFOB was observed to have complex pH- and ionic-strength dependent effects on Pb sorption to mmt. Ternary surface complexes were observed when both Pb and DFOB were present, under pH conditions at which Pb-DFOB complexes form in solution.

In order to explore more thoroughly Pb carbonate formation, experiments were conducted in which cerussite ($PbCO_3$) and/or hydrocerussite ($Pb_3(CO_3)_2(OH)_2$) were grown in the presence and absence of DFOB. DFOB was found to strongly affect the crystal size and habit of the Pb(hydroxy)carbonate precipitates. XAS analysis of structure is ongoing.

Bacterial Necromass as a driver of bacterial weathering

STEPHEN SUMMERS*[1,2], CHARLES S. COCKELL[3] AND ANDREW S. WHITELEY[2]

[1]Department of Planetary Science, The Open University, UK, stemme@ceh.ac.uk (* presenting author)

[2]Molecular Microbial Ecology Laboratory, Centre for Ecology & Hydrology, UK, aswhi@ceh.ac.uk

[3]School of Physics and Astronomy, University of Edinburgh, UK, c.s.cockell@ed.ac.uk

Background

The rock – soil interface (critical zone) is where many crucial geochemical processes occur. This region of the Earth's crust is an important source of nutrients that are required for life; however these are locked away in minerals unavailable to most biota. Recent studies have shown that bacteria can play a pivotal role in the release of these elements in a biologically available form [1, 2]. Many bacteria that show the ability to weather minerals are known to be heterotrophic [3], yet the environments that are most significant when discussing weathering are limited in organics. We have investigated the question: can heterotrophic bacteria in the critical zone use isotopically labelled bacterial necromass as a source of carbon? Plants have been shown to actively select for bacterial communities in rhizosphere by manipulating the environment and providing nutrients [4, 5], yet where does organics originate in areas known to have significant weathering but lacking in plants.

A lake site in Skorradalur, Iceland that has been shown to have significant rates of weathering at locations in some cases devoid of plants was investigated. We show that necrotic bacterial matter is a source of carbon for the organisms in the critical zone. Some of this necromass may be accounted for by fresh bacterial input during spring snowmelt.

Results and Conclusions

Stable isotope probing was used to show that most bacteria in the critical zone are heterotrophic and able to utilize bacterial necromass to drive metabolic activity. Exceptions to this were of Nitrospirales, some of which are lithoautotrophic [6] and Rhizobiales some of which are methanotrophic and are capable of using methyl alcohol and methane as a sole carbon source.

Using flow cytometry observed cell concentrations within snow packs covering sample site were measured to be up to 4.4 $x10^5$ cells per millilitre. This is a substantial influx of fresh organic matter each spring as snow melts.

U-Pb ages and Sr–Nd isotopic compositions of perovskite from the Yakutian kimberlites, Siberian Craton

JING SUN[1*], FU-YUAN WU[1], CHUAN-ZHOU LIU[1]

[1]Institute of Geology and Geophysics, Chinese Academy of Sciences, sunjing@mail.iggcas.ac.cn (* Presenting author)

Perovskite in kimberlites commonly contain high contents of U, Sr and Nd, and thus could provide effective constraints on the emplacement age and Sr-Nd isotopes of kimberlitic magmas [1, 2]. In this study, perovskite have been selected from 38 kimberlites from 10 fields in the Yakutian area, Siberian Craton, and analysed in-situ by LA-MC-ICPMS method. The obtained perovskite U-Pb ages suggest that kimberlites in the Yakutian field were emplaced in four episodes, ~420 Ma, ~360 Ma, ~220 Ma and ~160 Ma. Different kimberlite pipes in the same field were emplaced at the same time. Furthermore, all the diamondiferous kimberlites in Yakutian field were erupted around 360 Ma. The perovskites display $^{87}Sr/^{86}Sr$ ratios ranging from 0.70282 to 0.70375 and $^{143}Nd/^{147}Nd$ ratios from 0.51229 to 0.51271. The Sr-Nd isotope range displayed by perovskites is much narrower than that given by the whole-rock Sr-Nd isotopic compositions, i.e., 0.70318~0.70641 and 0.51048~0.51270, respectively [3]. On one hand, this suggests that whole-rock Sr-Nd isotope compositions of kimberlites have been contaminated during erupted route to surface. On the other hand, the relatively depleted Sr-Nd isotopic compositions shown by the perovskites also indicate that the Yakutian kimberlites belong to the Group-I kimberlite, and were derived from a similarly depleted mantle source.

[4] Isotope Laboratory, Department of Geosciences, University of Arkansas, Fayetteville, AR 72701, USA, fteng@uark.edu

The Bayan Obo REE-Nb-Th-Fe deposit, located in Inner Mongolia, North China, is the largest REE deposit and the second largest Nb deposit in the world. Its genesis is highly debated, ranging from carbonatite magmatism, alteration of sedimentary carbonate rocks, through deposition of carbonates on the sea floor accompanied by simultaneous metasomatism, to formation due to Caledonian subduction. None of the models so far proposed can fully explain all the major facts[1, 2]. The key problem is the relationship between carbonatite dykes, sedimentary dolomite, REE ore body and iron ore body. The REE ore bodies have trace element patterns and initial Nd isotope values identical to those of carbonatite dykes nearby, implying genetic links. Carbon isotopic composition of the carbonatite dyke is similar to the normal mantle $\delta^{13}C$ value of -5±2‰, but their O isotope compositions range from 13.9 to 16.4‰ for calcite, which are much higher than the mantle $\delta^{18}O$ value of 5.7±1.0‰. Consistently, the Mg isotopes of calcite carbonatite dykes range from mantle value to sedimentary values. All these indicate that the calcite carbonatite dykes have major sedimentary components, through recycling or assimilation, or a combination of both. By contrast, Mg isotopic compositions of ore bodies and dolomite carbonatite dykes are all close to mantle value, indicating major components from the mantle. The age of ore-forming monazite (330 to 760 Ma) is scattered with a main peak at about 400 Ma, roughly coincident with the evolution of the Central Asian orogenic belt nearby, but is much younger than carbonatite dykes (1300 Ma). Such large age dispersal indicates protracted mineralization driven by a persistent heat source for about 400 Ma. Considering that the host dolomite has high SiO_2 contents and carbon and oxygen isotopes distinctively different from those of carbonatite dykes, all these observations point to protracted steam-cooking of carbonatite by subduction released high-Si fluids, which leached Fe from the mantle wedge and, REE, Nb and Th from carbonatite, forming the Bayan Obo deposit in overlying sedimentary carbonate.

High-latitude aquatic ecosystems of the subarctic and arctic region have been shown to be influenced by climate fluctuations on short growing seasons for diatoms[1]. In our study[2], we reconstructed diatom production in Bothnian Bay, the subarctic northern tip of the Baltic Sea, by analysing Si isotopes in biogenic silica (BSi) perserved in sediments using MC-ICP-MS. The sediment core dated by ^{210}Pb gamma-ray spectrometer covered the period of 1820 to 2000, consisting of an unperturbed period from 1820 to 1950 and a second period affected by human activities from 1950 to 2000. The Si isotope values ranging between δ^{30}Si −0.18‰ and +0.58‰ in BSi were used to infer diatom production by using the Rayleigh model for fractionation patterns (Fig. 1). This exhibited that the production was correlated with air and water temperature, which in turn were correlated with the mixed layer depth. Especially after cold winters and deep water mixing, diatom production was limited. We also observed a shift of Si isotope values in the sediments after 1950, which is most likely caused by large scale damming of rivers which was heavily carried out between 1940 and 1960. Our findings offers a new way to estimate diatom production over much longer periods of time in diatom dominated aquatic systems, i.e. a large part of the world's ocean and coastal seas.

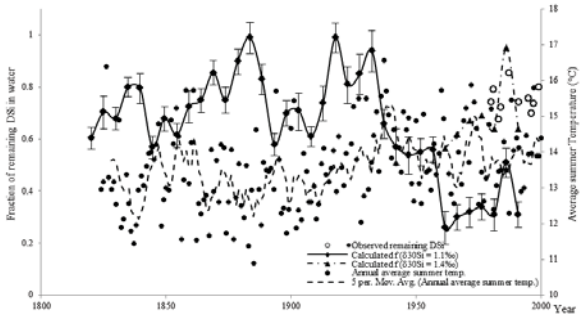

Figure 1: Fraction of the remaining DSi (f) in the water column reconstructed by the Rayleigh model, plotted with average summer air temperature through years. The inferior and superior error bars on f -values are the first quartile and third quartile for each f -value[2].

EXAFS studies of Fe speciation in natural stream waters

ANNELI SUNDMAN*, TORBJÖRN KARLSSON, PER PERSSON

Umeå University, Umeå, Sweden
anneli.sundman@chem.umu.se (* presenting author)
torbjorn.karlsson@chem.umu.se
per.persson@chem.umu.se

Introduction

Fe speciation in organic rich soils and aquatic environments depends on the interactions between Fe and natural organic matter (NOM)[1]. These interactions also have a large influence on the availability of nutrients such as phosphorus and thus on biological productivity in natural environments. Accordingly, the Fe-NOM interactions are of fundamental importance but the generally low Fe concentrations in natural stream waters prevent direct spectroscopic studies. In this work we have developed a gentle and non-invasive method for concentrating stream water samples using adsorption via electrostatic forces onto permanently charged particles. The Fe speciation in these samples was subsequently analyzed by means of EXAFS spectroscopy. Stream waters were collected at the well-studied Krycklan Catchment[2], 64°, 16'N, 19°, 46E, in northern Sweden, with Fe concentrations in the range of 8-40μM.

Results

EXAFS investigations of negatively charged metal model complexes concentrated by our method showed that no significant distortions were induced as compared to the solution structures, which is in accordance with previous results[3,4]. The local structures of Fe(III) complexes in stream water samples from a forested site were investigated by applying the same technique. The EXAFS results indicated that the Fe(III) speciation was dominated by mononuclear organic chelate complexes and hydrolyzed Fe with ferrihydrite-like structures. We have also performed EXAFS studies of Fe speciation in soil solutions and groundwater, and these results will also be discussed. Finally, the method is not limited to EXAFS and we will show how it can be applied to P-NMR studies of natural waters, facilitating differentiation between inorganic and organic phosphorus species.

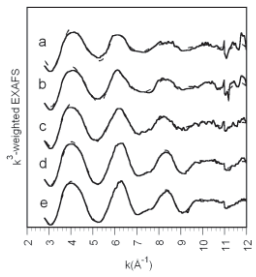

Figure 1. k^3-weighted EXAFS data from stream waters collected at the Krycklan Catchment[2], in February 2010, for a gradient series with a) 100%, b) 84%, c) 77%, d) 42% and e) 28% adsorption of Fe from the stream water. Solid lines represent experimental data and broken lines are fitted data.

Strontium stable isotope variations in lunar basalts

CHELSEA N. SUTCLIFFE[1*], KEVIN W. BURTON[2], IAN J. PARKINSON[3], DAVID COOK[1], BRUCE L. A. CHARLIER[3], DON PORCELLI[1], FATIMA MOKADEM[1], ALEX N. HALLIDAY[1]

In the terrestrial environment strontium stable isotopes may experience significant fractionation, both at low- and high-temperatures (e.g. [1,2]). Recent data for lunar basalts suggests that these rocks may possess light Sr stable isotope compositions ($\delta^{88}Sr$ = +0.16±0.07) [2] relative to mantle derived terrestrial basalts ($\delta^{88}Sr$ = +0.30±0.07) [2,3]. However, few samples have been analysed thus far, and at the ±50 ppm precision of these measurements, obtained using an MC-ICP-MS [2,3] smaller variations that may exist cannot be clearly resolved.

This study presents high-precision double spike TIMS data for $^{87}Sr/^{86}Sr$ (±5 ppm) $^{88}Sr/^{86}Sr$ (±10ppm) and $^{84}Sr/^{86}Sr$ (±20 ppm) for a suite of lunar basalts and highland rocks. These data indicate that there are significant and resolvable variations in $\delta^{88}Sr$ ranging from +0.30 for a ferroan anorthosite to +0.10 for a high-Ti Mare basalt. The lunar highland rocks (including anorthosites, troctolites and norites) possess a relatively small range of $\delta^{88}Sr$ values from +0.30 to +0.24 (0.06‰) whereas the mare basalts are distinctly lighter and encompass a larger range of $\delta^{88}Sr$ values, from +0.26 to +0.10 (0.16‰). The Mare basalts all possess negative Europium anomalies consistent with having been derived from a plagioclase depleted source, whereas the anorthosites are plagioclase rich. These observations suggest that the preferential incorporation of heavy Sr stable isotopes in plagioclase is the dominant mechanism controlling stable isotope fractionation in lunar basalts (similar to that seen in evolved terrestrial basalts [2]). Preliminary $^{84}Sr/^{86}Sr$ data suggests that the lunar rocks may possess slightly lighter compositions than terrestrial rocks, but this cannot be resolved at the present level of analytical precision. Taken together, these results clearly indicate that for the Moon primary igneous processes alone can generate significant variations in $\delta^{88}Sr$, without the biological fractionation and recycling that may occur on Earth.

Exclusive use of a soil gas hydrocarbon geochemistry to vector towards mineral deposits

DALE SUTHERLAND

Activation Laboratories Ltd., Ancaster, Ontario, Canada, dalesutherland@actlabsint.com

This Soil Gas Hydrocarbon (SGH) geochemistry has been scientifically shown to detect those hydrocarbons released from the decomposition of bacteria at the end of their life cycle. From a "you are what you eat" perspective, the 162 specific hydrocarbons in the C5 to C17 carbon series range that are able to be detected provide an information rich forensic signature of identification from the bacteria that were directly growing on specific types of mineral deposits.

The forensic signature has been tested through projects administered by the Canadian Mining Industry Research Organization (CAMIRO) as well as those conducted by the Ontario Geological Survey. The use of the hydrocarbon signature has been able to differentiate between barren and ore bearing conductors and geophysical targets of mineralization or kimberlites from naturally occurring signals such as from granite gneiss.

Although the SGH name implies the exclusive use of soils, this geochemistry is also able to use other sample media such as humus, peat, sand, till, submerged sediment, and even snow. As these hydrocarbons are relatively neutral species the state of the flow of hydrocarbons that migrate and geochromatographically disperse through the overburden can be captured by the surface area of the sample media taken in a survey. This capability is vital in areas of difficult terrain where a complete sample survey may cover swamps, lakes, peaty areas as well as high ground. This multi-media survey can be processed and mapped together without data leveling, thereby significantly reducing the bias in interpretation represented by areas where sampling was formerly not warranted.

Several independent studies have also illustrated the successful depiction of blind mineralization that is shallow or to depths in excess of 700 metres. Figure 1 illustrates additional penetrating capability of this nano-scale geochemistry at dramatically delineating gold mineralization beneath a basalt cap. Similar results have been shown over areas of permafrost.

As a forensic signature the identification and vectoring capability of SGH provides a high level of confidence. The robustness of this geochemistry has allowed it to be used to discover new resources in not only greenfield applications but has also delineated mineralized extensions in brownfield surveys.

Viscosity of carbon dioxide-bearing silicate melt at high pressure

AKIO SUZUKI[1*]

[1]Department of Earth and Planetary Materials Science, Tohoku University, Sendai, Japan, a-suzuki@m.tohoku.ac.jp (* presenting author)

Knowledge of the viscosity of silicate melts at high pressure is of importance for modeling igneous processes in the Earth's interior. In natural magmas, volatiles are dissolved and affects physical properties. It has been known that volatiles reduce the viscosity of magmas. However, very few studies have been performed to investigate the effect of volatiles on the viscosity at mantle pressures. In the present study, the viscosity of carbon dioxide-bearing jadeite melt has been determined up to 4 GPa. We adopted the falling sphere method for viscometry. Experimental detail has been described elsewhere[1, 2]. X-ray radiography technique enables us to measure the falling velocity of a platinum sphere in situ. Experiments were performed at the NE7A station at the High Energy Accelerator Research Organization (KEK). We used a Kawai type multi anvil apparatus driven by a DIA type guide block installed on the MAX-III apparatus. A charge-coupled device (CCD) camera with a YAG:Ce fluorescence screen was used as an X-ray camera. The present study shows that an addition of carbon dioxide produces a viscosity decrease.

Introduction

It is well established that the speciation, distribution and transport of radionuclides is profoundly influenced by microbial activities in the shallow aquifer. However, it remains to be challenging to predict microbial influences on radionuclide migration in the deep aquifer for geological disposal of radioactive wastes. Currently, there are two major gateways to the deep biosphere through long vertical boreholes from the surface or short horizontal boreholes from the underground tunnel. Neither approach is exempt from the disturbance of the steady biogeochemical state and microbiological populations established through the long evolutionary history within the fracture networks. Despite the disturbance, it is very critical to identify indigenous microbial populations that potentially affect the long-term behavior of radionuclides (e.g. biosorption and redox transformation) and contaminant ones playing short-term roles during the recovery from the disturbance by consuming artificially introduced oxidants.

Underground research laboratories for comparison

The Grimsel Test Site (GTS), central Switzerland, has been in operation since 1984. The GTS provides 400-500-m deep granitic groundwater from boreholes that vary in age from 1 to 25 years. The Mizunami URL (MIU), which is being constructed in central Japan, provides 200-400-m deep granitic groundwater since 2007. The microbial comparison of the URLs associated with freshwater groundwater might result in the clarification of microorganisms commonly associated with the deep granitic subsurface.

Key indigenous and contaminant microbial populations

16S rRNA gene sequence analyses were conducted for groundwater samples from the GTS and the MIU. Sequences related to "*Candidatus* Magnetobacterium bavaricum" of Nitrospirae were predominant in all GTS boreholes, while β-proteobacterial sequences were only obtained from 1-2 year old GTS boreholes. Similarly, the predominance of β-proteobacterial sequences was gradually shifted to that of Nitrospirae sequences within several years after horizontal drilling at the MIU. The detection of the common microorganisms from the geographically distinct URLs suggests that these microbes are cosmopolitan in the granitic aquifer, radionuclide interactions with which should be clarified to provide general and reliable information for the safety of geological disposal in granitic repositories.

Phototrophs in a Ferrous Ocean

Anoxygenic phototrophs capable of metabolically oxidizing Fe^{2+} to Fe^{3+} are believed to be responsible for the deposition of mixed-valence Fe-containing Banded Iron Formations (BIF) in a Precambrian atmosphere of low O_2 [1]. The evolution of oxygenic photosynthesis by cyanobacteria has long been regarded as the primary mechanism for a rise in atmospheric O_2 in the Paleoproterozoic [2], and this O_2 would have further reacted with abundant aqueous Fe^{2+} to contribute to the deposition of BIF. As BIF were deposited across a wide range of Earth history and represent several distinct depositional settings, they potentially recorded changes in the makeup of the marine biosphere, particulalry among the anoxygenic photo(ferro)trophs and cyanobacteria. We ask what these changes were, and whether or not they are recorded in the style and substance of BIF deposition.

To address this, we report on our attempts to co-cultivate marine species of cyanobacteria and a photoferrotroph under conditions relevant to the hypothosized Precambrian ferrous ocean. Both strains will be independently evaluated to determine what chemical and physical factors imposed by changing ocean chemistry could have limited growth. These include light intensity, temperature and trace element availability. The results will be useful to compare with datasets reporting the calculated abundance of trace elements (e.g. Ni, Co) in the Precambrian ocean [3]. Then, the spatial distribution of trace metals and phosphorus to Fe and organic carbon from cell-mineral precipitates of Fe-containing co-culture experiments will be used for late-stage diagenesis experiments at temperature and pressure conditions observed in BIF to determine whether any trace element signatures associated with the phototrophic metabolisms in a ferrous ocean would be retained through time. A combination of fluorescence-based metal dyes in confocal microscopy and scanning transmission X-ray microscopy (STXM) will be used to assess these relationships both before and after simulated diagenesis.

Analogues for Precambrian Microbial Communities

As ferrous-rich marine environments today are scarce, analogue environments to study the phototrophic biosphere as occurred in the Precambrian and its implications for BIF are lacking. However, laboratory experiments are most useful if relevant to natural systems. Therefore we will compare the results of our data with the natural distribution of cyanobacteria and photoferrotrophs from a circumneutral Fe-rich freshwater lake. As most knowledge about photoferrotrophs is currently sourced from work with pure cultures, further molecular, chemical and cultivation-based studies of these organisms in natural environments is warranted.

[5]USGS, Tacoma, WA (sheibley@usgs.gov)

The dynamic exchange of a coastal aquifer with sea water is a ubiquitous but still mostly inadequately quantified vector for nutrients and trace elements enroute to the sea. Biogeochemical reactions within this coastal aquifer/sea water mixing zone will transform many chemical species, including the redox sensitive- and microbially-mediated elements. As a result, this mixing zone can be a productive incubator zone for transformation products that rely on microbes or steep redox gradients. Geochemical and geophysical data from sites that extend from southern California to Puget Sound and Hawai'i will be used to assess submarine groundwater discharge (SGD) rates, scales, and constituent loadings. Unique geologic, climatic, and hydrologic characteristics define many west-coast U.S. and Hawaiian coastal systems. In these systems, the physical drivers and anthropogenic impacts on SGD are often unique and are assessed using a suite of naturally-occurring radionuclides (^{222}Rn and ^{223,224,226,228}Ra) and multi-channel electrical resistivity techniques. SGD is also evaluated as a sustained vector for nutrient (e.g., N and P) and trace element (e.g., Hg, U) loadings to nearshore environments and discussed in terms of ecosystem processes and impacts.

Coastal groundwater discharge near Kahekili Beach Park, Lahaina, Maui, Hawai'i

P.W. SWARZENSKI[1*], C.G. SMITH[2], C.D. STORLAZZI[1], L. DIAZ AND M.L. DAILER[3]

[1]USGS, Santa Cruz, CA (pswarzen@usgs.gov) (*presenting author)
[2]USGS, St. Petersburg, FL (cgsmith@usgs.gov)
[1]USGS, Santa Cruz, CA (cstorlazzi@usgs.gov)
[1]USGS, Santa Cruz, CA (ldiaz@usgs.gov)
[3]University of Hawai'i, Honolulu, HI (dailer@hawaii.edu)

This presentation describes a study conducted off Kahekili Beach Park, located just north of Lahaina on the west coast of Maui, Hawai'i, to better understand rates and drivers of coastal groundwater discharge and associated material transport into nearby coastal waters. This site has recently been well studied to examine how focused municipal wastewater plumes may be conveyed to the coastal waters by discharging groundwater [1, 2]. At this location there are multiple spring vents close to shore (water depth < 2m), where much lower salinity water can readily be observed discharging into the water column. There has also been a notable change in bottom type; this site was once dominated by corals and now is dominated by turf- or macro-algae [1]. This suggests a likely local nutrient imbalance that warrants further investigation. Previous reports have utilized dissolved nitrate - $\delta^{15}N$ records [1] as well as a suite of tell-tale organic pollutants [2] to infer focused municipal wastewater discharges at this location. Our study presents the first estimates of coastal groundwater discharge to this site based on the submarine groundwater discharge tracer, ^{222}Rn, and extends our understanding of the scales, magnitudes, and constituent loads conveyed by this submarine route.

Pore scale CO_2-brine-mineral interactions in caprock

ALEXANDER M. SWIFT[1*], DAVID R. COLE[2], MICHAEL V. MURPHY[2], JULIA M. SHEETS[2], SUSAN A. WELCH[2]

[1] The Ohio State University, Columbus, Ohio, USA, swift.63@osu.edu (* presenting author)
[2] The Ohio State University, Columbus, Ohio, USA

Although the carbon sequestration capacity of the Mount Simon formation in western Ohio has been the subject of much published work, less is known about the ability of the overlying Eau Claire to serve as a caprock over geologic time. Predicting this involves a better understanding of how mineralogic heterogeneity controls the nature and extent of precipitation (pore-closing) and dissolution (pore-opening) in response to CO_2 perturbation. Preliminary study of select rock core indicates that the Eau Claire comprises subfacies on the scale of cm to m dominated by quartz-rich sandstone, shale and carbonate. At the pore scale (mm to microns), the relative abundance and pore-accessibility of reactive minerals such as illite, iron oxides, pyrite, and chlorite become key factors in controlling local geochemical regimes.

Results are presented here from *in situ*, temperature- and pressure-corrected kinetic models of CO_2-saturated brine in contact with rock that draw upon pore, rather than bulk, mineralogies. 2D mineral and pore scan raster maps of thin sections are obtained using a field emission gun scanning electron microscope (FEG-SEM) equipped with QEMSCAN software that compares backscattered electron (BSE) and characteristic x-ray signals against a database of standard mineral patterns. These methods permit the analysis of how micron-scale mineralogical heterogeneity varies over distances of tens of vertical meters. As quantifying the effective reactive pore surface area is a key step in improving the predictability of reactive transport models used to assess the fate of CO_2 in the subsurface, the surface area of pores down to micron scale is estimated by summing pore-non pore pixel edges. A sensitivity study is performed on parameters of particular relevance: CO_2 fugacity (8 – 32 MPa), mineral proportions (informed by sample composition), and brine chemistry (date, location, and depth-matched with rock samples).

Preliminary results indicate that, because of the relative abundance of Mg- and Fe-rich minerals at pore surfaces, CO_2-saturated brine-rock interactions exhibit greater reactivity and are more pH-fO_2-dependent than is predicted by models based on the same samples but considering only bulk mineralogy.

Work is performed by the Subsurface Energy Materials Characterization and Analysis Lab at The Ohio State University, and is sponsored by the Dept. of Energy "Nanoscale Control of Geologic CO_2" Energy Frontier Research Center. Core is provided by the Ohio Department of Natural Resources.

Fate of magnetite nanoparticles in leachate-impacted groundwater

A.L. SWINDLE[1*] AND A.S. MADDEN[1]

[1]University of Oklahoma, Norman, OK, USA, (aswindle@ou.edu, amadden@ou.edu)

Nano-scale iron oxides, particularly magnetite, have been suggested as potential reductants for a number of environmental contaminants such as heavy metals, radionuclides, and volatile organics. Experiments have generally shown that magnetite is a viable reductant of a number of contaminants in a laboratory setting [1], though effectivness is influenced by iron-oxide particle size and the presence of additional cationic and anionic species [2]. However, key questions remain about the fate of magnetite nanoparticles in groundwaters with complex chemistry.

Magnetite nanoparticles were synthesized in the laboratory by partial oxidation of ferrous iron sulfate in a basic medium. A combination of TEM and XRD were used to characterize the reation products. A custom-made nanoparticle holder was designed to be compatible with the existing 1" OD groundwater wells at the USGS Norman Landfill Site. By means of this nanoparticle holder, magnetite nanoparticles were deposited on TEM grids and then inserted into a groundwater monitroing well at the USGS Norman Landfill Site. The particles were reacted for 10 days, retrevied from the site, and then stored in an anearobic chamber prior to anaylsis. The reaction products were anaylzed via TEM and compared to the intial characterization. Total volumes were calculated for both the initial synthesis products and the reacted magnetite particles. These volumes were compared to determine the volume of material lost and to calculate an approximate dissolution rate.

TEM characterization of the synthesis products indicated euhedral magnetite with a size range of 250 to 11 nm, along with euhedral goethite particles. Mineralogies identified in synthesis products via TEM were confirmed by XRD analysis. TEM analysis of the reacted particles revealed that the particles were subhedral, indicating dissolution of the magnetite particles, primarily at the corners and edges. Bright field images also indicated a textured surface on the reacted magnetite surfaces, which is also indicative of dissolution of the iron oxide particles.

Experimental results indicate that the magnetite particles lost 10 to 30 percent of their total volume over the 10 day time period. Interestingly, no clear trend between particle size and total volume lost was apparent in the data. An approximate dissolution rate of 2.9 (0.9) x 10^{-9} nmol/m^2*day was obtained using the TEM images.

Implications of noble gases in Stardust samples for the source of Earth's water

TIMOTHY D. SWINDLE

Lunar and Planetary Laboratory, University of Arizona, Tucson AZ USA, tswindle@lpl.arizona.edu

Comets as the Source of Earth's Water

Comets have long been considered a possible source of Earth's water. The compositions of comets would provide an obvious constraint, but the only compositional parameter that has been widely applied is the D/H ratio. Although most comets in which D/H have been measured have ratios a factor of two higher than Earth's oceans, a recent measurement of Comet Hartley 2 gave an Earth-like ratio [1], reviving interest in the idea of a cometary source.

Another compositional parameter that could prove powerful is the noble gas abundance in comets. Based on a spectroscopic measurement of the Ar/O in the coma of Comet Hale-Bopp [2], Swindle and Kring [3] argued that if comets had brought in the Earth's water, orders of magnitude more noble gas would be in Earth's atmosphere than there presently is. However, that measurement has not been replicated, and other measurements suggest much lower noble gas abundances in comets, giving only upper limits [4].

More recently, noble gases have been measured in samples returned from the coma of Comet Wild 2 by the Stardust mission, so it is appropriate to revisit the argument, considering only the noble gases in the dust.

Extrapolating Stardust measurements to Xe in comets

Marty et al. [5] measured He and Ne in Stardust samples, and concluded that the dust contained ~0.1 cm^3STP of Q-type ^{20}Ne per gram of dust (~9 x 10^{-5} g_{Ne}/g). If we conservatively assume that comets are 10% dust, that would mean that to bring in an amount of H_2O equivalent to the Earth's oceans, 3 x 10^{-4} of Earth's mass [6] would also bring in more than 1000 times as much Ne as is currently present in the atmosphere (~10^{-12} g_{Ne}/g). However, Ne is light enough that it is possible that it would not be retained during cometary impacts (although its molecular weight is higher than that of H_2O). If we consider Xe instead, the ^{20}Ne/^{132}Xe (molar) ratio in Q-type gas is 3.2, which would mean that an ocean's worth of cometary water would contain more than 10,000 times as much ^{132}Xe as the present atmosphere. It is difficult to envision ways to lose that amount of Xe, although the argument does depend on the identification of the Stardust Ne as Q-type. Furthermore, this argument only applies to the dust, and does not even consider the ice, which could have large amounts of noble gases as well.

Once again, noble gas abundances appear to be a problem for arguing for a cometary source for Earth's water, but more definitive measurements are clearly needed.

Isotopic constraints on water and carbon fluxes in Langat Basin, Peninsular Malaysia: A Reconnaissance Study

MUHAMMAD.I.SYAKIR[1,2*], IAN.D.CLARK[1], JAN VEIZER[1]

[1]University of Ottawa, Dept. of Earth Sciences, Ottawa, Canada, misha104@uottawa.ca (*presenting author)
[2]Universiti Sains Malaysia, School of Industrial Technology, Penang, Malaysia

Introduction

Evapotranspiration is a nexus for planetary energy and carbon cycles, but it remains poorly constrained. Here we use stable isotopes of Oxygen and Hydrogen to partition flux of water due to plant transpiration from the direct evaporative flux from soils, water bodies and plant surfaces in the tropical watershed of Peninsular Malaysia.

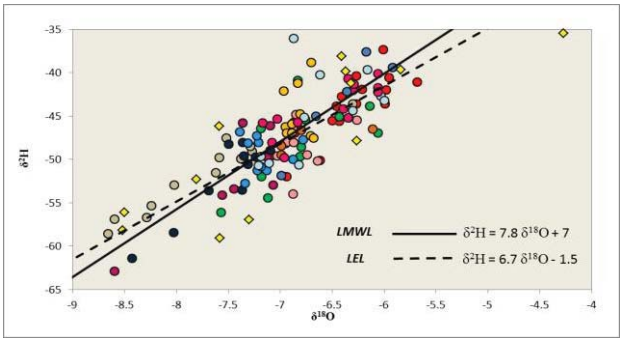

Figure 1 : Intersection of Local Meteoric Water Line (LMWL) and the Local Evaporative Line (LEL) in the Langat Basin.

Results and Conclusions

Mean annual rainfall, obtained from 30 years of hydrological data, is ~2078 mm. Tentatively, 45% of this precipitation returns to the atmosphere via transpiration (T), with 38% partitioned into discharge (R), 9% into interception (I_n), and 8% into evaporation (E_d), emphasizing the role of water cycle as a "conveyor belt" essential for nutrient transport in terrestrial ecosystems [1,2]. The flux of carbon from the atmosphere to the tropical ecosystem of the watershed, related to this transpiration water flux via water utilization factor (WUE), is about 505 g C m^{-2} yr^{-1}.

Metagenomic Analysis of Inactive Hydrothermal Sulfides from Lau Basin

JASON B. SYLVAN[1*] AND KATRINA J. EDWARDS[2]

[1]University of Southern California, Los Angeles, CA, USA, jsylvan@usc.edu*

The East Lau Spreading Center (ELSC) and Valu Fa Ridge comprise a ridge segment in the southwest Pacific Ocean where rapid transitions in the underlying mantle lenses manifest themselves by gradients in seafloor rock geochemistry. At the spreading center in the north, basaltic host rock extrudes while the influence of subduction in the south creates mainly basaltic andesite host rock, with a continuous gradient between these two end members. We studied the geology and microbial diversity of seafloor silicate rock samples and inactive sulfide chimney samples collected along the ELSC and Valu Fa Ridge by X-ray diffraction, elemental analysis, thin section analysis, bacterial 16S rRNA sequencing and metagenomic analysis. Here, we discuss results from the inactive sulfides. On a chimney collected from the ABE vent field, the outside portion of the chimney was dominated by sulfur oxidizing Gammaproteobacteria in the SUP05 clade whereas the inside conduit of the same inactive chimney was dominated by the sulfate reducers in the deltaproteobacterial family Desulfobulbaceae. An inactive sulfide chimney sampled from Tui Malila vent field, where host rock is more strongly influenced by dewatering reactions from the subducting plate, hosted a starkly different bacterial community; sulfur oxidizing Epsilonproteobacteria in the genera *Sulfuromonas* and *Sulfurovum* were recovered from the same sample along with sulfate reducing Desulfobulbaceae and methane oxidizing Gammaproteobacteria in the order Methylococcales, indicating that this sample was either recently inactive or in the final stages of cessation of venting. We also present here the preliminary analysis of metagenomes sequenced from these samples using an Ion Torrent next generation sequencing machine.

The record of early crustal evolution preserved in detrital zircons from Mount Murchison metasedimentary rocks, Western Australia

P.J. SYLVESTER[1*], A.K. SOUDERS[1] AND J.S. MYERS[2]

[1]Department of Earth Sciences, Memorial University, St. John's, NL, Canada (*psylvester@mun.ca, kate.souders@mun.ca)
[2]Department of Applied Geology, Curtin University, Perth, WA, 6845, Australia (myersm@iinet.net.au)

The Mt. Narryer and Jack Hills metasedimentary belts of the Narryer Terrane of Western Australia have been the subject of intense study for almost thirty years because they contain ca. 4.35 Ga detrital zircons, which are the oldest minerals known on Earth. These rocks also contain numerous younger populations of Hadean and Archean detrital zircons of diverse provenance, preserving a rich archive of information on early crustal evolution. Largely ignored has been a third major sequence of metasedimentary rocks in the Narryer Terrane, located at Mt. Murchison, 27 km south-southeast of Mt. Narryer and 98 km southwest of the Jack Hills. The detrital zircon population at Mt. Murchison can provide insights into the extent of Hadean sources in the Narryer Terrane, and whether magmatic events that produced detrital zircons in this region were episodic or continuous during the Archean.

The Mt. Murchison metasedimentary belt is 5 km long and 2 km wide, and contains fuchsitic quartzite, bedded coarse-grained quartzite, glassy quartzite, and quartz pebble conglomerate that appear similar in appearance to mature clastic units at Mt. Narryer and the Jack Hills. We have determined the U-Pb ages of detrital zircons in a sample of fuchsitic quartzite from Mt. Murchison using laser ablation-inductively coupled plasma mass spectrometry. One-hundred-thirty-nine detrital zircon grains in the sample are concordant within 10%. Seventy percent of the grains have $^{207}Pb/^{206}Pb$ ages that fall within four populations: 3125 ± 40 Ma (16%), 3235 ± 40 Ma (23%), 3445 ± 40 Ma (18%) and 3540 ± 40 Ma (13%). The oldest grain has a $^{207}Pb/^{206}Pb$ age of 3955 ± 12 Ma (2s); the youngest grain is 3001 ± 20 Ma (2s).

The detrital zircon population of the Mt. Murchison sample differs from those of quartzites and conglomerates from Mt Narryer and the Jack Hills in the paucity of grains older than 3.6 Ga, and the presence of a large population of 3.1 – 3.2 Ga grains. On the other hand, the 3.4 Ga age peak in the Mt. Murchison sample is also a prominent detrital zircon age population in the Jack Hills, and 3.5 Ga sources contributed to all three metasedimentary belts. This suggests that while there was significant age heterogeneity in the detrital sources of the Narryer Terrane, there were also some common sources that linked the paleodrainage systems of the Mt. Murchison, Mt. Narryer and Jack Hills areas.

When combined, the detrital zircon age data for all three metasedimentary belts define a rather continuous record of major magmatism in the Narryer Terrane from *ca.* 3100 to 3650 Ma. This implies unusually long-lived and continuous (rather than episodic) magmatic processes for crustal growth in the early Archean. Reconstructing the record of ages of clastic sedimentary sources in ancient terranes requires analysis of multiple depositional units of paleodrainage systems.

PGE abundances in upper mantle xenoliths from the Carpathian-Pannonian Region

CSABA SZABÓ[1] KEIKO HATTORI[2], WILLIAM GRIFFIN[3] , SUE O'REILLY[3] AND LÁSZLÓ ELŐD ARADI[1]

[1]Lithosphere Fluid Research Lab, Eötvös University, Budapest, Hungary (cszabo@elte.hu)
[2]Department of Earth Sciences, University of Ottawa, Canada (khattori@uottawa.ca)
[3]GEMOC, Department of Earth and Planetary Sciences, Macquarie University, Australia

The contents of Os, Ir, Ru, Rh, Pt and Pd were determined in lherzolite xenoliths and their sulfide grains (up to 150 μm) from the Carpathian-Pannonian region (CPR) to evaluate the abundance of the highly siderophile elements in the subcontinental lithospheric mantle beneath the region of the Alpine-Mediterranean area. The studied locations include the Styrian basin (western CPR, Austria), Bakony—Balaton-Highland (central CPR, Hungary), Nógrád-Gömör (northern CPR, Hungary, Slovakia), and the East-Transylvanian basin (eastern CPR, Romania).

Total PGE contents range between 7 and 21 ppb regardless of location. Ir-type PGEs are overall high, 5-12 ppb, which confirms the residual mantle nature of the xenoliths. The ratio of Ir- and Pd-type PGEs varies between 0.83 and 2.83. Os/Ir ratios in xenoliths from Styrian and East-Tranylvanian basins are slightly below the chondritic ratio, whereas those from Bakony—Balaton-Highland are above the chondritic value. Ru/Ir is ca. 30 % higher than the chondritic value in the majority of xenoliths from Styrian and East-Transylvanian basins. In contrast, xenoliths from the Bakony—Balaton-Highland show chondritic Ru/Ir, except xenoliths most strongly depleted in Al. These PGE ratios do not show correlations with Al. Pt and Pd contents and their ratios with Ir-type PGEs correlated with Al, as expected, due to incompatible nature of Pt and Pd during partial melting in the Bakony—Balaton-Highland xenoliths, which have the widest range in Al contents. In situ PGE analyses on sulfide grains (mss, chalcopyrite and pentlandite) show positive correlations of Os, Ir, Ru and Rh, except in sulfides from the Bakony—Balaton-Highland and some sulfides from Nógrád-Gömör and East-Transylvania, whereas Pt and Pd correlate poorly with the Ir-type PGEs. The total concentrations of PGEs range between 4 and 796 ppm. The majority of the PGE patterns show high and variable abundances of Os, Ir, Ru and Rh, with decreasing abundance from Rh to Au and a strong negative Pt anomaly. Sulfides in xenoliths from the Bakony—Balaton-Highland, being basically mss, show a smooth negatively sloped PGE pattern from Os to Au.

Whole-rock and in situ sulfide grain analyses demonstrate that the upper mantle beneath the CPR shows a district-scale variation in PGE abundances. Although the xenoliths show no evidence for modal metasomatism, the variation can be explained by different degrees of partial melting and cryptic metasomatism.

Complex calc-alkaline volcanism recorded in Mesoarchaean supracrustal belts in SW Greenland

[3]Department of Geology, Lund University, Sweden anders.schersten@geol.lu.se

Abstract

In this geochemical study we investigate the petrogenesis of three Mesoarchaean co-magmatic supracrustal belts (Ravns Storø, Bjørnesund and Perserajoorsuaq) situated in southern West Greenland. They comprise mainly amphibolites with a tholeiitic basaltic composition and leucoamphibolites with a calc-alkaline andesitic composition. Both lithological units are cut by aplite sheets of tonalite-trondhjemite-granodiorite (TTG) composition with U-Pb zircon ages of c. 2900 Ma. Lu-Hf and Sm-Nd isochrons based on whole rock samples yield ages of 2990 ±41 Ma and 3020 ±78 Ma, respectively. Leucoamphibolites from the three supracrustal belts show apparent chemical mixing trends between tholeiitic amphibolites and TTG gneisses end-members. By assimilation-fractional-crystallisation (AFC) modelling we can show that one group of leucoamphibolites can be explained by contamination of the parental melts by a TTG-like end-member and another group of high P_2O_5, La and Nb leucoamphibolites can be explained by contamination involving a hypothetical low-silica adakite (slab-melt) end-member. However, the leucoamphibolites are juvenile with $\varepsilon Nd_{(2970Ma)}$ from +2.1 to +3.5 and $\varepsilon Hf_{(2970Ma)}$ of +3.5 to +4.3. Thus, the mafic source of the felsic contaminant melts must have been derived from a depleted mantle source more or less at the same time (<60 Ma) as the volcanism took place. Contamination by older continental crust is not a viable explaining of the data.

Accordingly, our preferred interpretation of the geochemical and isotopic data is that the protoliths of the supracrustal rocks formed in an island arc setting, where early tholeiitic volcanism gave way to calc-alkaline volcanism in a maturing island arc. The apparent AFC trends are best explained by in-situ partial melting of basaltic arc crust to form juvenile TTG- and adakite-melts that mixed with mafic magmas or contaminated their mantle source to produce the calc-alkaline leucoamphibolite protolith. This model has important implications for the general interpretation of other Archaean supracrustal belts, because AFC and chemical mixing trends towards a TTG-like end-member are not uniquely diagnostic of crustal contamination, but may rather reflect processes operating at source levels in volcanic arcs such as melting-assimilation-storage-homogenisation (MASH) or slab-melt metasomatism of their mantle source. This study strongly argues for the operation of uniformitarian subduction zone processes as far back as at least 3000 Ma.

Understanding the formation and properties of Titan's aerosols with the PAMPRE laboratory experiment

In order to support the treatment and interpretation of data collected by the Cassini and Huygens instrumentation, our team developped in 2004 a laboratory experiment based on a radio-frequency reactive plasma to produce analogues of Titan's aerosols (or "tholins"). This experiment, named PAMPRE, enables to produce tholins under variable controlled conditions compatible with the present and past Titan's upper atmosphere ones. The originality of PAMPRE, compared with other experimental set-ups used to porduce tholins, comes from its capability to generate and maintain the tholins inside the plasma without any wall effects. This specificity thus allows to study the tholins production and growth directly in situ by using the appropriate analytical diagnostics.

The studies we do with PAMPRE can be shared in four distinct actions:

1. Study the physical and chemical properties of tholins. This part is originally the most important one since it is partly dedicated to produce reference data which can be compared with observational data. We also study the influence of the production conditions on the tholins properties to better understand the context in which Titan's aerosols can be produced.
2. Characterize the plasma chemistry in order to constrain the chemical pathways leading to the production of solid organic particles directly from the gaseous phase. This part is obviously correlated to the chemistry that occurs in Titan's atmosphere to generate the aerosols.
3. Characterize the physicla properties of the plasma. This original task is very important to understand the influence the context in which the tholins are produced in the experimental set-up. This makes easier the transposal of our results obtain in laboratory to the Titan's atmosphere.
4. More recently we started the study of the evolution in time of Titan's tholins we produce in the context of Titan's geological times.

The goal of this paper is to present an overview of results obtained in the different branches of study of Titan's tholins with the PAMPRE experiment, with an emphasize on the most recent ones.

Fluxes of sulfide-derived sulfate in the Rio Grande valley

ANNA SZYNKIEWICZ[1*], DAVID M. BORROK[1] AND DAVID VANIMAN[2]

[1]University of Texas at El Paso, Geological Sciences, El Paso TX, USA, aaszynkiewicz@utep.edu (* presenting author), dborrok@utep.edu

Sulfide oxidation is an important weathering pathway in surface environments. However, few data are available to address the contributions and fluxes of sulfide-derived SO_4^{2-} in hydrologic systems. In order to better understand this process, we measured the seasonal fluxes of SO_4^{2-} and the $\delta^{34}S$-$\delta^{18}O$ of riverine SO_4^{2-} as well as sulfate-rich salt efflorescenses in three watersheds connected to the upper Rio Grande valley. In this region, the $\delta^{34}S$ of hydrothermal and biogenic sedimentary sulfides differ by 20-30 ‰ compared to S from evaporites. Therefore, the contribution and fluxes of sulfide-derived SO_4^{2-} can be estimated using S isotope mass balance constraints.

In the Red River, a small tributary to the Rio Grande within the Taos Plateau in northern New Mexico, sulfide-rich mineralization in the form of hydrothermal veins and disseminated pyrite undergoes oxidation in natural alteration scars and abandoned mine waste piles. In April and August of 2010, the measured $\delta^{34}S$ and $\delta^{18}O$ of riverine SO_4^{2-} varied from -2.5 to +1.3 ‰ and from -7.1 to -4.0 ‰, respectively. These variations were consistent with the previously reported $\delta^{34}S$ of pyrite (-13.6 to +2.7 %), and the $\delta^{34}S$ and $\delta^{18}O$ values of gypsum/jarosite (-12.1 to +2.6 ‰ and -9.3 to +3.1 ‰) formed by surface oxidation of hydrothermal sulfides. In the Red River valley, nearly 100 % of aqueous SO_4^{2-} appears to be sourced by sulfide oxidation. The measured flux of sulfide-derived SO_4^{2-} was higher during the snowmelt in April (19.3 tons/day) compared to baseflow conditions in August (15.2 tons/day).

In the Rio Chama and Rio Puerco, tributaries to the Rio Grande in western and central New Mexico, sulfides occur as biogenic pyrite in Cretaceous shale and coal formations. Sulfate-rich salt efflorescences are common weathering products in surface outcrops of these formations. Analysis by X-ray diffraction shows that these are largely Mg, Na, and Ca sulfates (e.g., starkeyite or hexahydrite, thenardite, and gypsum) and $\delta^{34}S$ analyses indicate that the sulfate in these phases formed by sulfide oxidation. Between 2009 and 2011, the contribution of sulfide-derived SO_4^{2-} to the total S load varied widely in the Rio Chama (from 48 to 95 %). S isotopes indicated mixing of SO_4^{2-} from the dissolution of salt efflorescence (-25.2 to -9.5 ‰) and Jurassic evaporites (+15.1 to +17.7 ‰). In the lower reaches of the Rio Chama, the fluxes of sulfide-derived SO_4^{2-} varied widely between Nov 2009 (10.5 tons/day) and Apr 2010 (134.3 tons/day). These variations, however, were to some degree controlled by water releases from upstream reservoirs. Similar contributions of sulfide-derived SO_4^{2-} were calculated for the semi-arid Rio Puerco (68 % of the total S load) during the snow melt season. Because less water is available in the Rio Puerco, the fluxes of sulfide-derived SO_4^{2-} were significantly lower (~3.8 tons/day) compared to the Rio Chama. This investigation indicates that much of the SO_4^{2-} (>50 %) in the upper Rio Grande valley is derived from sulfide oxidation in the surrounding watersheds.

Possible source of iron-60 in the early solar system based on recent estimates of its initial abundance

SHOGO TACHIBANA*

[1]Department of Earth and Planetary Science, The University of Tokyo, Hongo, Tokyo, Japan.
tachi@eps.s.u-tokyo.ac.jp (* presenting author)

The former presence of short-lived radionuclides (SLRs) in the early solar system (^{10}Be, ^{26}Al, ^{36}Cl, ^{41}Ca, ^{53}Mn, ^{60}Fe, ^{107}Pd, ^{129}I, and ^{182}Hf) has been inferred from excesses in the abundances of their daughter nuclides in meteorites, which are linearly correlated with the abundance of a parent element. The SLRs with half-lives ($\tau_{1/2}$) shorter than 5 million years (Myrs) could have been produced either by energetic-particle irradiation in the early solar system or by stellar nucleosynthesis just prior to or shortly after the birth of the solar system. Iron-60 ($\tau_{1/2}$=2.62 Myrs [1]) is effectively formed only by stellar nucleosynthesis, and its initial abundance in the early solar system could constrain the birth environment of the solar system. It has been found that ion microprobe studies on ^{60}Fe in the solar system [2-5] overestimated its initial abundance due to statistical bias for data reduction [6]. Recent studies using MC-ICPMS and MC-TIMS have shown that the initial abundance of ^{60}Fe in the solar system, $(^{60}Fe/^{56}Fe)_0$, could be as low as 10^{-8} [7-13], which could be comparable or lower than the galactic background. However, recent ion microprobe analyses with a proper data reduction method showed that there are chondrules with solid evidence of live ^{60}Fe and that the inferred initial ratio is in the range of $(3\text{-}5)\times10^{-7}$ [14].

These recent findings imply either that the initial abundance of ^{60}Fe in the solar system could be ~10^{-8} [10, 11] or that ^{60}Fe was heterogeneously distributed in the early solar system [9, 12, 14]. In this talk, I will discuss a possible source of ^{60}Fe in the early solar system and the birth environment of the solar system based on recent estimates of the abundance and distribution of ^{60}Fe in the solar system.

Neodymium isotopic ratios recorded in calcareous foraminiferal tests and associated authigenic minerals have been used to trace past water masses although exact origin of preserved Nd signals is still a matter of debate [1-3]. We determined, for the first time, Nd distribution in two species of planktonic foraminifera (*Globigerinoides ruber* and *Neoquadorina dutertrei*) and coexisting authigenic minerals from a marine sediment core in the Panama Basin. Elemental mapping of Nd, Ca, Fe, Mn, and Si was performed using NanoSIMS and electron probe microanalysis (EPMA) for uncleaned tests from two selected time slices (15.6 kyr and 129 kyr) together with Scanning Electron Microprobe (SEM) imagery. EPMA and SEM images indicate the existence of Fe-rich framboidal minerals inside of test pores and inner chambers, in particular for the older samples. This phase is estimated to be pyrite. The younger sample presents also Fe and Mn-rich patches on the inner test wall that is evaluated to be Mn-Fe oxides. Neodymium intensity in Fe-Mn oxides and oxidized pyrite is much higher than in foraminiferal calcite. For all analyzed samples, Nd distribution in foraminiferal tests is randomly heterogeneous with no systematic feature such as Nd-rich layer, species-specific difference, and primary calcite and crust. Relationship between Nd and Fe, and between Nd and Mn reveals that the most efficient Nd carrier is oxidized pyrites, possibly Fe oxy-hydroxides. This suggests a central role of Fe minerals to Nd cycle during diagenesis. Since Nd related to the authigenic precipitates reflects pore water signal (a mixture of scavenged, bottom water and soluble fraction from bulk sediments), conflicting origin of Nd isotopic signals from sedimentary foraminiferal tests could be at least partly explained by contribution of pore water-derived Nd.

Ediacaran carbon isotope anomaly records shallow marine event, not entire ocean

MIYUKI TAHATA[1]*, YUICHIRO UENO[1], YUSUKE SAWAKI[2], RYOHEI KIKUMOTO[1], MANABU NISHIZAWA[2], TSUYOSHI KOMIYA[3], NAOHIRO YOSHIDA[4], SHIGENORI MARUYAMA[1]

[3]The University of Tokyo, Tokyo, Japan
[4]Tokyo Institute of Technology, Kanagawa, Japan

The Ediacaran is one of the most important periods in the history of life when multicellular animals firstly appeared on the earth. However, we still poorly understand the relationship between the abrupt biological evolution and environmental change. Ediacaran sections record the largest $d^{13}C$ arnomaly through the Earth's history, named Shuram excursion [1, 2] . The observed excursion may reflect extensive remineralization of large organic matter in the Ediacaran ocean [2, 3], or merely the result of diagenetic alteration [4]. However, marine sediments must have been globally preconditioned in a unique way, to allow ordinary and local process to produce an extraordinary and widespread response [5]. We analyzed carbon and nitrogen isotopes by using drill core samples from four different depositional settings in South China: shallow marine Three Gorges and Weng'an sections, and deeper Tianping and Shiduping sections. The new results of deeper sections show high carbon isotope ratio and no negative excursion in spites of high spacial resolution. Weng'an section in shalow shelf also shows only smaller negative excursion (>-4‰) compare to that of Three Gorges section in another shallow marine setting. Thus, the limited appearance of the negative $d^{13}C$ excursion in shallow marine settings may suggest that extensive remineralization took place only in shallow part of the organic-carbon-rich Ediacaran ocean. Alternatively, shallow section preferentially suffered from diagenetic alteration possibly in response to sea-level fall, though the regressive trend is not evident. On the other hand, $d^{15}N_{TN}$ in Three Gorges shows long-term gradual decrease from the Shuram excursion to early Cambrian, which may rather reflect change in long-term oceanic signal.

Elemental partitioning and Eu^{2+}/Eu^{3+} XANES calibration between synthetic KREEP basalt, apatite, and whitlockite vs. T and f_{O_2}

N.D. TAILBY[1,2*], D. TRAIL[1,2] AND E.B. WATSON[1,2]

[1]Department of Earth and Environmental Sciences, Rensselaer Polytechnic Institute, Troy, NY, USA.

*tailbn@rpi.edu (presenting author)

Apatite, a common accessory phase found in a broad range of rock types, is known to host a number of important trace elements (U, Th, REEs, Sr, etc). The purpose of this research is to synthesize and equilibrate apatite from KREEP analogue melts as a function of temperature (T) and oxygen fugacity (f_{O_2}) in order to calibrate an apatite crystallization redox sensor.

The experimental method incorporates the use of seven different solid-state media buffers (ranging from -magnetite-hematite to graphite-CO-CO_2, representing ($\Delta f_{O_2} \approx 12$ log units) contained within evacuated silica tubes to control f_{O_2}. KREEP glasses are artificially doped with P_2O_5 to ensure apatite saturation [1-2] and enriched in REE (including La, Ce, Sm, Eu, Gd and Lu) in order ensure cocentrations sufficient for x-ray analysis (including EPMA and XANES). Experiments are carried out at 1000 – 1175 ˚C, incorporating conditions ranging from subsolidus to near-liquidus. Crystalline phases co-existing with apatite include olivine, plagioglase and whitlockite.

As indicated in a number of previous works [e.g., 3-4] the spectral components comprising the Eu L_3 XANES region are sensitive to $Eu^{3+}/\Sigma Eu$. Experimental results here show systematic increases from almost no Eu^{2+} in apatite at NNO to almost 45% Eu^{2+} at the graphite-CO-CO_2 buffer. Similar changes in $Eu^{3+}/\Sigma Eu$ are seen the synthetic glasses, thus indicating that Eu valence behaviour can be used as a valence or redox sensor for basaltic source melts that exist at low f_{O_2} (relative to terrestrial environments).

REE partitioning results for apatite (and where possible, whitlockite) are similar to those previously reported within the literature [5], indicating equilibria. The combined results of partitioning and XANES provide the first experimental constraint on redox sensitive geochemical processes that control trace element systematics within phosphates.

Grain scale pressure heterogeneity produced through volume change associated with mineral reaction

TAJČMANOVÁ L.[1], POWELL R.[2], PODLADCHIKOV Y.[3], VRIJMOED J.[3] AND MOULAS E.[1]

[1]Department of Earth Sciences, ETH Zurich, Switzerland, lucataj@gmail.com (* presenting author)

[3]Department of Earth Sciences, University of Lausanne, Switzerland

Recent work on melting, corona textures and phase precipitation developed in high metamorphic-grade rocks has focused on the chemical potential relationships that account qualitatively for the spatial and chemical relationships involved. There are two related ways in which this work can be advanced. The first involves using or devising diffusion coefficients to move towards quantitative modelling. The second, more critical step is to realize that mineral reaction cannot take place independently of the strength of its immediate environment. We will consider various aspects of this, on the basis that the diffusional relaxation modifies the elastic state of the material and affects its mechanical properties. As the induced stress may have a profound effect on diffusion in a solid, the elastic and chemical response of the material must be taken into account simultaneously. In geomaterials, only limited information exists on reactions that involve chemical transport combined with reaction-induced stress, but the mechanical feedback of volume change that is involved in chemical reaction in rocks may significantly control the progress of reaction. Pressure variations that existed at the grain scale during decompression and cooling of higher-pressure rocks are likely to have influenced the final microstructure. Our data based on numerical modelling show that pressure variations may be generated and maintained on a geological time scale as a result of the mechanical feedback of the rock during metamorphic reactions which take place in a restricted space.

Decrease of the potential of oxalic acid and other organic acid aerosols as cloud condensation nuclei by the complex formation with metal ions

YOSHIO TAKAHASHI AND TAKEMA FURUKAWA*

[1]Hiroshima University, ytakaha@hiroshima-u.ac.jp

Secondary organic aerosols (SOA) play a key role on the solar radiation balance in troposphere, since SOA can act as cloud condensation nuclei (CCN) due to its high hygroscopic nature. Oxalic acid is one of the most dominant components of SOA, which has cooling effects of the earth by acting as CCN. However, it is uncertain whether the oxalic acid can exist as free oxalic acid or metal-oxalate complexes in aerosols, even if there is a largedifference in their solubilities into water. Consequently, XAFS measurement was conducted to demonstrate the presence of metal-oxalate complexes.

Size fractionated aerosol samples were collected in Tsukuba (located at northeast about 60 km from Tokyo) using a low-volume Andersen-type air sampler. The sampler had eight stages and a back-up filter. The sampling was conducted during winter and summer in 2002.

Calcium oxalate was observed in finer particles in each period from Ca K-edge XANES, and its fractions among total Ca were approximately 20%. Similarly,, Zn oxalate was also detected in finer particles from Zn K-edge XANES and EXAFS. The [Zn-oxalate] / [Zn]total ratio in each period clearly increased with the decrease in the particle diameter. This result revealed that Zn-oxalate was formed in the aqueous phase at particle surfaces or in cloud processing. In other words, Zn-oxalate was abundant at the particle surface, resulting from the increase in the [surface]/[bulk] ratio with decreasing particle size. Based on (i) total concentrations of oxalate, Ca, and Zn determined by ion-chromatography and ICP-AES analyses and (ii) Ca- and Zn- oxalate fractions obtained by XAFS, we determined the fraction of metal-oxalate complexes among total oxalate in aerosols. In winter, Ca- and Zn- oxalate fractions reached about 60% of total oxalate in the ranges of 1.1-2.1 μm and 0.65-1.1 μm, while the value was about 60-80% in the same particle size range in summer. On the other hand, Ca- and Zn-oxalates are highly insoluble, showing that the complexes cannot act as CCN. Therefore, the ability of oxalic acid as CCN is needed to be reconsidered, because most of oxalic acid in aerosols exists as metal-oxalate complexes as shown by XAFS spectroscopy in this study. Moreover, the formation of stable metal-oxalate complexes at particle surface can inhibit the chance of the particle's activation to produce other chemical species.

Primitive Basalts from the Mariana Volcanic Front

Pagan is an active volcano located in the volcanic front of the central Island Province of the Mariana arc (18°07'N) and is one of the largest volcanoes in the Mariana arc; its main edifice rises from a base ~3,000 m below sea level and has a volume of 2,160 km^3 [1]. Tamura et al. (2011) demonstrate the existence of near-primitive, phenocryst-poor lavas at NW Rota-1 volcano in the Mariana arc, which is located about 40 km west of the volcanic front. These magnesiana basalts are petrographically distinct cpx-olivine basalt (COB) and plagioclase-olivine basalts (POB) [2].

The active Pagan volcano has erupted near-primitive lavas on its submarine flanks. The least fractionated compositions recovered from the NE flank (HPD1147) extend to higher MgO (7-11 wt %) and Mg# (60-70), than have ever been sampled from Pagan island lavas.

The Fo contents of olivine (up to Fo_{94}) and Cr-number of spinels (up to 0.8) suggest that these magmas formed from high degrees of mantle melting. There are three geochemical groups of cpx-olivine basalt (COB1, COB2 and COB3). TiO_2, Na_2O, K_2O, Rb, Nb are lowest in COB1 and highest in COB3. COB3 have steeper LREE-enriched patterns but the REE patterns of COB1 show contrasting LREE-depleted patterns, suggesting that COB1 formed from higher degrees of mantle melting. On the other hand, COB1 have the highest Ba/Th ratios and COB3 have the lowest, suggesting that a shallow subduction component is more important for COB1 than COB3, with COB2 intermediate. COB1, COB2 and COB3 show a negative trend on the Ba/Nb-Nb/Yb diagram (Fig. 1), suggesting that greater subduction components resulted in larger degrees of melting.

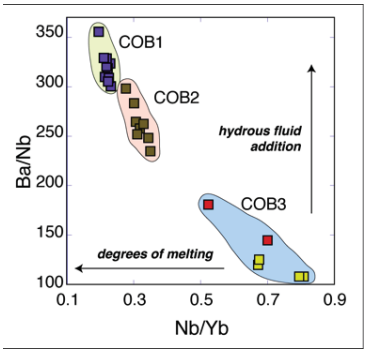

Figure 1: Ba/Nb vs Nb/Yb. The higher Ba/Nb of the COB1 indicate that the COB1 contain greater abundances of slab-derived subduction components than the COB2 and COB3. Nb/Yb suggests that the degree of melting of the COB1 source is higher than for the COB2 and COB3.

[3]Department of Civil and Environmental Engineering, University of Tennessee, 62 Perkins Hall, Knoxville, Tennessee 37996, USA, jparker@utk.edu

A one-time 2-hour EVO injection in a fast flowing aquifer resulted in decreased U(VI) flux to an surface stream for over a year. A model was developed to couple EVO hydrolysis, production and oxidation of long-chain fatty acids (LCFA), glycerol, acetate and H_2, reduction of nitrate, Fe(III), U(VI) and sulfate, and methanogenesis with growth and decay of microbial functional groups. Literature values were used for U(VI) sorption and microbially-mediated reduction reactions with acetate and H_2. Microcosm test data were used to estimate hydrolysis, glycerol fermentation, and LCFA oxidation parameters. The model was implemented in PHT3D to model coupled processes in the field test.

The model approximately matched the observed aqueous acetate, nitrate, Fe, U (Figure 1), and sulfate concentrations, and decribed the trends of growth and decay of microbial functional groups. While the lab-determined parameters were generally applicable for the field-scale simulation, the hydrolysis rate constant was estimated to be an order of magnitude faster in the field than in the microcosms. Sulfate reducer biomass was predicted to accumulate near the injection wells and along the side boundaries of the treatment zone where electron donors (LCFA) and electron acceptors (sulfate) from the surrounding environment met. Consequently, biogenic U(IV) accumulation in these locations was predicted (Figure 2).

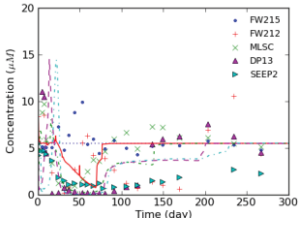

Figure 1 Observed (points) vs. calculated (curves) aqueous U(VI) concentrations

Figure 2. Predicted U(IV) distribution at 50 days

While EVO retention and hydrolysis characteristics were expected to control the treatment longevity, these modeling results indicated that electron acceptors such as sulfate not only compete for electrons but also may play a conducive role in degrading LCFA and enhancing U(VI) reduction and immobilization. The models could be useful for further research and bioremediation design.

Abstract

Stable Zn isotope signatures offer a potential tool to trace the mechanisms of Zn uptake and transfer within plant-soil system. In this study, we determined Zn isotopic compositions in three ecotypes of the Zn hyperaccumulator *Noccaea caerulescens* collected at a Zn-contaminated site (Viviez), a non-contaminated site (Ste Eulalie) and a serpentine site (Vosges) in France. The Zn-tolerant species *Silene vulgaris* collected from Viviez was also studied for comparison. While the δ^{66}Zn differentiated substantially among ecotypes, *N. caerulescens* exhibited a similar pattern with an enrichment in heavy Zn isotopes of 0.40–0.72‰ from soil to root, followed by a depletion in heavy Zn from root to stem (–0.05 to –0.31‰) and from stem to leaf (–0.05 to –0.22‰). The positive or negative shift of isotopes is probably attributed to the high ability of Zn accumulation and translocation in the hyperaccumulator, as δ^{66}Zn in *N. caerulescens* showed a significant and negative correlation with Zn concentration and bioconcentration factor. In *S. vulgaris*, however, the root was slightly depleted in heavy Zn with respect to soil, indicative of an ion-channel controlled diffusion into root cell under Zn excess conditions. The mass balance yields bulk Zn isotopic composition between plant and soil Zn $\Delta\delta^{66}Zn_{plant\text{-}soil}$ of –0.01‰ to 0.63‰ in *N. caerulescens* and –0.05‰ in *S. vulgaris*. We confirm that quantifying Zn stable isotopes is useful to study Zn accumulation pathways in plant and to document Zn status in media.

Cr(III) oxidation by biogenic maganese oxides

YUANZHI TANG*, COLLEEN M. HANSEL

School of Engineering and Applied Sciences, Harvard University, Cambridge, MA 02143, USA. ytang@seas.harvard.edu (*presenting author), hansel@seas.harvard.edu

Chromium (Cr) is a significant anthropogenic metal contaminant in soils and aquatic systems due to its widespread industrial applications. The toxicity and transport behavior of Cr depends strongly on its valence state. Cr(VI) compounds are typically soluble, mobile, bioaccessible, and are considered carcinogenic upon inhalation exposure. Cr(III) generally forms sparingly soluble (oxyhydr)oxides and is a essential micronutrient.

The redox transformation between Cr(III) and Cr(VI) in the environment is strongly mediated by (bio)geochemical reactions involving iron (Fe) and manganese (Mn) (oxyhydr)oxides, with Mn oxides (MnOx) being the only known natural oxidant of Cr(III). Understanding the impact of reaction conditions and MnOx structure are key for assessing the transport and fate of Cr. Given the much faster rate of microbially mediated Mn(II) oxidation as compared to solution or mineral-surface-catalyzed oxidation, MnOx are generally considered biogenic. However, most previous studies on the structural impacts of MnOx on Cr(III) oxidation were either limited because of the use of sythetic MnOx or complicated by the microbe species used, which required the presence of cells for MnOx production. Recent studies of *Roseobacter* sp. AzwK-3b, a bacterium that oxidizes Mn(II) through the production of extracellular superoxide and maintains oxidative activity in the cell-free filtrate[1,2], provides a good opportunity for studing the structure-reactivity relationship of biogenic MnOx toward Cr(III) oxidation.

In this study, we examined the roles of light, organics, pH, and structure of biogenic MnOx on Cr(III) oxidation. MnOx produced by the cell-free filtrate of *R.* AzwK-3b were aged in an organic-rich (K) medium for varied amounts of time under light or dark conditions, which induced structural change from a hexagonal birnessite phase to triclinic birnessite phase. MnOx with different structures were then reacted with Cr(III) at varied pH, concentration and time in K medium or artificial sea water (ASW) under light or dark conditions. Batch uptake results show that Cr(III) oxidation efficiency is highest at near neutral pH (7.2). With the same MnOx, under light conditions, the oxidation effiency is higher in the organic-rich medium than ASW. For fixed solution composition and varied MnOx age, a negative correlation is observed between the age of MnOx and oxidative reacitivity in the presence of organics and light, whereas no changes in reactivity is shown under ASW and dark conditions. These results strongly point to the role of photo-induced organic radicals. We propose that the Mn(II) produced from the oxidation of Cr(III) and reduction of MnOx is recycled in the system under organics and light conditions, and is responsible for the continuous oxidation of Cr(III). Ongoing structural analysis of the initial and reacted MnOx by synchrotron X-ray absorption spectrosocpy (XAS) will provide more insights on the reaction kinetics and mechanisms.

Coseismic fluid-rock interaction in an active fault zone estimated from Sr speciation analysis of fault gauge

MASAHARU TANIMIZU[1,2*], TSUYOSHI ISHIKAWA[1,2], YOSHIO TAKAHASHI[2,1], WONN SOH[1], SHENG-RONG SONG[3]

[1]JAMSTEC, Nankoku, Japan, tanimizum@jamstec.go.jp
[2]Hiroshima Univ. Higashi-Hiroshima, Japan
[3]Natonal Taiwan Univ., Taipei, Taiwan

Chemical behavior of trace elements during fluid-rock interaction is generally estimated on the basis of the change in their concentration in solid or fluid phases. Changes in mineral phases associated with fluid-rock interactions are discussed based on the correlation with concentration changes of elements, but the trace element-hosting phases themselves have been identified scarcely by spectroscopic observation. This is because XRD analyses can detect only major mineral phases hosting major elements, and cannot applied to the host mineral phase estimation for trace elements.

In this presentation, we applied XAFS (X-ray Absorption Fine Structure) analysis to fault-gauge system to understand the behavior of elements related to the coseismic fluid-rock interactions. XAFS is a powerful spectroscopic tool to estimate chemical species of elements from local electron environment condition around the objective elements. The Chelungpu fault in Taiwan was selected for this purpose. The Taiwan Chelungpu-fault Drilling Project (TCDP) was undertaken after the the Chi-Chi earthquake (M7.6; 1999), and gauge samples were collected from three fault zones from 1100 m to 1300 m in depth from Hole-B core samples. Distinct changes observed in concentration for various trace elements at the center of the fault zone relative to the adjacent rocks are interpreted as a result of coseismic fluid-rock interactions at above 350 degrees centigrade [1]. For example, Sr concentration increased twice at the center of the fault zone with distinctly lowering $^{87}Sr/^{86}Sr$ ratio. The host mineral phase of Sr was estimated from XANES analysis of Sr, Ca, and S.

XANES spectra of Ca and S and literature data [2] suggested that potential host phase of Sr newly produced at the center of the fault zone is calcite, gypsum, and plagioclase. XANES spectra of Sr from the samples at the center of the fault zone were consistent with that of albite (sodic plagioclase) among the candidate minerals. The production of albite phase enriched in Sr indicates occurrence of high temperature fluid more than 250 degrees centigrade, which is consistent with the previous discussion [1] estimated from elemental concentration increase/decrease trends. Occurrence of such high-temperature fluids during the earthquake will play an important role to the fault weakening.

Remediation of Heavy Metals in Nano-Materials

REBECCA TANNEY,[1*] KEON JEFFREY[1], MARIA ALFREDSSON[1]

[1]University of Kent, Canterbury, United Kingdom, rt274@kent.ac.uk

Remediation Techniques for Heavy Metals in Soil

Zeolites act as molecular sieves by crystallising in cage and channel structures. There are three proposed mechanisms that zeolites use to immobilise heavy metals; modification of the pH of the soil, sorption of metals onto mineral surfaces, and cation exchange process[1].

The aim of this project is to determine the effectiveness of zeolite-A to act as a remediation tool for lead and arsenic in contaminated soils.

Pyrite ash is a waste product from the production of sulphuric acid characterised as mostly iron oxides and silicate *nanoparticles*. The material contains high levels of arsenic and lead up to 15,000 and 24,000 mg/kg, respectively.

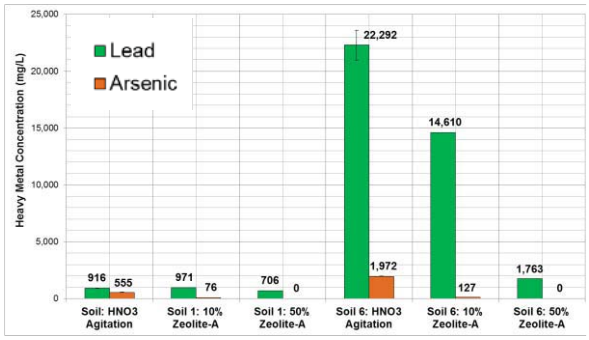

Figure 1 - Concentration of Soil Leachate following Remedial Action with Zeolite-A Additives at 10% and 50% Quantities Compared to Original Leachate Concentrations (mg/L)

Results and Conclusion

Zeolite-A has been found to give positive results as a remediation technique. Two soil samples, 1 and 6, were collected from a pyrite ash contaminated site. The particle size is around 100 nm, and the pH of the two samples are 1.8 and 5.5, respectively. It was found that zeolite-A more readily adsorbs arsenic rather than lead (see Figure 1).

A 10% weight dosage of zeolite-A successfully immobilised 86% of the arsenic in sample 1, and 93% from sample 6. A 50% dosage of zeolite-A removed 100% of the arsenic in both soil samples. Zeolite-A was found to be less efficient remediating lead, which showed using 10% zeolite-A, only 34% was removed.

Further experiments will be carried out using XRD, XRF, AAS, and SEM-EDX. We aim to fully understand the complexation and insertion mechanisms for lead and arsenic, and to determine the potential of zeolite-A as an affordable and accessible method of remediation.

Carbon fluxes beneath cratons: Insights from West Greenland kimberlites and carbonatites

S. TAPPE[1, 2*], K.A. SMART[2], A. STRACKE[2], R.L. ROMER[3], A. STEENFELT[4] AND K. MUEHLENBACHS[1]

[1]University of Alberta, Edmonton, Canada, tappe@ualberta.ca (*presenting author)
[2]Westfälische Wilhelms-Universität, Münster, Germany
[3]GeoForschungszentrum, Potsdam, Germany
[4]Geological Survey of Denmark and Greenland, Copenhagen, Denmark

Kimberlite and carbonatite magmas intruding cratonic lithosphere are considered the deepest probes into Earth's mantle. In this setting their co-existence is commonly interpreted to represent a primary melting sequence of carbonated peridotite at >150 km depths, possibly as deep as the transition zone. The carbon involved in this magmatism is thought to be either of primordial origin or derived from recycled subduced oceanic crust [1].

To better understand carbon fluxes beneath cratons and their role in the deep carbon cycle, we have studied kimberlite dyke swarms and associated carbonatite intrusions of the North Atlantic craton in West Greenland [2, 3]. Our new Nd-Hf-Pb isotope data suggest that both magma types were derived from a common convective upper mantle source. Moreover, the absence of hallmark recycled oceanic crust signatures such as highly radiogenic Pb and decoupled Nd-Hf isotope systematics are indicative of a primordial mantle origin of the carbon involved in Greenland kimberlite and carbonatite magmatism. Based on phase relationships and geochemistry, including carbon isotopes, we identify Greenland kimberlites as near-primary melts (-6 to -4‰ $\delta^{13}C$). The intrusive carbonatites (-4 to -2‰ $\delta^{13}C$), however, represent mixtures of cumulus crystals and liquid. The kimberlites and carbonatites appear to be linked by a two-stage fractionation process that commenced at uppermost mantle depths. First, liquidus olivine+phlogopite were removed from kimberlitic carbonate-silicate melts at high-T, leading to residual carbonate-rich melt fractions. Second, upon continued ascent into the cratonic crust and cooling, these carbonate-rich melts precipitated calcite+dolomite along with minor olivine+magnetite [2].

Rayleigh carbon isotope fractionation modelling suggests that 70-to-90 vol% of mantle-derived carbonate involved in this deep magmatism is now captured in the intrusive carbonatite bodies. Thus, it appears that CO_2 outgassing associated with kimberlite and carbonatite magmatic activity is volumetrically insignificant compared to global basaltic magmatism, and that carbonatite intrusions represent a major cache of primordial mantle carbon.

$^3He/^4He$ in volcanic and hydrothermal fluids of the Mexican subduction zone

YURI TARAN[1*] AND SALVATORE INGUAGGIATO[2]

[1]Institute of Geophysics, Universidad Nacional Autonoma de Mexico, taran@geofisica.unam.mx (* presenting author)
[2]INGV-Palermo, Italy, s.inguaggiato@pa.ingv.it

New and published data on $^3He/^4He$ in volcanic and hydrothermal fluids of Mexico are discussed in terms of the structure and geodynamics of the Mexican subduction zone that extends from the Gulf of California at ~ 22°N to Tacana volcano on the border with Guatemala and includes at least three apparently independent volcanic areas: a ~700 km-long Trans Mexican Volcanic Belt (TMVB), a short, ~150 km-long Chiapanecan Volcanic chain (CVC), and Tacana volcano that belongs to the Central America Volcanic Arc (CAVA). The TMVB is a volcanic front that originates from the subduction of two oceanic plates beneath the continent: a mini Rivera plate at north and the Cocos plate further to south. The subduction of the Cocos plate is also responsible for the CVC and Tacana volcanism. In spite of a complicated geometry of the TMVB, high-temperature hydrothermal fluids from deep wells and natural manifestations of four drilled geothermal fields along the TMVB (La Primavera, Los Azufres, Los Humeros and Acaculco) are characterized by high and uniform $^3He/^4He$ maximum values of 7.2Ra to 7.5Ra (Ra = $1.39x10^{-6}$, air $^3He/^4He$ ratio). Numerous thermal groundwater systems along TMVB discharge gases with a wide spectrum of $^3He/^4He$ ratios from 2 to 6Ra with higher values in the western part, close to the triple point of intersection of three rift-like structures: Chapala, Colima and Tepic-Zacoalco. El Chichon, the only active volcano of CVC is characterized by MORB-like $^3He/^4He$ values of 7.7Ra to 8.1Ra in the crater fumaroles, while in fumaroles and hot springs of the Tacana volcanic complex much lower values of <6.2Ra were measured. A high-temperature (850°C) fumarole of Colima volcano discharged gas with $^3He/^4He$ of 6.6Ra. Distribution of He isotopes adequately responses on the complex tectonic structure of the western part of TMVB together with the fore-arc area that includes Jalisco Block, a newly forming terrain originated from the present day complex tectonic mobility and bordered by Colima and Tepic-Zacoalco rifts and the Rivera plate subduction trench. He-isotopes clearly mark deep fault systems surrounding the Jalisco Block and shed light on the geometry of the Cocos-Rivera plate boundary close to the trench. $^3He/^4He$ anomalies in coastal thermal springs near Colima graben may be interpreted as being provided by a difference in the initial dip angle of the subduction and thus indicating a gap between plates and permeability for mantle He.

Chemical interpretation of mantle electrical heterogeneities in MORB source regions

PASCAL TARITS*[1], DAVID SIFRE[2], CECILE GRIGNE[1], MALCOLM MASSUYAU[2], LEILA HASHIM[2], SOPHIE HAUTOT[1], FABRICE GAILLARD[2]

[1] Domaines Océaniques, IUEM, Place Nicolas Copernic, F29280 Plouzané, France, tarits@univ-brest.fr (* presenting author)
[2] CNRS-INSU, Université d'Orléans, ISTO, UMR 7327, 45071, Orléans, France, gaillard@cnrs-orleans.fr

The electrical conductivity of mantle rocks being greatly affected by partial melting [1], the MELT magnetotelluric surveys have allowed major improvements in the knowledge of melt pathway, melt extraction and melt formation in MORB source regions [2]. The connection between electrical structure and melt chemistry remains however difficult to establish.

Here, analyses and interpretations of the MELT magnetotelluric data are discussed to infer the mantle structure down to the transition zone. Magnetotelluric response tensors inverted for a 3-D isotropic conductivity structure allows identification of strong electrical heterogeneities, with profils showing elevated conductivity from the transition zone up to depth where MORB are formed. Such conductive plumes are observed in the south and the north of the studied area, while the central zone is in contrast poorly conductive. The results suggest a fairly complicated scheme for melt migration under this portion of the EPR but it must reflect chemical heterogenities allowing volatile-rich low melt fractions [3] to wet peridotite grain boundaries along some profils whereas others regions remain 100% solids.

Based on new laboratory data on volatile-rich carbonated melts, we discuss these heterogeneities in terms of heterogenity in mantle redox state. Carbonated melts are stable and connected from the transition zone to the depth of MORB formation if redox conditions are sufficiently oxidizing [4]. Otherwise, diamond is stable and chemically enriched carbonated melts are not or poorly involved in MORB generation. This may generate chemical heterogenities in MORB.

Copper Partitioning in CO_2-Bearing Melt-Vapor-Brine Systems

BRIAN TATTITCH[1*], PHILIP CANDELA[1], PHILIP PICCOLI[1], ROBERT BODNAR[2], LUCA FEDELE[2]

[1]Laboratory for Mineral Deposits Research, University of Maryland, College Park, USA, bctatti@geol.umd.edu (*presenting author)
[2]Virginia Tech, Blacksburg, USA

Analysis of fluid and melt inclusions from arc-related intrusions and porphyry copper deposits (PCD) reveal that many fluid inclusions from PCD are typically characterized by $X_{CO2} < 0.10$, which is lower than that found in volatile phases exsolved from shallow (e.g., 5 to 10 km), arc magmas, in general (X_{CO2} up to order ~ 0.45). This disparity remains to be resolved.

The efficiency with which copper can be removed from arc magmas into exsolving volatile phases is a function of the competition between crystalline phases (± liquid sulphides), and the exsolving vapor ± brine. Experiments in melt-vapor-brine systems permit the investigation of the partitioning of copper between silicate melts and volatile phases under magmatic conditions. However, the effect of CO_2 on melt-volatile phase equilibria relevant to the formation of PCD has remained unconstrained. In this study, the partitioning of copper in CO_2-bearing, sulfur-free and sulfur-bearing, experiments may provide additional insights into copper partitioning and the generation of PCD.

We present results from experiments performed at 800 °C and 100 MPa in CO_2-bearing, sulfur-free and sulfur-bearing melt-vapor-brine systems with X_{CO2} (bulk vapor ± brine) = 0.10 and 0.38. The compositions of vapor and brine inclusions and run-product glasses were used as proxies for the compositions of the magmatic phases. The salinities of vapor inclusions that nucleated clathrate (CO_2 ± H_2S clathrate) upon cooling were determined via Raman analysis and microthermometry [1]. The partitioning of copper between brine and vapor ($D^{b/v}_{Cu}(\pm 2\sigma)$) increases from 25(±6) to 100 (±30) for sulfur-free experiments and from 11(±3) to 95(±23) for sulfur-bearing experiments, as X_{CO2} is increased from 0.10 to 0.38. The partitioning of copper between vapor and melt increases with the addition of sulfur at $X_{CO2} = 0.10$: ($D^{v/m}_{Cu}(\pm 2\sigma)$) = 9.6(±3.3) (sulfur-free, metaluminous melt); 18(±8) (sulfur-bearing, peralkaline melt); and 30(±11) (sulfur-bearing, metaluminous melt). These values are to be contrasted with ($D^{v/m}_{Cu}(\pm 2\sigma)$) = 2(±0.8) at $X_{CO2} = 0.38$ (the effect of sulfur cannot be distinguished at this mole fraction of CO_2). These data demonstrate that changes in the salinity of the vapor and brine, which are controlled by changes in X_{CO2}, play a major role in controlling copper partitioning in sulfur-free, CO_2-bearing systems. Sulfur-bearing experiments demonstrate that magmatic vapors are enriched in copper in the presence of sulfur at low X_{CO2}. However, the enrichment of copper in the magmatic vapor is suppressed for sulfur-bearing systems at high X_{CO2}. These data indicate that the efficient removal of copper from silicate melts into vapor ± brine is mitigated by high concentrations of CO_2. Furthermore, the poisoning effect of CO_2 is more pronounced for sulfur-bearing volatile phases. As a result, high concentrations of CO_2 may play a negative role in the formation of PCD.

Variations of catchment P in stream water constrained by oxygen isotopes in phosphate

HEINRICH TAUBALD[1*], KARIN TONDERSKI[2], LOTTA ANDERSSON[3], AND RASMUS ROENNBERG[2]

[1]University of Tübingen, Isotope Geochemistry, 72074 Tübingen, Germany, taubald@uni-tuebingen.de (* presenting author)

[3]SMHI, 60176 Norrköping, Sweden, Lotta.Andersson@smhi.se

Introduction

We present oxygen isotope measurements (δ^{18}Op) on dissolved inorganic phosphate (DIP) from stream water (outflow of catchment), field drains and rural sewage/waste water to trace and quantify the contribution of different sources of P to the total P discharge from a catchment in South Sweden. Recent studies by Young et al. [1] proved that δ^{18}Op values can be an efficient tool to study sources and transport pathways for dissolved phosphate. A periodic sampling was performed between March 2009 and October 2011, sample handling, and isotope measurements were done similar to the procedures described by McLaughlin et al [2]. Due to significant concentrations of DOC activated carbon powder was added prior to filtering in order to remove organic matter (modified after Gruau et al. 2005 [3]).

Results and Conclusion

δ^{18}Op values of field drains vary from +8.0 to +15.7 ‰, sewage/waste water samples show δ^{18}Op values of +12.1 to +16.2 ‰, stream water at catchment outflow shows a seasonal variation between +10.3 and +15.8 ‰, the δ^{18}Ow of the ambient water ranges seasonally between -9.0 to -13.5 ‰, all values reported relative to V-SMOW2. δ^{18}Op values of sewage and waste waters as potential contaminants are in good agreement with recent data from Young et al [1]. A comparison of δ^{18}Op with δ^{18}Ow shows that most samples are not in oxygen isotope equilibrium, thus their δ^{18}Op probably reflects the isotope signature of the P source. Isotopic variations of field drains correlate with DIP concentrations and might reflect mixing processes with different waste and/or sewage sources. Covarations in isotopic signal and DIP concentrations in the stream water (catchment outflow) are also best explained by individual and possibly changing contributions from different P sources. Interestingly δ^{18}Op in stream water shows a seasonal signal, a phenomenon only recently observed by Angert et al. [4] for soil δ^{18}Op. Further detailed geological background informations and hydrological data in particular are necessary to fit these data into a model.

The hydrothermal architecture of the coeval Horne and Quemont deposits was visualized by 2D and 3D modelling using Kriging methods on a suite of whole-rock stable isotope and geochemical data. Hydro-thermal mapping integrated both surface and subsurface data: 416 δ^{18}O values (2.7 to 16.3‰), 4845 analyses of SiO_2, H_2O, MgO, Al_2O_3, S and wt.% H_2O, as well as SiO_2/Al_2O_3 ratios and REE data for intrusive and volcanic rocks. Zones of alteration about the steeply-dipping Horne deposit were mapped in 3D, to depths up to 2 km. The Quemont deposit is centered on the Powell pluton, which intruded into a volcanic-filled, caldera-type, or rift-graben structure, but the Andesite and Horne Creek Faults removed evidence of Horne-related up-flow zones and intrusions.

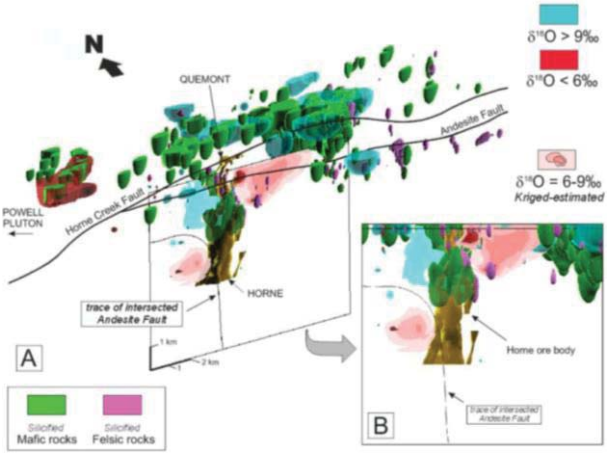

Figure 1: 3D model of the Horne hydrothermal system

Cooling of hydrothermal fluid by cold seawater in permeable rocks led to marked footwall silicification at the Horne deposit. Stratigraphic stability of the hydrothermal system may explain its large sulfide tonnage.

Separate magmatic hydrothermal systems influenced development of significant ore bodies in the area. Robust 2D and 3D data integration are needed to better understand these complex systems.

Fluorescence is a highly sensitive phenomenon capable of detection at concentrations below PPM which is widely used. A recurring problem in mineralogical and petrological applications of fluorescence is that this sensitivity leads to the collected data representing a number of convoluted signals that make interpretation difficult. We present results from two complementary time resolved (TR) techniques Photo luminescence (PL) extensively used in biological applications as Fluorescence lifetime imaging microscopy. (FLIM) and TR X-ray Excited Optical Luminescence (XEOL) Results are presented from some obviously hetrogeneuos minerals and also examples from some with much less obvious heterogeneity. The (XEOL) is collected on the I18 microfocus beamline at the Diamond Light source. The system can be used to simutaneously collect X-ray Absorption spectra or X-ray flourescence (XRF) and simultaneuosly collect (CW) (XEOL), or (TR) (XEOL). This enables the combination of very high sensitivity with accurate quantification. Analysing the different decay lifetimes and ratios for a spatially resolved point emissions ~ 3/3 micron. Alows us to deconvolute the complex fluorescent signal. CW XEOL spectral data from 200-900nm collected from the same spatial resolution allows us to compare identified features with the literature. We also discuss mapping capabilities in both (XRF) and (CW) (XEOL) as either a function of either wavelength or incident photon energy.

Fluorescence intensity and lifetime map (figure1) collected from a Polished section of Microcline from the Derry Township Quebec The map is ~ 0.5µm square collected using a confocal (TR) multiphoton pulsed laser excitation

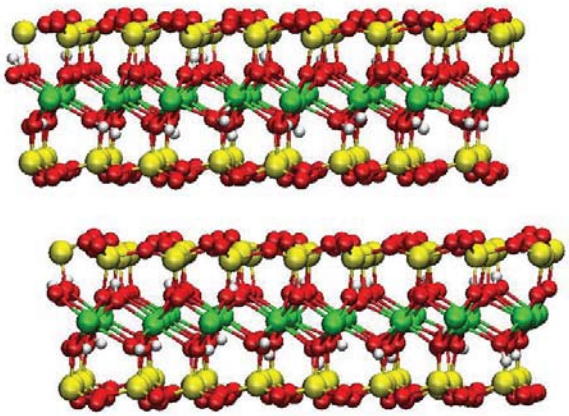
Accurate force fields built from ab-initio: the case of clays

SAMI TAZI*, MATHIEU SALANNE, BENJAMIN ROTENBERG AND PIERRE TURQ

UPMC Univ Paris 06, CNRS, ESPCI, UMR 7195 PECSA, F-75005 Paris, France
sami.tazi@upmc.fr (* presenting author)

Section heading

Molecular scale studies are essential for the prediction of sorption onto minerals such as clays, in particular in the context of the geological disposal of radioactive waste. The current state-of-the-art force field for clays, ClayFF [1], reproduces well several properties. However, it does not account for polarization, which is known to play an important role at solid liquid interface, in particular in influencing chemical specificity of cation sorption. We develop a polarisable force field for clays from DFT calculations, using on the one hand a force/dipole-fitting procedure, which provides a high degree of transferability [2], and on the other hand a systematic derivation using maximally localized Wannier functions [3].



Results and conclusion

We present here how the polarisable force field is constructed. We then demonstrate its validity by comparing structural properties to experimental data and to the current state-of-the-art non-polarisable force field ClayFF [1].

Pressure-induced anomalous isotopic fractionation of Li in magmatic hydrothermal systems

A. J. TEAGUE[1*], D.M. SHERMAN[1], J. D. BLUNDY[1], P. A. E. POGGE VON STRANDMANN[2]

[1]School of Earth Sciences, University of Bristol, Bristol, UK, alex.teague@bristol.ac.uk (*presenting author)

[2]Department of Eartyh Sciences, University of Oxford, Oxford, UK

Lithium has been demonstrated to undergo significant fractionations in geological environments, both elementally and isotopically. Such fractionations have been shown to occur due to various processes, with both chemical and kinetic effects contributing to the observed partitioning. Isotopic fractionation in particular, has been used to constrain processes of fluid release in the slab and mantle wedge through to the degassing of magmas and the subsequent condensation of hydrothermal fluids and fumarolic gases.

In this study, lithium isotope fractionation between synthetic granite and aqueous Cl bearing fluids was investigated experimentally. Experiments were conducted at 800°C and between 1.0-2.8 kbar, with the salinity of the fluid varying between 0, 0.1, 1 & 10 wt% NaCl. A strong systematic fractionation of ^{7}Li into the fluid of 1 - 10‰ was observed, with the strongest fractionations occurring at higher Cl concentrations. However, the most marked effect is that caused by pressure, with the fractionation doubling between 2.0 and 2.8 kbar.

Ab initio calculations of isotopic fractionation between $Li(H_2O)_4^+$ and $LiCl_n(H_2O)_{4-n}^{1-n}$ predict values of Δ^7Li ($Li(H_2O)_4^+$-$LiCl_2(H_2O)_2^-$) near +5 ‰ at 1000°C but in ideal gas at zero pressure. Accordingly, we would expect the fluid to increasingly favour the light isotope due to Cl complexation. However, we find that the fluid strongly favours the heavy isotope with increasing Cl. We attribute this to a very strong pressure effect on isotope fractionation between $Li(H_2O)_4^+$ and $LiCl_n(H_2O)_{4-n}^{1-n}$. For a 0.1*m* Cl solution Δ^7Li (fluid-glass) increases by 4‰ with a 0.8 kbar pressure increase.

In summary, Li is light enough to still undergo substantial isotopic fractionation even at magmatic hydrothermal temperatures. However, the effect of pressure is comparable, and opposite, to that of temperature and complexation by Cl. The interpretation of Li isotopes measured in natural systems must account for these competing effects. On the other hand, the isotopic composition of Li offers potential as a geobarometer at elevated T.

Petrografic and geochemical characteristic of metagreywackes (Central Portugal): implication of Zr content

MARIA RIBEIRO[1] HELENA C.B. MARTINS[1] DANIEL TEIXEIRA[1*]

[1] Centro Geologia da Universidade do Porto, DGAOT – FCUP, R. Campo Alegre, 4169-007 Porto, Portugal (*maribeir@fc.up.pt)

Introduction

Petrography and geochemistry (major, trace and rare earth elements) of two greywackes samples from the Upper Proterozoic to Lower Cambrian "Complexo Xisto-Grauváquico – CXG" (Central Portugal) have been investigated as support of subsequent mineralogical study of zircons. The two samples: Alv 51 and Alv 55 are close one to another (ca 20m), being the last near a fault zone.

Results

The petrographic and geochemical studies have shown significant differences: (i) Alv 51 is a metagreywacke in chlorite zone conditions, with a clastic texture and an anisotropic mica-quartz matrix. Anisotropy is marked by a spaced anastomosing foliation, with microlithons controlled by the size of quartz and plagioclase porphyroclasts. Detrital zircons are presents as accessory mineral with euhedral oscillatory zoning crystals (60-120 μm). (ii) Alv 55, near the fault zone, presents heterogranular granoblastic texture, with quartz, chlorite, calcite, muscovite, sphene and rutile, resulting from local hydrothermal metamorfism. Detrital zircons are not identified, but chlorite shows pleochroic haloes associated with very small zircons (1-2 μm) and abundant rutile needles.

The major elements composition of the samples is quite different: Alv 51 is richer in SiO_2 and K_2O while Alv55 present higher content in all the others major elements, especially in MgO, TiO_2, P_2O_5, but also in CaO and Na_2O. The trace elements content is also very different. Alv 55 shows an enrichment of LREE, Ba, Sr, Ni, Cr, and especially Hf, Th and U. This sample has higher Zr content (Alv 55 Zr= 376ppm; Alv 51 Zr = 275ppm). The UCC [1] normalized spider plot highlights these differences.

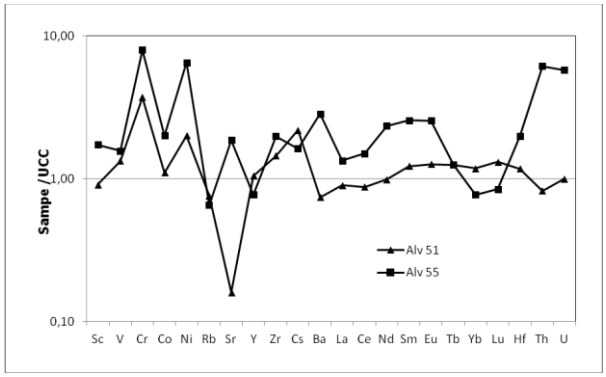

Figure 1: UCC [1] normalized spider plot.

The high content of Cr, TiO_2 LREE, Hf, Th and U and low contents of HREE in Alv55 may suggest that the Zr is partly associated with the rutile (anatase) and not only with the zircon. The incorporation of Zr in rutile, by substitution of Ti is favored by increasing temperature and is used as geothermometer [2].

The importance of electron microprobe dating of monazite from some granites of northern Portugal

R. J. S. TEIXEIRA[1]*, A. M. R. NEIVA[2] AND M. E. P. GOMES[3]

[1, 3]Department of Geology, University of Trás-os-Montes e Alto Douro, Vila Real and Geosciences Centre, University of Coimbra, Portugal, rteixeir@utad.pt, mgomes@utad.pt (* presenting author)

[2]Department of Earth Sciences and Geosciences Centre, University of Coimbra, 3000-272 Coimbra, Portugal, neiva@dct.uc.pt

Ten Variscan S-type granites (G1 to G10) occur in Carrazeda de Ansiães region, northern Portugal, intruding Precambrian to Ordovician metasedimentary rocks. The U-Pb ID-TIMS data obtained in zircon and monazite from these granites yield crystallization ages comprised between 329.9 ± 0.8 Ma and 316.2 ± 0.7 Ma. The variation diagrams of these peraluminous granites and their minerals and the whole-rock REE patterns, whole-rock $\delta^{18}O$ values of 10.55 – 11.86 ‰, the different mean whole-rock values of $(^{87}Sr/^{86}Sr)_i$ and εNd_t for G1 (0.7097 ± 0.0000; -6.3), G2 (0.7149 ± 0.0008; -8.2), G4 (0.7112 ± 0.0006; -8.0), G5 (0.7124 ± 0.0007; -7.5), G7 (0.7156 ± 0.0005; -8.5) and G8 (0.7155 ± 0.0007; -8.4) point to the existence of distinct pulses of magmas, which were probably formed by the partial melting of heterogeneous metasedimentary rocks. Three differentiation series are distinguished: a) G2 and G3, b) G5 and G6 and c) G8, G9 and G10.

The zircon systematics are generally complex due to Pb loss and to the presence of inherited cores, but the latter can also affect some of the monazites. Therefore, the fast and low cost age determination on monazites, by electron microprobe, using the U-Th-Pb method [1], can be a useful tool in the interpretation of U-Pb ID-TIMS data. Its high spatial resolution can allow a detailed study of heterogeneities inside the same crystal, in areas with diameters as small as 5 µm. The monazite populations from the granites of the three differentiation series show ages similar to those from the ID-TIMS U-Pb results: 321 ± 6 Ma for G2, 318 ± 5 Ma for G3, 319 ± 7 Ma for G5, 319 ± 7 Ma for G6, 316 ± 7 Ma for G8, 315 ± 4 Ma for G9 and 315 ± 9 Ma for G10. However, in the rims of all monazite crystals and internal domains related to the rims, ages from 281 ± 8 Ma to 298 ± 9 Ma were also obtained, which should correspond to recrystallization events. On the other hand, in monazites from granites G6 and G9, inherited components were detected, presenting ages of 352 ± 7 Ma and 345 ± 5 Ma (Figure 1), which can explain the U-Pb age spreading of some concordant monazites in granite G9.

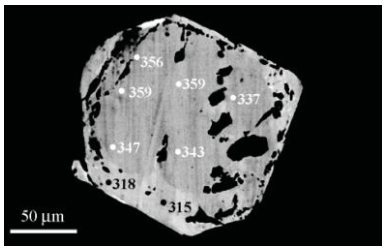

Figure 1: BSE image of a monazite from granite G9, with ages (in Ma) determined by electron microprobe.

Arsenic speciation and distribution controls throughout Murshidabad, West Bengal, India

KATHERINE TELFEYAN[1*], SANKAR M.S[2], SAUGATA DATTA[2], SOPHIA FORD[2], KAREN JOHANNESSON[1]

[1]Tulane University, New Orleans , LA, USA, ktelfeya@tulane.edu (* presenting author)

[1]Kansas State University, Manhattan, KS, USA, sdatta@ksu.edu

Over 2% of the world's population lives in the Bengal Delta, the world's largest fluvial-delta system. However, the rapid burial of Himalayan sediments has ultimately resulted in the release of arsenic (As) from sediment grains and tragically affected the health of millions of people [1]. In January 2012, field surveys of four blocks in the Murshidabad district of West Bengal, India were conducted, sampling tubewells, irrigation water, ponds, and sediment cores. Two sites, Beldanga and Hariharpara located east of the Ganges distributary, Bhāgirathi-Hooghly River, whereas Nabagram and Kandi are located to the west of the river. High As is associated with gray, reduced sediments, whereas low As is associated with orange-brown, oxidized sands [2]. Field test kits show total As concentrations ranging from less than 10 ppb to greater than 500 ppb. Eight groundwater samples were passed through ion exchange columns to separate As(III) from As (V) for analysis. Reductive dissolution of iron hydroxides is the primary cited cause of As mobilization. However, the source of the organic matter responsible for the reduction of iron and As is not fully understood. Previous studies have suggested human and animal waste, surface ponds, irrigation return-flow, and in situ organic matter at depth [3,4]. Analysis of dissolved organic carbon is discussed with regards to potential sources. In addition to organic matter, As concentrations are compared to those of other trace elements, such as Fe and Mn, that also vary as a function of redox conditions and pose health problems in Murshidabad.

[3]IMBE, CNRS Aix Marseille Univ., Marseille, France.
[4]Duke University, Durham NC, USA.
[5]CEINT, Durham NC, USA.
[6]LEMIRE CNRS CEA,Aix Marseille Univ, St Paul lez Durance, France.

In the past decade, there has been a growing concern about the use of nanoparticles/nanomaterials which are now present in 1000+ consumer products. There is no established current state of the art regarding the risks associated with the manufacturing and use of nano-enabled products, but rather a large collection of a somewhat contradictory literature. The vast variety of parameters and processes (physico-chemical, (micro)biological, (eco)toxicological...) is the source of a complexity level that cannot be easily resolved.

Hazard is the factor that is generally studied first but the multiplicity of experimental protocols makes it difficult to efficiently used these data. The exposure cannot be easily defined because of the complex interplay of intrinsic properties of the nanomaterial, their process dictated surface modification(s), and the evolution of their speciation during aging in regular use, accidental release or disposal scenarios.

A way to circumvent experimental artifacts in the determination of environmental exposure is to let nature have its way. Of course, for practicality, nature needs to be "harnessed", and experiment management/monitoring becomes a predominant issue. The use of mesocosms, i.e. downscaled ecosystems with in sizes ranging from a table top aquarium to backyard swimming pools, is the most promising way to achieve relevant evaluation of environmental exposure to-/ bioavailability of- nanomaterials at varying stages of their life cycle.

The current work demonstrates how such mesocosm experiments need to be implemented in terms of operational setup to be relevant for the assessment of exposure scenarios. First results provide a validation of this approach.

Magnesium isotopic composition of the lower continental crust: A xenolith perspective

FANG-ZHEN TENG[1*], WEI YANG[1,2] AND ROBERTA L. RUDNICK[3]

[1]Isotope Laboratory, Depart. of Geosciences, University of Askansas, Fayetteville, AR, USA, fteng@uark.edu (*presenting author)
[2]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China, yangw@mail.iggcas.ac.cn
[3]Isotope Geochemistry Laboratory, Department of Geology, University of Maryland, College Park, MD, USA, rudnick@umd.edu

The large isotope fractionation during low-temperature water-rock interactions and limited fractionation during igneous differentiation make Mg isotopes a potentially powerful tracer of the influence of chemical weathering on the continental crust composition. Magnesium isotopic composition of the upper continental crust is highly heterogenous [1], and on avarage heavier than the mantle [e.g., 2]. By contrast, the Mg isotopic composition of the hydrosphere, as represented by seawater [e.g., 3], is very light. The distinct Mg isotopic distribution among the mantle, upper continental crust and the hydrosphere is interpreted as a result of continental weathering, during which light Mg isotopes are partitioned into the hydrosphere relative to the weathered regolith [4].

Better understanding the Mg isotopic cycling between the crust, mantle and hydrosphere requires knowledge of the bulk crustal Mg isotopic composition, which is heavily influenced by the deep crust. Here, we report Mg isotopic data for two sets of well-studied lower crustal granulite xenoliths from North Queensland, Australia (Chudleigh and McBride suites) [5, 6]. The Chudleigh granulites are a suite of cogenic crystal cumulates derived from mafic magmas that intruded and assimilated the preexisting lower crust. Their mineralogy varies from olivine-bearing assemblages to plagioclase-garnet-clinopyroxene assemblages indicating a range of equilibrium temperatures (600 to 1000 ºC) and depths (20 to >40 km). McBride granulites range from mafic to felsic bulk compositions, with most of them formed through mixing between mantle-derived basalts and preexisting crust. Overall, these two sets of granulite xenoliths match the estimated composition of the lower crust and hence are ideal for studying the average Mg isotopic composition of the lower crust.

Magnesium isotopic compositions of Chudleigh xenoliths are homogenous and mantle-like, with δ^{26}Mg varying from -0.3 to -0.2‰. By contrast, δ^{26}Mg of McBride xenoliths is highly variable from -0.7 to +0.2‰, significantly overlapping that of the upper continental crust. The contrasting behaviors of Mg isotopes between Chudleigh and McBride xenoliths mainly reflect their different proportions of mantle vs. crustal Mg. Based on these xenoliths, the lower continental crust has a heterogneous Mg isotopic composition, with a weighted average δ^{26}Mg of -0.2‰, which is similar to that of the upper crust, but slightly heavier than the mantle.

8a. Mineral growth and dissolution: modern approaches to molecular-level reaction mechanism determination with implications for toxic metal sequestration, biomineralization, and engineering

Magnesium is the second most widely occurred metal component in carbonates next only to Ca, but low temperature precipitation of anhydrous Mg-CO_3 phases has proven virtually impossible. The difficulty encountered herein is often attributed to the highly hydrated character of Mg^{2+}. The seemingly clear understanding in the role of water leads to an interesting question: will magnesite precipitate if the formation of aqueous hydration shell is breached or prevented? Meanwhile, a plethora of literature data documented the occurrence of dolomite in the presence of sulfur reducing bacteria SRB, leaving no lucid explanation for the kinetic effect of water. The ultimate goal of our research is to address these issues through experimentally testing the follwoing hypotheses: (1) weakend solvation shell around Mg^{2+} will lead to $MgCO_3$ crystallization if dehydration is the kinetic hindrance and (2) sulfide is the ultimate mediating agent for SRB facilitated dolomite formation.

Crystallization experiments were carried out in dry organic and organo-aqueous binary solvents and in the presence of sulfide ions. Experimental results indicate (1) Anhydrous $MgCO_3$ precipitates under dry conditions but appears in amophous form instead of crystalline magnesite. (2) Crysalline anhydrate only forms when both Mg and Ca are present in organic solvent. XRD identifies the occurrence of dolomite with ~37% $MgCO_3$ in solutions containing 1:1 ratio of Mg and Ca. (3) The presence of minute amount of water in organic solvents leads to the precipitation of hydrated magnesium carbonate. (4) Tri-hydrate Mg-CO_3 nesqhehonite is the dominant phase in binary solvent, similar to the result in pure aqueous environments. However, the presence of organic solvent greatly accelerate the crystallization kinteics. (5) Input of solutions with Mg/Ca = 5 instantly halts the growth on seeded calcite crystals in saturated solutions. However, in situ AFM observations on the (104) faces reveals the inhibation tackles primarily nulceation but not step flow despite the change of hillock morphology. (6) The retardation effect of Mg is greatly alleviated, if not eliminated at all, when the input solutions contains 0.5 mM sulfide. Initial effect of Mg changes the hillock from the rhombic to a tear-drop mophology, but continued growth leads to step bunching in the $< \bar{4}41 >$ directions and ultimately a return to the cleavage form.

These observations indicate that the crystallization of Mg-containing carbonate may be inhibited both kinetically and energetically. The kinetic effect is shown by the formation of metastable hydrous phases in the presence even minimal amount of water. However, the inhibition on step nucleation but not step flow, as well as the lack of crystalline $MgCO_3$ phase in dry solvents, suggest the difficulty for Mg^{2+} and CO_3^{2-} to establish ordered long-range structures.

The Leaching of Heavy Metals from Steel Slag in Panzhihua Region

YANGUO TENG[1*], JIE YANG[2], ZHENGQI XU[3]

[2] College of Water Sciences, Beijing Normal University, Beijing City, China, yangjie8769@163.com

[3] Department of Geochemistry, Chengdu University of Technology, Chengdu City, xuzhengq@163.com

Introduction

From 1970s to nowadays, approximately 3000000 t/a steel slag were dumping in Panzhihua region. [1] Heavy metals such as V, Cr, and Ni will influence environmental quality when they leach from slag pile. [2] In order to investigate the leaching of heavy metals from steel slag, some experiments were carried out.

Material and Method

The steel slag was selected in Baguanhe slag pile in Panzhihua region, and the chemical composition was Al_2O_3 1.69%, CaO 51.2%, Cr_2O_3 0.11%, FeO 10.66%, MgO 4.55%, MnO 1.54%, P_2O_5 0.37%, SiO_2 10.05%, TiO_2 5.33%, V_2O_5 6.35%. The steel slag was grounded and seived through d<0.075 mm, then 7 steel slag samples (each sample weight was 140 g) were put into 7 beakers which were added 100 ml pH=1, 3, 5, 7, 8, 10, 12 acid or alkali solutions, respectively. After 14 days soaking and shaking, heavy metals in the solution were detected by ICP-MS.

Results and Discussion

The leaching of heavy metals from slag was shown in Figure 1. When the pH value of solution was 1, the leaching of heavy metals was highest. And when the pH value of solution was 3, 5, 7, 8, 10, and 12, the concentration of heavy metals varied not obviously. Cr and Ni in leaching solution exceeded to Identification standards for hazardous wastes - Identification for extraction toxicity (GB5085.3-2007), which threatend regional environmental safety.

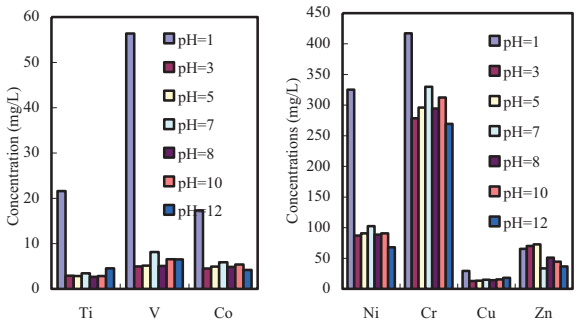

Figure 1: Heavy metas in solution after 14 days slag leaching

Conclusion

The steel slag which contained some heavy metals was hazardous waste. Heavy metals could release from the leaching of steel slag, especially, Cr and Ni would pollute water and soil.

Ion exchange model for reversible sorption of divalent metals on calcite

EMMANUEL TERTRE[1*], CATHERINE BEAUCAIRE[2] AND JACQUES PAGE[2]

[1]Université de Poitiers - CNRS, UMR 7285 IC2MP, Poitiers, France, emmanuel.tertre@univ-poitiers.fr (* presenting author)
[2]CEA, DEN/DANS/DPC/SECR/L3MR, Gif-sur-Yvette, France, catherine.beaucaire@cea.fr; jacques.page@cea.fr

Problematic and objectives

Previous studies dealing with electrokinetic properties of the calcite/water interface have shown that Ca^{2+} and CO_3^{2-} are the main species determining the potential of the calcite surface [1 among others]. This is particular true when systems are in equilibrium with both calcite and a fixed $p_{CO2(g)}$ value, a common case of environment conditions. However, most of the thermodynamic models proposed in literature describing the surface speciation of calcite do not predict a significant contribution of sorbed Ca(II) [2 among others]. Therefore, the aims of this study are (1) to propose a model, based onto the ion exchange theory, able to describe the reversible sorption of Ca(II) at the calcite surface and (2) to apply this model to some divalent metals (*e.g.*, Zn(II), Cd(II) and Pb(II)). Note that aqueous metallic cations presented in natural waters are always in competition with Ca^{2+} and H^+ for sorption sites located on mineral surfaces. Therefore, these two latter species should be systematically included in all models predicting sorption of divalent metals on calcite.

Methodology and main results

Concentrations of Ca(II) sorbed reversibly on the calcite are obtained using a previous methodology based on isotopic measurements [3]. Data are obtained at different pH using solutions saturated with both calcite and a fixed $p_{CO2(g)}$ value (from 10^{-5} to 10^{-2} atm.). Concentration of sorbed Ca(II) is significant as suggesting by previous electrokinetic data and is practically constant in the [7 - 9.5] pH range to a value close to $1.2\pm0.4\ 10^{-3}$ eq.kg^{-1}. Such value is in agreement with total sorption site density calculated by crystallographic considerations. Experiment data are fitted to obtain a selectivity coefficient between Ca^{2+} and H^+. Using previous published experimental data [4 among others] fitted metal-protons selectivity coefficients are also proposed for reversible sorption of Zn(II), Cd(II) and Pb(II) on calcite. Finally, the model was used to calculate the contribution of calcite to the sorption of Cd(II) on a natural and complex solid (*e.g.*, calcareous aquifer sand).

Plio-Pleistocene evolution of water mass exchange and erosinal input in the Nordic Seas

CLAUDIA TESCHNER[1*], MARTIN FRANK[1], BRIAN A. HALEY[2], JOCHEN KNIES[3]

[1] GEOMAR | Helmholtz-Centre for Ocean Research Kiel, Wischhofstr. 1-3, Kiel, Germany, cteschner@geomar.de (* presenting author)
[2] COAS, Oregon State University, Corvallis, OR 97331-5503, USA
[3] Geological Survey of Norway, Leiv Eirikssons vei 39, NO-7491 Trondheim, Norway

The Arctic Ocean and Norwegian-Greenland Seas (NGS) are presently one of the most important areas for deep water formation in the Northern Atlantic Ocean. Therefore, it is particularly essential to better understand Plio-Pleistocene variations of the circulation in these areas. Significant climatic and oceanographic changes occurred during this period of time including the major intensification of the Northern Hemisphere Glaciation (starting at 2.82 Ma) and the Mid-Pleistocene Transition (1.5 – 0.5 Ma).

To reconstruct erosional input and water mass exchange between the NGS and the Arctic ocean we use the composition of the radiogenic isotopes neodymium (Nd), lead (Pb) and strontium (Sr). For this purpose, we leached the authigenic metal oxide phase on sediments particles [1] of different ODP Sites in the Norwegian-Greenland Seas (Site 911, 986, and 644) and in the North Atlantic Ocean (Site 982).

The first analyses were performed on sediment samples from northernmost ODP site 911 (Leg 151, in 900 m water depth) located on the southeastern slope of the Yermak Plateau in the Fram Strait. Today this location is strongly influenced by the inflow of Atlantic water from the NGS, which is supported by the core top εNd value agreeing well with Atlantic values [2]. Based on these results, downcore samples covering the past 5 million years were analysed.

The record of the Yermak Plateau shows no significant general trend with time, but a very high variability with more radiogenic Nd isotope data during glacial periods at 0.72 Ma, 1.36 Ma, 2.4 Ma, and 2.69 Ma. These shifts indicate major inflow of waters influenced by highly radiogenic source areas, either by the Icelandic basalts in the south or by the Siberian Putorana flood basalts in the hinterland of the Kara/Laptev Sea region. The εNd data suggest that mixing of water masses from the Arctic Ocean and the NGS have controlled the Nd isotope signatures of deep waters on the Yermak Plateau since the onset of the Northern Hemisphere Glaciation (NHG). In contrast, the Pb istotope data of deep waters in the Fram Strait appear to have been dominated by glacial weathering inputs from old continental landmasses, such as Greenland or parts of Svalbard since 2 Ma.

In order to better understand past water mass exchange between the Norwegian-Greenland Seas and the North Atlantic Ocean we will compare these data with isotopic records of ODP Sites 986, 644 (NGS), and 982 (North Atlantic Ocean).

Tracing magmatic fluid in hydrothermal deposits within subduction zone setting

S. TESSALINA

John de Laeter Centre of Isotopic Research, Curtin University, Perth, Australia, Svetlana.Tessalina@curtin.edu.au

The metals in sea-floor hydrothermal systems may arise purely from the interaction of circulating sea-water with host rocks, or there may be an admixture from the fluid escaping from magtma at depth. Here we present direct evidence for the involvement of magmatic fluid in the formation of Volcanogenic Massive Sulphide (VMS) deposits in Devonian arc rocks of the Southern Urals, Russia.

The plot of isotope data for the hydrothermal chimneys from the Yaman-Kasy VMS deposit defines the best-fit line with the age of 362±9 Ma. The molybdenite sample from the Kul-Yurt-Tau VMS deposit shows the model age of 363.4±0.5 Ma. These ages are similar to that previously reported from the Urals VMS deposits [1,2] and younger than presumed biostratigraphic ages of ore-hosting rocks. The observed ages post-date the subduction of older Proterozoic blocks from adjacent East-European continent, which was constrained at 380-372 Ma from the high-pressure metamorphic rocks in the area [3]. The subducted Proterozoic rocks have distinct low radiogenic $^{206}Pb/^{204}Pb$ isotopic signature, which was identified in VMS deposits in fore-arc and arc setting, diminishing with a distance from the subducted front and annihiliating in the back-arc setting where the magmatic contribution was not detected.

Based on presented radiogenic isotope dataset, we conclude that the VMS deposits fromation was initiated after the continent has collided with the volcanic arc. This stage of Urals development was identified as hydrous suprasubduction melting characterised by large scale granitoid magmatism [4]. The generation of volatile-rich felsic magma at shallow depth may be due to the entrance of less dense continental blocks which shallowed the angle of slub subduction. Felsic magma may be produced by melting of cumulates remaining from previous melting events. Metal-rich magmatic fluid is released from volatile-rich felsic magma, which are prelevant at convergent margin setting. Indeed, the presence of magmatic aqueous-carbonic fluid with significant contents of H_2S has been previously detcted at some of the Urals VMS deposits [5].

Based on presented data, we conclude that the arc-continent collision played a major role in Urals VMS systems formation. The similar relationship my be established for younger hydrothermal systems in Banda arc. The collided arcs host a large number of mineral deposits worldwide, but until now the role of continent in mineral deposits formation was not fully understood. Here we show that the collision event is directly responsible for mineral deposits formation within Devonian volcanic arc of Southern Urals. The tectonic processes involved in arc-continent collision could be responsible for the mineral deposits formation worldwide.

Stable Pb isotope ratios as mid-1800s stratigraphic markers for sediments from Eastern Canada lakes

ANDRÉ TESSIER[1*], CHARLES GOBEIL[1], AND RAOUL-MARIE COUTURE[2]

[1]Université du Québec, INRS-ETE, Québec, Canada, atessier@ete.inrs.ca and charles.gobeil@ete.inrs.ca (* presenting author)

[2]University of Waterloo, Earth and Environmental Sciences, Waterloo, Canada, raoul.couture@uwaterloo.ca

We determined the vertical distribution of Pb concentrations and stable Pb isotope ratios in ^{210}Pb-dated sediment cores from 10 headwater lakes located in various regions of Southern Québec, Eastern Canada. The depth profiles of stable Pb isotope ratios show, for the post-19th Century period, the influence of several isotopically distinct anthropogenic sources of Pb, including mainly Pb emitted from two Canadian smelters and from leaded gasoline combustion in Canada and in the United-States. A most interesting feature of the profiles, however, is the presence of sharp peaks of Pb stable isotope ratios at 1-2 cm below the depth of detectable unsupported ^{210}Pb (i.e., corresponding to mid-1800s) in sediments of most of the seasonally anoxic lakes where bioturbation is negligible. Minor amounts of Pb, whose isotopic signature was significantly different from that of Pb from local natural sources, were deposited in many lakes at an early stage of industrialisation in North America. Using a binary mixing model and assuming that natural Pb concentrations and isotopic compositions are given by the pre-industrial sediments in the cores, we find that the isotopic composition of most (>50%) of the non local Pb added to the sediments at this time period was typical to that of the Upper Mississippi Valley Pb ores. This observation is consistent with the previous work of Lima et al. (2005) [1] in laminated (varved) sediments of the Pettaquamscutt River, Rhode Island. These authors argued that, during the mid-19th Century, mining and smelting activities in the Mississipi Valley were responsible for most anthropogenic Pb emissions in North America and propose to use the chronology of these emissions as a stratigraphic marker for sediments deposited in the Northeastern USA. Our results confirm this conclusion and suggest that it can be generalized to all Eastern North America.

Following the Chernobyl nuclear disaster, contaminated soils, vegetation and other radioactive debris were buried *in situ* in trenches. It is now well known that micro-organisms play an essential role in contaminant mobility in soils. In the case of radionuclides, the interactions engaged could retain or induce their transfer from the trenches. However, radionuclides might also exert toxic effects on the micro-organisms and hence reduced their role in the transfer. This study focused on the impact of a radioactive environment on bacterial community's diversity with an underlying question: did a chronic radioactive exposure lead to the extinction of bacterial diversity?

To address this issue, a pyrosequencing-based analysis of 16S rRNA genes was conducted on radionuclides contaminated and non contaminated control samples. The huge diversity obtained by this technique was illustrated by an average of 19,000 sequences per sample, with 963 genera and 39 phyla represented. The 4 most predominant phyla, detected in all samples, were *Chloroflexi*, *Proteobacteria*, *Acidobacteria*, and *Verrucomicrobia*. Some phyla, as *Thermotogae*, were clearly more represented in control samples and seemed to be sensitive to radioactivity. Those results refined the conclusions previously given based on genetic fingerprinting method (DGGE) on the same samples [1]. Results indicated that a long term exposure to radionuclides did not lead to extinction of bacterial diversity in Chernobyl T22 trenches soils. A statistical analysis (principal component analysis) of the pyrosequencing data evidenced however a clear distinction of bacterial community between contaminated and control samples.

The pyrosequencing data will permit the selection of a bacterial model among a collection of 250 heterotrophic aerobic cultivable isolates provided from these contaminated and non contaminated areas. This model strain will be further used for laboratory experiments to study interactions with some radionuclides of the trenches (^{137}Cs, U, ^{90}Sr).

Sr isotopes reveal new insights about the source of turquoise at the Aztec Templo Mayor

Alyson M. Thibodeau[1]*, Leonardo López Luján[2], David J. Killick[3], Joaquin Ruiz[1]

[1]Department of Geosciences, University of Arizona, Tucson, Arizona, 85721, USA
(*correspondence: amthibod@email.arizona.edu)
[2]Museo Templo Mayor/INAH, Mexico City, Mexico
[3]Department of Anthropology, University of Arizona, Tucson, Arizona, 85721, USA

Turquoise [$CuAl_6(PO_4)_4(OH)_8 \cdot 4H_2O$] was highly valued in late Postclassic Mesoamerica (900-1521 CE), especially by the Mixtecs and the Aztecs, who used it as part of elaborate mosaics and other ceremonial and status objects. Because turquoise mineralization in North America is primarily restricted to the present day southwestern United States (U.S.) and northern Mexico, archaeologists have identified these regions as likely sources of turquoise found thousands of kilometers away in archaeological sites across Mesoamerica. However, despite more than a century of speculation about acquisition of turquoise by Mesoamericans through long-distance trade networks with the Southwest U.S., no geochemical data has been published in support of this idea.

To address this question, we use Pb and Sr isotope geochemistry to investigate the geologic origin of turquoise found in multiple offerings throughout the Aztec Templo Mayor in Mexico City. We directly compare the isotopic ratios obtained for Templo Mayor turquoise to the isotopic signatures of turquoise samples from over 16 areas of turquoise mineralization in the southwestern U.S. and northern Mexico. Initial results indicate that the Sr isotopic signature of at least some of the turquoise from the Templo Mayor ($^{87}Sr/^{86}Sr < 0.706$) is distinct from the isotopic signatures of all turquoise samples (n=200) examined from the southwestern United States and northern Mexico ($^{87}Sr/^{86}Sr > 0.706$).

Turquoise is a supergene mineral that forms in the oxide zone and it acquires trace amounts of Pb and Sr through weathering processes associated with its formation. It particular, it often forms from the weathering of igneous rocks rich in copper, phosphorous, and aluminum, and is commonly precipitated in the open spaces and fractures of such rocks. We tentatively interpret the unique and relatively unradiogenic Sr isotopic signature of turquoise from the Templo Mayor to indicate the turquoise was mined from a source or sources in Mexico. This provisional interpretation is supported by (1) the empirical contrast between $^{87}Sr/^{86}Sr$ ratios of turquoise from Templo Mayor and the $^{87}Sr/^{86}Sr$ ratios of turquoise from the southwestern U.S., and (2) the existence of igenous rocks with similar Sr isotope ratios ($^{87}Sr/^{86}Sr<0.706$) within the Mexican Volcanic Belt and the Sierra Madre Occidental which could theoretically host small pockets of turquoise mineralization. This interpretation implies the Aztecs did not have to acquire turquoise through interregional trade networks with the Southwest and thus provides fundamentally new insights into the nature of proposed long distance interactions between these areas.

Low oxygen events in the Laurentian Channel during the Holocene

BENOIT THIBODEAU[1]*, ANNE DE VERNAL[2] AND AUDREY LIMOGES[3]

[1]AORI-University of Tokyo, Kashiwa, Japan, thibodeau@aori.u-tokyo.ac.jp (* presenting author)
[2]GEOTOP-UQAM, Montréal, Canada, devernal.anne@uqam.ca
[3]GEOTOP-UQAM, Montréal, Canada, limoges.audrey@courrier.uqam.ca

Recent warming in the Laurentian Channel bottom water has been observed in the St. Lawrence Estuary [1] and Gulf [2]. This warming might be linked to an enhanced proportion of warm Atlantic water entering the Laurentian Channel and could be the main cause of the year-round hypoxia observed during the last 30 years in bottom waters of the lower Estuary. We observed a temperature trend of similar amplitude in a low sedimentation rate box-core located in the Esquiman Channel. Warm bottom waters conditions, however, are not exclusive to the recent time interval as shown by data from the lower part of the core, which is also characterized by low $\delta^{18}O$ values in *Globobulimina auriculata* and occurrence of both *Brizalina subaenariensis* and *Oridorsalis umbonatus*. Such data suggest the existence of low-oxygen and high temperature conditions in the bottom water of the Esquiman Channel 6-4 ka ago. These conditions are likely related to the inflow of Atlantic water in the Gulf of St. Lawrence through the Cabot Strait and the Laurentian Channel, possibly linked to large scale ocean circulation changes in the northwest North Atlantic. Hence, our results highlight the sensitivity of bottom water properties in the Gulf of St. Lawrence to North Atlantic circulation patterns.

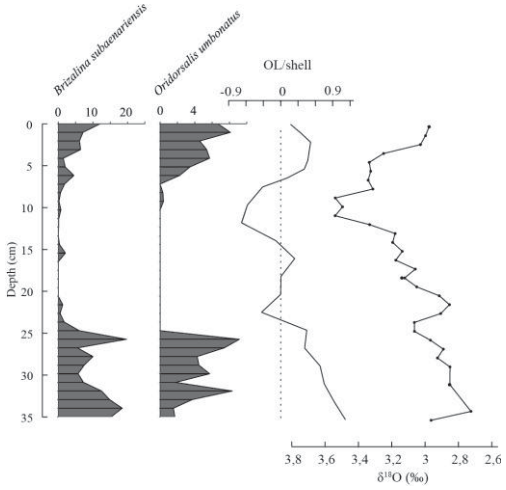

Figure 1: Abundance of *B. subaenariensis* and *O. umbonatus* (%), calcium carbonate dissolution index (logarithm of the foraminifer linings vs shells ratio) and oxygen isotope composition in *G. auriculata* against depth in core CR06-TCE.

Adding uptake kinetics and surface entrapment to geochemical models

BRUNO THIEN[1]*, DMITRII A. KULIK[1], ENZO CURTI[1]

[1]Paul Scherrer Institut, 5232 Villigen PSI, Switzerland, bruno.thien@psi.ch (* presenting author)

Experimentally measured trace element partitioning between a host mineral and the aqueous solution often depends on precipitation or recrystallization rates and is frequently irreversible, as shown by the occurrence of zoned crystals. Kinetic-dependent trace element uptake can be realistically simulated using partial-equilibrium aqueous- solid solution (sorption) thermodynamic models. This means that in a reaction-path sequence of equilibrium states, some amounts of relevant phases, end members, or sorbed species must be declared metastable according to time-dependent kinetic rate laws.

In this context, we considered three uptake kinetics models: Growth Entrapment (GE) [1], Surface Reaction (SR) [2], and Adsorption – In-Diffusion (AD) [3]. Each model predicts a final metastable solid-aqueous distribution of trace elements or isotopes. However, different mechanisms and parameters are invoked: the competition between mineral growth and near-surface diffusivity (GE); purely kinetic laws for gross forward and backward reaction rates for host and trace components (SR); or diffusion of trace component into the solid (AD). All models can adequately describe the trace element uptake (Fig.1) for single element/host mineral pairs (Sr/calcite, Ra/barite, P/goethite) under simplifying assumptions, such as the constancy of growth rate and of the aqueous composition.

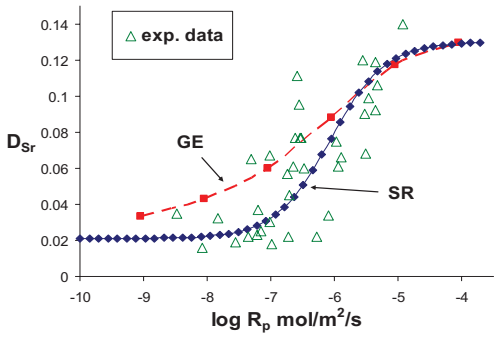

Fig 1.: Sr distribution coefficient in calcite *vs* precipitation rate.

In order to make them applicable in geochemical reactive transport simulations, these models are currently implemented in the GEM-Selektor code (http://gems.web.psi.ch) in integrated forms that control time-step-dependent metastability constraints in the Gibbs energy minimization algorithm [4]. This tool can also account for changes in solid and aqueous chemistry that may occur upon the uptake in a closed system (e.g. from pore solution), while keeping track of surface areas of minerals during growth or dissolution.

The research leading to these results has received funding from the European Atomic Energy Community's Seventh Framework Programme (FP7/2007-2011) under grant agreement n° 269688.

Late Cretaceous Evolution of Southern Hemisphere Seawater Neodymium Isotope Composition

DEBORAH J. THOMAS[1*], DANIEL P. MURPHY[2]

[1]Texas A&M University, College Station, TX, United States, dthomas@ocean.tamu.edu (*presenting author)
[2]University of Southampton, Southampton, United Kingdom, D.Murphy@noc.soton.ac.uk

Background

The predominant source of dissolved Nd to the oceans is the weathering and drainage of subaerially exposed terranes. Nd has become a commonly used tracer of water mass provenance (and hence deep-water circulation patterns) because water masses essentially form with the Nd isotopic signature of the weathering inputs in the region of formation. However, temporal variations in the isotopic composition of the water mass may result from changes in the composition of the weathering inputs.

Studies of modern river dissolved and particulate Nd isotopic composition indicate that fine fraction sediments record the same isotopic signature as the dissolved inventory [1]. Thus, we can reconstruct changes of Nd inputs to a given ocean basin through analysis of the detrital sediments in conjunction with the seawater composition. Here we apply this strategy to reconstruct the history of deep-water formation from 8 sites in the Indian and Atlantic sectors of the Southern Ocean during the Late Cretaceous.

Late Cretaceous Reconstructions

During the Cenomanian to early Campanian, the South Atlantic was divided into several distinct basins [2]. Previous work demonstrated that deep-water production in the Southern Ocean became the primary source of deep water in the South Atlantic during the early Campanian [2]. New seawater and detrital Nd isotope data from DSDP Sites 361, 511, 530 and 690 help constrain the timing of the subsidence of deep water gateways. By 75 Ma all sites in the South Atlantic shared a common water mass.

New data from Indian Ocean ODP Sites 763, 765, 766 and 1138 suggest that variations in the composition of weathering inputs controlled the overall evolution of proto-Indian Ocean water mass composition. Such variations were driven by the emplacement and subdidence of the Kerguelen Plateau and Broken Ridge during the Late Cretaceous. Weathering of subaerially exposed portions of these terranes caused Indian Ocean seawater Nd isotope values to increase, coincident with the peak of the mid-Cretaceous warmth. As the LIPs subsided below sea level, the input of radiogenic weathering products diminished and the isotopic composition of intermediate and deep waters in the region decreased, reflecting the weathering inputs from older terranes. The Indian Ocean sites extend the record of high-latitude deep-water formation back into the Early Cretaceous, prior to the onset of the mid-Cretaceous peak warmth. The growing body of data supports a mode of MOC in part characterized by high-latitude downwelling during the peak of greenhouse warmth of the Mesozoic.

Probing the effects of organic ligands on mercury biouptake

SARA THOMAS*, TIEZHENG TONG, ISABELLE JI, AND JEAN-FRANÇOIS GAILLARD

Northwestern University, Evanston, USA, sarathomas2007@u.northwestern.edu (* presenting author)

Introduction

Methylation of mercury (Hg) only occurs afer Hg has passed through the bacterial cell membrane [1]; therefore, understanding the mechanisms of Hg biouptake is essential to gain insight into the fate of Hg in the environment. Hg has a strong affinity for organic ligands, which influence Hg speciation and subsequenly its transport across the bacterial cell membrane. The relationship between Hg complexation in aquatic systems and its biouptake remains poorly understood, partially due to the difficulty of directly measuring intracellular Hg. One approach for monitoring the biouptake of Hg is to use a luminescent whole-cell biosensor [2]. In this study, we employed a chromosomally-based biosensor to examine the effects of various organic ligands (*e.g.*, EDTA, NTA and three thiol-containing ligands) on Hg uptake by bacteria in presence of 50nM of Hg.

Main results

In the presence of EDTA and NTA, we observed a slight increase in Hg biouptake. On the other hand, we found that biouptake of Hg in the presence of cysteine was highly dependant on the concentration of the ligand, consistent with the results of Schaefer & Morel [3]. From 0.1 to 10μM of cysteine, we observed a significant increase in Hg biouptake while 100 and 1000μM of cysteine resulted in a dramatic drop in biosensor signal. Both glutathione and penicillamine enhanced Hg biouptake when they were present at low concentrations, with the lowest concentration (0.1μM) leading to the highest biosensor signal. As their concentration reached a certain threshold (10μM for glutathione and 100μM for penicillamine), Hg uptake was severely inhibited.

We calculated the chemical speciation of Hg in the exposure medium using ChemEQL with thermodynamic constants selected from the JESS database [4]. Results show that in most instances Hg was predominantly complexed by the added organic ligands, indicating that Hg-ligand complexes contribute to Hg biouptake.

Significance

This study suggests that Hg biouptake can be promoted by the presence of organic ligands in solution. Our results parallel the findings from Hg biomethylation experiments, indicating a promising application of biosensor for studying Hg biouptake.

The fate and bioavailability of carbon in soil undergoing frequent shifts in redox status are tightly coupled to iron cycling We examined the influence of dynamic redox conditions on soils from the Bisley Site of the Luquillo Critical Zone Observatory in Puerto Rico. These soils contained ~2 g kg^{-1} C and ~62 g kg^{-1} Fe that resides predominately in a nano-crystalline Fe^{III} oxyhydroxide phase with an ^{57}Fe Mössbauer spectra most similar to nano-goethite. We conducted eight-week incubations of triplicate soil slurries subjected to 0 - 21% O_2 redox oscillations with a ratio of time under oxic to anoxic conditions of 1:6at three frequencies (3.5-d, 7-d, and 14-d). HCl-extractable Fe^{II} was reduced to less than 30 mmol kg^{-1} soil during all oxic cycles and increased to >140 mmol kg^{-1} soil and included a significant contribution from $Fe^{2+}_{(aq)}$ during the reducing cycles. As the experiment progressed, the rate of Fe reduction increased, and the Fe^{II} concentration reached a plateau of ca. 160 mmol kg^{-1} during each reducing cycle. This coincides with the amount of Fe extractable by citrate-ascorbate and the portion of Fe^{III} that magnetically orders between 77K and 13K in the Mössbauer spectra. By the end of the experiment newly precipitated Fe could be re-reduced in less than three days. Synthesis of this experimental data within our preliminary numerical model suggests temporal dynamics of Fe(II) can be explained by minor increases in the population of Fe reducers accompanied by progressive reductive dissolution of recalcitrant Fe(III) solid phases. To further constrain the rapid turnover of iron oxides, we probed the susceptibility of soil Fe phases toward Fe^{II}-facilitated atom exchange using isotopically-labeled Fe^{2+}(aq) coupled with a numerical model. We found that aqueous Fe atoms can be exchanged with both the labile (0.5 M HCl-extractable) and bulk (7M HCl-extractable) Fe pools, with turnover times on the order of hours and months, respectively.

Quadrupolar corrections and increased accuracy for non-bridging oxygen measurements in silicate glasses using ^{17}O NMR

LINDA M. THOMPSON[1*], JONATHAN F. STEBBINS[1]

[1]Department of Geological and Environmental Science, Stanford University, Stanford, USA, lison@stanford.edu (* presenting author)

Abstract

Oxygen-17 nuclear magnetic resonance (NMR) has been used to investigate glass and melt structure, providing useful insights. In particular, ^{17}O NMR is being used to measure the non-bridging oxygen (NBO) content as a way to test structural models in a wide variety of glasses, especially metaluminous aluminosilicate glasses where NBO are present. Because of the importance of accurate measurements in these areas, we have synthesized a crystalline barium silicate, $BaSiO_3$, and a barium silicate glass, $(BaO)_{0.43}(SiO_2)_{0.57}$, in order to test the accuracy of this technique. These samples were chosen for the resolution between the NBO and BO components of the spectra, to reduce the sources of error introduced by overlapping. For the $BaSiO_3$, correcting the observed intensities for the quadrupolar effects as in Massiot et al., 1990[1], we measure an NBO content of 67.6% versus the known value of 67.7%. Applying the same correction technique to the glass gives a measured NBO content of 58.4 % ± 0.7% versus the 55.5% ± 1.6% expected from stoichiometry (based on EMPA analysis). Comparison with the frequently used technique of sideband subtraction shows that this method offers a simple and robust correction, especially in glasses where estimates must be made for the asymmetry and average quadrupolar values. By improving our knowledge of the accuracy of this technique, we should be able to provide new insight into questions such as the presence of absence of measureable amounts of free oxide ions or oxygen triclusters in both simple silicate and more complex aluminosilicate glasses.

Evidence for the role of carbonate melts in the origin of superdeep diamond inclusions from the Juina-5 kimberlite, Brazil.

A.R. THOMSON[1*], M.J. WALTER[1], S.C. KOHN[1], B.C. RUSSELL[1], G.P. BULANOVA[1], D. ARAUJO[2] AND C.B. SMITH[1]

[1]School of Earth Sciences, University of Bristol, Bristol, BS8 1DR, UK, andrew.thomson@bristol.ac.uk (* presenting author)
[2]Instituto de Geociências, Universidade de Brasília, CEP 70910-900 Brasília, DF, Brazil

Over the past 30 years multiple studies of inclusions in naturally occurring diamonds have observed minerals which must have formed at sublithospheric depths in the earth [1]. In a recent study [2], lower mantle minerals interpreted to have formed in a basaltic protolith were found as inclusions in diamonds from the Juina-5 kimberlite, Brazil. These inclusions demonstrate subduction of ocean floor material into the lower mantle, and implicate diamond formation in the deep mantle from carbon-bearing fluids or melts.

This study reports the finding and analysis of new inclusions from the Juina-5 kimberlite. We find multiple examples, to complement those previously reported, of phases corresponding to those stable in a basaltic protolith at transition zone and lower mantle pressures. Most inclusions have undergone retrograde reactions and/or unmixing during acsent to the surface. Inclusions include several examples of unmixed NAL phase, iron-rich phases similar to TAPP, and multiple calcium- and titanium-rich phases with perovskite stoichiometry.

During the study samples have been analysed both by electron microbe and SIMS to determine major and trace element compositions. Early results show that the calcium perovskite phases are highly enriched in incompatible elements including REE and HFSE, but are depleted in LILE. The trace element enrichments and abundance patterns are very similar to Ca-Ti-perovskite inclusions found in the Collier-4 kimberlite [3], located approximately 50km from Juina-5. Consistent with previous results [3], we interpret these inclusions as crystallisation products of small degree melts from subducted carbonated basaltic crust. Melting of carbonated basalt may occur in thermalized lithosphere stranded in the transition zone or lower mantle [4]. The melt can then be reduced upon infiltration into surrounding mantle, which is reducing and likely bearing a free metal phase; the carbonate component of the melt is thus reduced and forms diamond by redox freezing [5].

Removal of volatile groundwater contaminants in vertical soil filter systems: quantitative process analysis

MARTIN THULLNER[1*], CECILIA DE BIASE[2], ULI MAIER[3] AND SASCHA E. OSWALD[4]

[4] Institute of Earth and Environmental Sciences, University of Potsdam, Potsdam, Germany, sascha.oswald@uni-potsdam.de

Biodegradation of groundwater contaminants is a common remediation strategy but the assessment of the remediation success is challenged by abiotic processes leading to contaminant concentration reductions without the desired destructive mass removal. In unsaturated subsurface systems volatile contaminants might enter the soil air and such volatilization might eventually be a significant contribution to contaminant mass removal and to emissions of contaminants into the atmosphere. Any assessment of the fate of volatile contaminants in such systems thus needs to distinguish between the contribution of biodegradation and of volatilization to observed contaminant removal.

The present study focuses on the processes controlling the removal of benzene and MTBE from groundwater applied to pilot scale vertical flow filter systems. The soil filter systems were intermittently irrigated by the contaminated groundwater which led to a highly transient flow and transport system. Measured contaminant concentrations indicated a high mass removal [1] but did not allow for a quantitative assessment of individual removal processes due to the high spatio-temporal dynamics of the systems. To obtain such quantitative analysis conservative solute tracer tests, stable isotope fractionation and measurements of natural radon concentration in the treated groundwater [2] were used as additional data basis for a reactive transport modeling approach. Numerical simulations using the model MIN3P considered variably saturated flow, the transport of species in the water and the gas phase as well as the biogeochemical transformation of reactive species.

The model allowed for reproducing the experimental data and the model results suggest that for the investigated volatile compounds biodegradation is the dominating mass removal process with volatilization contributing only to minor or negligible amounts. These results indicate that also gas phase gradients of volatile compounds can be affected by biodegradation suggesting the unsaturated zone to act as a biofilter for contaminants in the soil air.

Phosphate effects on copper and lead sorption to ferrihydrite

C. TIBERG[1*], J.P. GUSTAFSSON[2], C. SJÖSTEDT[2], I. PERSSON[3]

[1]Swedish University of Agricultural Sciences, Dep. of Soil and Environment, Uppsala, Sweden, Charlotta.Tiberg@slu.se*

[3] Swedish University of Agricultural Sciences, Dep. of Chemistry, Uppsala, Sweden, Ingmar.Persson@slu.se

Introduction

Elevated concentrations of phosphate can retard transport of copper and lead in soil. More detailed knowledge about the mechanisms behind this is of interest for example in risk assessments of contminated soils. It is well known that the mineral pyromorphite is formed at high concentrations of lead and phosphate in combination with high pH. This effect has been used to immobilize metals in remediation of contaminated soil. It has also been shown that the sorption of lead and copper to iron oxide surfaces [1, 2] may be enhanced in precence of phosphate but the details of how phosphate interacts with copper/lead and iron oxide has not yet been established, and there are seemingly contradictory results [1, 3]. This mechanism acts also at low concentrations of metal and phosphate when no precipiatates are formed.

Methods

Here, batch experiments, X-ray absorption spectroscopy (EXAFS) and surface complexation modeling with the three-plane CD-MUSIC model has been used to study the effect of phosphate on sorption of copper and lead to ferrihydrite. The aim is to investigate what surface complexes that are formed and to derive new and improved surface complexation constants.

Results and conclusions

The results show that addition of phosphate increases the sorption of copper and lead to ferrihydrite in batch experiments as compared to the same system without addition of phosphate. The effect is stronger than predicted by the CD-MUSIC model when considering electrostatic interactions only and as will be shown, the results from EXAFS analysis support this observation. The EXAFS results show, in agreement with earlier studies [4, 5], that copper and lead form bidentate mononuclear complexes on ferrihydrite in systems without phosphate. However, in the presence of phosphate, other complexes are formed. The results are being used to suggest new surface complexation constants for reactions that consider ternary interactions.

Carbonatite metasomatism: evidence from geochemistry and isotope composition (U-Pb, Hf, O) on zircons from two Precambrian carbonatites of the Kola Alkaline Province

MARION TICHOMIROWA[1*], MARTIN WHITEHOUSE[2], AXEL GERDES[3], JENS GÖTZE[1]

[1]TU Bergakademie Freiberg, Inst. Mineralogie, tichomir@mineral.tu-freiberg.de (* presenting author)
[2]Swedish Museum of Natural History, martin.whitehouse@nrm.se
[3]Goethe University Frankfurt,gerdes@em.uni-frankfurt.de

Zircon grains from two Precambrian carbonatites of the Kola Alkaline Province (Siilinjärvi, Tiksheozero) were studied by in situ geochemical and isotope investigations. Zircon domains which preserved the primary mantle signatures were identified by a combination of microscopic investigations of thin sections of the carbonatite rocks and separated zircon grains (optical microscopy, SE, CL, BSE images).

In case of the 2.6 Ga old Siilinjärvi carbonatite complex, the new carbonatite melt batch caused mainly solid state recrystallisation of former zircon grains. Zircon regions which preserved the primary signatures yielded high HREE/LREE ratios, undisturbed U-Pb ages, ε_{Hf} values close to CHUR (chondritic uniform reservoir), $\delta^{18}O$ values typical for the mantle, and Ti concentrations in accordance with known carbonatite melt temperatures. The solid state recrystallisation of zircon caused by carbonatite metasomatism led to (i) diffusion driven loss of HREE, Th, U, (ii) partial disturbance of the U-Pb system, (iii) a small shift of the $\delta^{18}O$ toward lower values.

In difference, in the 2.0 Ga old Tiksheozero complex the infiltration of a new carbonatitic melt led to dissolution-reprecipitation of former zircon grains. Dissolved-reprecipitated zircon grains often have a spongy texture with a lot of micro-inclusions of apatite, calcite and phlogopite. Apatite micro-inclusions seem to be most abundant according to elevated Th and U concentrations, lowered $\delta^{18}O$ values and increased Hf isotope ratios in such domains. These tiny apatite inclusions seem to be responsible for the widely occurring disturbance of the U-Pb dating system and for the unusually high Th/U ratios (>1) in many carbonatitic zircons worldwide. Hf and O isotope values varied widely even within a single zircon grain.

The Distribution of Gallium in the Nechalacho REE deposit, NWT, Canada

ALEXANDER TIMOFEEV* AND A.E. WILLIAMS-JONES

McGill University, Department of Earth & Planetary Sciences, alexander.timofeev@mail.mcgill.ca (* presenting author)

The layered Nechalacho Nepheline Syenite at Thor Lake, which is located within the alkaline to peralkaline Blachford Lake Complex near Yellowknife, Northwest Territories, is a potential source of exploitable gallium. It also contains large reserves of Rare Earth Elements (REE), Y, Nb, Ta and Zr, which are most enriched in the Basal Zone, an altered eudialyte cumulate layer [1]. Intense hydrothermal alteration involving replacement of primary magmatic mineral assemblages by a potassic assemblage comprising K-feldspar, biotite and magnetite, was followed by late albitisation.

Bulk-rock geochemical analyses and analyses of secondary minerals indicate that the Nechalacho Nepheline Syenite has unusually high concentrations of gallium, and that this element was both enriched and depleted by hydrothermal processes. Gallium occurs in concentrations more than a magnitude higher than its average concentration in crustal rocks. Similar enrichments are rare in nature, and the Nechalacho deposit therefore provides an excellent opportunity to identify the geochemical and mineralogical factors controlling the distribution of this element. Gallium can substitute for Al^{3+}, Fe^{3+} and other elements with similar valence and ionic radius, but is rarely found in a mineral dominated by this element.

Aluminium-bearing minerals from samples of the Nechalacho Nepheline Syenite with bulk rock Ga contents of 150 ppm or higher were analysed using the electron microprobe, following petrographic analysis. These samples are not unusually enriched in the REE. Analyses over the entire depth of a single drill hole were used to evaluate the relative importance of magmatic and hydrothermal processes to gallium enrichment.

Albite, orthoclase, biotite, chlorite, and allanite, in order of decreasing modal proportion, contain appreciable gallium. By contrast, the content of Ga in the Fe^{3+} mineral, aegirine, is below the limit of detection (≈140 ppm). Median Ga concentrations were ~ 250 ppm in albite, biotite, and chlorite and ~150 ppm in orthoclase. Variations of 200 ppm Ga or higher were observed in individual albite and orthoclase grains, and are linked to hydrothermal alteration. Fluid inclusion-rich zones in albite and orthoclase are characterised by significantly lower Ga contents than fluid inclusion-poor zones, in both albitised and non-albitised samples. Previous studies of the aqueous mobility of gallium suggest that hydroxyl and fluoride complexation may play a role in the hydrothermal mobilisation of gallium [2]. Chloritisation of biotite resulted in a Ga enrichment of ~ 150 ppm. Trends in gallium concentration for individual minerals along a single drill hole vary with the degree and nature of the alteration of the host rocks. Based on the observations presented here, albite and biotite are the principal hosts of Ga in the Nechalacho Nepheline Syenite, Ga enrichment was partially independent of REE concentration and Ga was both enriched and depleted by hydrothermal processes.

Ten millennia of North Atlantic seasonality: evidence from stable isotope values of micromilled molluscs

SANDRA TIMSIC[1*], WILLIAM P. PATTERSON[1], BRUCE M. EGLINGTON[1], AND JOHN T. ANDREWS[2]

[1]University of Saskatchewan, Geological Sciences, sat903@mail.usask.ca (* presenting author); bill.patterson@usask.ca; bruce.eglington@usask.ca

[2]University of Colorado, Institute of Arctic and Alpine Research, John.T.Andrews@colorado.edu

Seasonality in temperature, the difference between winter low and summer high temperatures, is one of the dominant causal variables that determines the distribution of species through time. Bivalves are particularly valuable proxies of seasonality because growth bands of bivalve shells archive high-resolution records of temporally discrete environmental information, including water temperature recorded by $\delta^{18}O$ and diet/metabolism by $\delta^{13}C$ values. Here, we present a record of North Atlantic Holocene seasonality derived by computer-controlled micromilling of well-preserved mollusc shells recovered from a near shore marine core in NW Iceland. Thirty-seven aragonitic bivalve specimens retrieved from the core were sequentially micromilled concordant with growth banding to retrieve carbonate aliquots with subseasonal resolution, and then analysed for $\delta^{18}O$ and $\delta^{13}C$ values. Previous research [1] observed significant variations in seasonal temperature in this region over the period ~360 B.C to ~A.D 1660. Here, we extend this seasonality record back to ~10,650 cal years BP, thus providing the first ~10,000-year record of climatic snapshots ~1 to 9 years in duration for the North Atlantic.

Our sampling resolution (generally 30-50μm) generated subseasonal (*e.g.* weekly to bi-monthly) $\delta^{18}O_{(CaCO3)}$ and $\delta^{13}C_{(CaCO3)}$ records from molluscs that recorded ambient seafloor water temperatures during their lifetimes. Most of the molluscs were from the genera *Macoma*, *Nuculana*, and *Thyasira*, all recovered from a single core (core ID: MD99-2266). The temperature record archived as $\delta^{18}O_{(CaCO3)}$ values was calculated assuming a constant bottom water value of 0.1‰ (based on ~50 years of $\delta^{18}O$ measurements from the bottom waters of our study region) and using an aragonite temperature-fractionation relationship [2].

Our results indicate that the oldest 1/3 of the record (~10,100 – 7,600 cal yr BP) displayed maximum summer temperatures ~2°C higher than the subsequent period from ~7,000 – 4,500 cal yr BP, while the winter temperatures were similar throughout both periods. Sporadic warm periods after 4,500 cal yr BP are evident, where the maximum summer temperatures reached ~7 to 9°C at ~4,500 and ~3,400 cal yr BP. The highest reconstructed temperatures of the entire 10,000-year record occurred during the Roman Warm Period (~200 B.C. to A.D. 400), higher than modern temperatures (typically ranging between -1 to 11°C). Temperatures calculated for the Little Ice Age were similar to those from ~10,100 to 7,600 cal yr BP and 4,500 – 2,000 cal yr BP.

(* presenting author)

Background

Historic gold mining activities in Nova Scotia, Canada, have left behind large amounts of spent and weathered tailings material that usually contains very high arsenic concentrations. Several of the larger abandoned mining sites are in proximity of residential areas, raising potential concerns about arsenic export off-site via surface and/or ground water flow. Previous studies have found elevated arsenic concentrations in surface, pore and ground waters at the sites. Since physical and chemical speciation have significant impacts on arsenic mobility and toxicity, we investigated if colloidal arsenic species existed in the waters at these sites.

Methods

64 surface water, ground water and pore water samples were collected at three locations within two abandoned gold mine sites in Nova Scotia in May 2011. Samples were analyzed for colloidal arsenic, as well as other colloidal constituents, by asymmetric flow-field flow fractionation-inductively-coupled plasma-mass spectrometry (FFF-ICP-MS), for dissolved arsenic species by anion-exchange chromatography-ICP-MS, and for total dissolved arsenic by ICP-MS.

Results

Colloidal arsenic fractions were encountered only in a small number of the collected samples. In those samples, colloidal arsenic constituted < 20 % of the total dissolved arsenic. Most of the colloidal arsenic was associated with iron-based mineral particles of 6 – 9 nm mean diameter. Based on the iron/arsenic ratio of these colloids, they appeared to be either discrete iron-arsenic minerals like scorodite, or iron (oxy)hydroxide with adsorbed arsenate. In one sample, we also obtained some tentative evidence of arsenic being associated with very small (< 2 nm mean diameter) organic matter-based colloids, which also contained iron and manganese.

To our knowledge, this is one of the first reports of the existence of colloidal arsenic in ambient samples. At the studied sites, colloidal arsenic was only an infrequent and minor component of the total dissolved arsenic concentration during the conducted sampling campaign, and therefore probably not very important for the overall transport and toxicity of arsenic in these systems.

Acknowledgments

Funding for this study was provided by the National Science and Engineering Research Council of Canada (NSERC) through a Strategic Project Grant. The assistance of Mike Parsons (Natural Resources Canada), Heather Jamieson, Andrew Gault and Stephanie DeSisto (Queen's University) and Laura Tyler (Trent University) before and during the field campaign is gratefully acknowledged.

The Study of the Sequence Stratigraphy and the Sedimentary Enviroment of Ordovician in Southern Margin of Sichuan Basin

YANG WEI[1] ,ZHANG TINGSHAN[2*],LIU ZHICHENG[3] , AND MIN HUAJUN[4]

minesky@126.com

Southern margin of Sichuan Basin contains well developed Ordovician, which carbonate rocks in this area are well developed and widely distributed except for the Wufeng Formation in upper Ordovician and the Meitan Formation in lower Ordovician, those are clastic deposition. According to the data analysis of outcrop and bore hole in the study area, the sequence stratigraphic framework of Ordovician was established using the application of theories in carbonate sequence stratigraphy, combined with petrology, paleontology, the characteristics of carbon and oxygen isotopic, six third-order sequences were developed from the Lower Ordovician to the Upper Ordovician, and each sequence can be subdivided into transgression systems tract (TST) and high systems tract (HST),but be lack of the lowstand system tract(LST) because the study area of Ordovician was mainly located on a carbonate platform. On this basis, it is shown that the broadly open sea shelf type with flat floor and the platform sediment model are well developed in the study area of Ordovician. There were two large scale sea-level rise in the Ningguo period of the Lower Ordovician and Wufeng period of the Upper Ordovician between Linxiang period. Under the effect of sea-level changes, the carbonate platform was rapid coverd by the accumulation of siliciclastic. During the period the western Yangtze plate developed a wide sea shelf and shale deposited, which occurred carbonate platform drowning incidents. The results reveal that the carbon and oxygen isotopic migration are consistent with the process of environment changes. Sea level changes were the principal factor that controlled the development of Ordovician depositional system in southern margin of Sichuan Basin of Ordovician. It is found that the carbon and oxygen isotopic change in the grain size sediment is not only closed to the sea-level changes, but better identify to the condensed section, sequence boundaries et al, which can be used as a reliable secondary sign to determine the sequence stratigraphy division and the depositional environment.

Mg isotopes in natural waters: what do they mean?

EDWARD T TIPPER[1]

[1]Dept. Earth Sciences, University of St Andrews, Fife KY16 9AL, UK, ett@St-Andrews.ac.uk

It has been known for decades that river water elemental or isotopic ratios are controlled by mixtures of end-members with differing compositions. The compositions of such end-members are either inherited from heterogeneity in the orginal lithological sources (e.g., carbonate, silicate and evaporite) or from process-related fractionation of elemental or isotopic ratios during weathering. Distinguishing process-related variations from lithological mixing trends is a problem fundamental to partitioning weathering fluxes between different sources, and are a fundamental problem for quantifying the carbon consumption associated with silicate weathering. In most catchments, distinguishing chemical signatures in river waters related to lithology from those related to weathering processes is complex because of heterogeneous lithology.

New isotopic tracers such as the isotope ratios of Mg therefore have the potential to help deconvolve the extent to which rivers reflect mixing, or the extent to which rivers have compositions which are chemically evolved by physicochemical processes. In a geological context this is similar to distinguishing fractionational crystallisation from magma mixing. The stable isotopes of Mg offer important advantages over more common place isotope ratios such as Sr, that have been used for decades. This is because they have the potential to trace both source and process effects of one the major cations in solution rather than just source effects of a trace cation. It is now more than a decade since Mg isotope ratios have been published on natural waters, but progress in using them to place constraints on the origin of solutes requires careful calibration before the data can be successfully applied.

Almost all published Mg isotope data on natural waters falls between the end-member δ^{26}Mg values of the carbonate and silicate rocks that are drained. This could suggest that waters simply relfect mixing between end-members, but coherent relationships with elemental ratios that have typically been used to infer mixin relationships are rare. This leads to a catch22 scenario: Is it possible to infer a mixing relationship using an X/Mg ratio when δ^{26}Mg doesn't show the same relationship?

In simple mono-lithological catchments where there is inferred to be a single source of Mg, δ^{26}Mg is apparently fractionated and co-varies with Li isotopes. The relationship between Mg and Li is complex. Li isotopes are thought to be strongly influenced by clay, but the precise relationship between Mg, Li and clay is not yet known. The mixing versus process problem will be discussed with examples, illustrating what we have learned so far from Mg isotopes in natural waters, and the many things that Mg isotopes still have to tell us about.

Immobilisation of hexavalent actinides in cementitious materials: Evidence for structural incorporation in calcium-silicate-hydrates

Abstract]

Cementitious materials are an important component of the multi-barrier concepts developed in many countries for the safe disposal of low and intermediate level radioactive waste in deep geological repositories. Studies of the retention of radionuclides by cementitious materials have focused predominantly on adsorption as the relevant uptake process. However, other immobilization processes, such as incorporation in the solid matrix, may take place and, thus, exert a beneficial effect on radionuclide retardation. Calcium silicate hydrates (C-S-H), the major cement constituent, are characterized by high recrystallisation rates making them an ideal system for the incorporation of radionuclides present in cement-based repositories.

In the present study, wet chemistry and luminescence spectroscopy experiments have been performed under high pH conditions, with the aim of determining the speciation of hexavalent actinides (An(VI)), U(VI) and Np(VI), in C-S-H. Batch sorption experiments have been carried out with C-S-H and titanium dioxide, a solid phase stable under high pH conditions and often used as a model material for surface complexation studies. Comparison of the sorption of U(VI) and Np(VI) on both solids allows the influence of incorporation processes on the immobilisation of hexavalent actinides by C–S–H to be determined.

The An(VI) sorption behaviour on TiO_2 and on C-S-H phases appeared to be nearly identical; R_d values were found to decrease with the increasing predominance of negatively charged species in the aqueous phase suggesting the weaker sorption of these actinyl anions. Uranyl-doped C–S–H exhibited inhomogeneously broadened luminescence bands following non-selective laser excitation at liquid helium temperature (4K). Luminescence spectra following selective resonant laser excitation showed these broad band structures to consist of a superposition of many overlapping narrower bands associated with slightly different non-interacting uranyl luminescence centers in a disordered environment indicating incorporation in the amorphous C–S–H structure. The characteristics of the luminescence spectra provided information on the local coordination geometry of the incorporated uranyl moiety leading to the conclusion that it is incorporated in the C–S–H interlayers. The study shows that, under high pH conditions, the wet chemical behaviour (pH dependence and effect of aqueous Ca concentration) is similar for An(VI) incorporated in the interlayers of C–S–H and uranyl bound on the surface of TiO_2.

Microbial transport through rock and its importance for microbially-induced mineral precipitation

DOMINIQUE J. TOBLER[1*], SUSITHRA LAKSHMANAN[1] AND VERNON R. PHOENIX[1]

[1]School of Geographical and Earth Sciences, University of Glasgow, Glasgow, G12 8QQ, UK (*correspondence: dominique.tobler@glasgow.ac.uk)

Emerging bio-technologies offer natural, minimally invasive and cost-effective methods for dealing with environmental remediation and engineering problems. Microbially-induced mineral precipitation could become one of these innovative technologies as it has shown great potential for soil stabilisation, solid-phase capture of pollutants and porosity sealing to control leakage at nuclear waste depository and CO_2 storage sites. Critically, deployment strategies for microbially-induced processes are heavily dependent on the movement, homogeneous distribution and viability of micro-organisms over long injection distances. Problematically, we have little understanding of how microorganisms are transported in subsurface rock environments.

Initial data on bacterial transport through sandstone clearly showed that bacteria get easily immobilised in rock compared to packed sand [1] (Figure below). This is a significant problem as most previous bacterial transport studies have been undertaken on homogeneous packed sand; data which clearly cannot be used reliably to predict bacterial transport through rock. Furthermore, the subsurface is inherently heterogeneous, leading to preferential flow paths, and this will greatly affect bacterial transport behaviour.

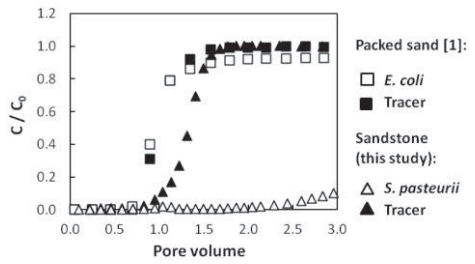

Figure: Breakthrough curves for bacteria (10^8 cells/ml) and a conservative tracer (0.3 mM NO_3).

Here, Breakthrough Curve (BTC) analyses were extended to quantify the effect of rock composition, heterogeneity and injected bacterial density on bacterial transport through porous and fractured rock. BTC data was modelled using colloidal filtration theory to obtain information about the dispersivity and sticking efficiency of injected microorganisms. This data was then used to develop and test improved injection strategies for the application of microbially-induced mineral precipitation to seal subsurface rocks. For this, different rock cores were subjected to repeated cycles of ureolysis-driven calcite precipitation until a significant decrease in permeability was measured. The spatial distribution of the produced calcite fill, and thus the effectiveness of the applied injection approach, was quantified using scanning electron microscopy.

Involvement of recycled silica-rich pyroxenite in continental intraplate magmatism: Evidence from alkaline basalts in NW Kyushu, SW Japan

SATOSHI TOKESHI[1*], RYOJI TANAKA[1], KATSURA KOBAYASHI[1], AKIO MAKISHIMA[1] AND EIZO NAKAMURA[1]

[1]The Pheasant Memorial Labaratory for Geochemistry and Cosmochemistry, Institute for Study of the Earth's Interior (ISEI), Okayama University at Misasa, Tottori, Japan, tokeshi@misasa.okayama-u.ac.jp

Abstract

Recycled silica-rich materials such as pyroxenite (eclogite) are important sources of mantle-derived magmas not only in oceanic magmatism but also in continental intraplate magmatism [1]. Here, we show an evidence for presence of the silica-rich pyroxenite in the continental intraplate magmatism by using major and trace elements and Sr-Nd-Pb-Hf isotopes for Miocene alkaline basaltic lavas from northwestern Kyushu, SW Japan. The alkaline lavas, defined by silica versus total alkali contents, are mostly normative hypersthene. In contrast, alkali basalts with normative nepheline are scarce. Their primitive mantle-normalized trace element patterns show strong enrichment in incompatible elements and remarkable negative spikes in B, Pb and Li, and some of the alkaline lavas show slightly weak depletions in high-field strength elements (HFSE). The isotopic compositions in the alkaline lavas significantly correlate with major elements (e.g. SiO_2, MgO, CaO, Na_2O and CaO/Al_2O_3) and trace element ratios (e.g. Nb/U, Zr/Hf and Sr/Nd). These correlations cannot be explained either by shallow-level magma chamber processes such as fractional crystallization and in situ crustal assimilation, or variable degree of partial melting of a homogeneous mantle source. Instead, constraints from coupling between the major element compositions and those of partial melts of the silica-rich pyroxenites from high pressure experiments (e.g. [2] and [3]), and the negative correlation of $^{176}Hf/^{177}Hf$ versus Zr/Hf, these indicate the involvement of the recycled silica-rich pyroxenite within an asthenospheric upwelling that triggered the continental intraplate magmatism. The correlations between the isotopic compositions and trace element ratios further suggest that the recycled silica-rich pyroxenite was derived from oceanic basaltic protoliths metasomatized by overlying sediment. It is thus inferred that the recycled pyroxenite and its peridotite matrix were major sources of the normative hypersthene melts and the normative nepheline melts, respectively. Mixing between their melts derived from lithologically and chemically distinct end-members would have taken place at low pressures in melt conduits and magma chambers. The involvement of crustal recycling might be closely linked with tearing of subducted stagnant slab beneath the East Asia.

Introduction

Fe-Mn crusts were collected by *ROV Hyper Dolphin* / *RV Natsushima* (NT09-02 Leg.2 cruise) at the depth interval between 2,990 and 950 mbsl of the #5 Takuyo Smt directly from the outcrops using manipulator and underwater diamond saw. These samples allowed us to investigate systematically the temporal and depth variations of the geochemical compositions in the Fe-Mn crusts.

Os isotope compositions

Os isotope compositions in the surface layer (<3 mm) of the Fe-Mn crust coincide very well with those of present seawater values ($^{187}Os/^{188}Os$ ~1.06) regardless of the water depth. This result indicates that Fe-Mn crusts in the #5 Takuyo Smt are formed hydrogenetically and have a potential to provide paleoceanographic information. So, we measured Os isotope compositions perpendicular to the growth layer and applied the Os isotope stratigraphy (e.g., [1, 2]) to estimate the growth rate of the Fe-Mn crust. From the upper section of the sample, we found similar Os isotope profile with that of marine Os isotope evolution curve established from seafloor sediments. A negative Os isotope excursion ($^{187}Os/^{188}Os$ ~0.73) was also found around 36 mm depth from the surface layer. Given that this excursion reflects eruption of the Columbia River flood basalts during the middle Miocene [2], the growth rate of our Fe-Mn crust is estimated to be 3 mm/My. This is nearly consistent with the results of ^{10}Be dating method (ca. 4 mm/My). In the lower section, we found large deviation of Os isotope compositions from that of marine Os isotope evolution. This deviation can be explained either by the occurrence of growth hiatus (~34 Ma) or effects of phosphatization. Previous studies have reported hiatus [2-4]. Growth hiatus may record some global event, such as marine redox change. Alternatively, pronounce phosphatization of the older crust may cause the deviation [5]. Our result suggests that secondary phosphatization effects have to be taken into account when using the Os isotope stratigraphy.

Noble gases as proxies for the transport of deep pore fluids in the Lake Van (Turkey) sediments

YAMA TOMONAGA[1*], MATTHIAS S. BRENNWALD[1], ROLF KIPFER[1,2,3]

[1]Eawag, Swiss Federal Institute of Aquatic Science and Technology, Water Resources and Drinking Water, Duebendorf, Switzerland, tomonaga@eawag.ch (* presenting author)
[2]Institute of Biogeochemistry and Pollutant Dynamics, Swiss Federal Institute of Technology (ETH), Zurich, Switzerland
[3]Institute of Geochemistry and Petrology, Swiss Federal Institute of Technology (ETH), Zurich, Switzerland

The accumulation of non-atmospheric noble-gas isotopes allows tracing the geochemical origin and transport processes of the pore fluids in unconsolidated sediments [e.g. 1]. For instance, the abundance of terrigenic helium (He) isotopes reflects the residence time and transport dynamics of the dissolved species in the pore space. The $^{3}He/^{4}He$ ratio of terrigenic He can be used to constrain the geochemical origin of the pore fluids [1,2].

Lake Van (Turkey) is one of the largest terminal lakes and the largest soda lake on Earth. The lake basin is situated in a tectonically active region characterized by the presence of major faults and volcanoes and is known to accumulate mantle fluids [1,2,3]. Helium isotopes are therefore expected to yield insights into the origin and transport processes of terrigenic fluids in the sediment pore space and their release into the water body of Lake Van.

In summer 2010 the ICDP PaleoVan drilling project collected 220 m long sediment cores from Lake Van with the aim to study the past climate conditions in eastern Anatolia [4,5]. Within the frame of this deep-drilling project we collected bulk sediment samples for noble-gas analysis [6,7].

In this work we present He concentrations measured in the pore water of the ICDP PaleoVan sediment samples. These results are compared with He concentration profiles from short cores (< 2 m) taken at different sites throughout the lake basin [1] and discussed in terms the deep fluid transport in the Lake Van sediments.

Abstract

The global mid-ocean ridge (MOR) system is a 60,000 km submarine volcanic mountain range that crosses all of the major ocean basins on Earth. Along the MOR, sub-seafloor circulation of seawater exchanges heat and elements between the ocean crust and seawater. The amount of iron (Fe) released by hydrothermal venting to the ocean per year is similar in magnitude to that of global riverine runoff. Until recently, measurement and modeling activities to understand the contribution of hydrothermal Fe to the ocean budget have been largely neglected.

The goal of the present research is to identify and quantify the forms of Fe present in hydrothermal plume particles to better understand the bioavailability, geochemical reactivity, and transport properties of hydrothermal Fe in the ocean. Direct Fe speciation data in hydrothermal plume precipitates has been reported only twice. This lack of data reflects how difficult it has been to obtain high quality samples and measure Fe speciation in the complex physical-chemical mixtures that compose hydrothermal plume particulates. These challenges have slowed our understanding of hydrothermal Fe speciation and transport, as well as the potential contribution of hydrothermal Fe to the global ocean budget.

On-going sediment trap deployments and new *in situ* filtration equipment are making it easier to obtain great samples. Improved synchrotron-radiation X-ray microprobe instruments and data analysis tools are making measurements of Fe speciation accessible and hold promise for quantitative research applications. In this contribution, the application of synchrotron-radiation X-ray microprobe to the mapping and quantification of Fe valence states and species will be discussed for hydrothermal plume particles collected by sediment trap and *in situ* filtration at the East Pacific Rise 9-10 N.

Timing and source of cold seeps at the northern slope of South China Sea: Evidence from U/Th dating and Sr isotopes

HONGPENG TONG[1], DONG FENG[2], HAI CHENG[3, 4], SHENGXIONG YANG[5], HONGBIN WANG[5], ANGELA M. MIN[4], R. LAWRENCE EDWARDS[4] AND DUOFU CHEN[1, 2 *]

Methane-rich fluid and gas expulsion often leads to authigenic carbonate formation close to the seafloor along continental margins. These carbonates represent excellent geochemical archives of methane emanation and possibly gas hydrate destabilization. Here, we report U/Th dating and Sr isotopes of seep carbonates from Shenhu area and Dongsha area on the northern continental slope of South China Sea. The obtained data will be used to discuss the timing of cold seep activity and potential driving processes involved and the source of fluids as well. The U/Th ages of the carbonates span a long time interval. Especially, carbonates from Shenhu area show a wide range of U/Th ages, between 152 ka and 330 ka. In contrast, carbonates from Dongsha area reveal U/Th ages between 42 ka and 77 ka. However, most of the carbonates revealed U/Th ages that point to formation during sea level lowstand. In addition, some of the studied carbonates, for example, samples from Site 3 of the NE Dongsha area have positive $\delta^{18}O$ isotopic signatures, presumably caused by gas hydrate dissociation. The results suggest that enhanced fluid flow during these time intervals closely related to sea level variations associated with glacial/interglacial cycles and possibly environmental change that affected the stability of gas hydrate reservoirs. The $^{87}Sr/^{86}Sr$ ratios of the carbonates range between 0.709025 and 0.709259. Specifically, samples from SW Dongsha display less radiogenic values, that are lower than that of modern seawater (0.709175). The carbonates must have formed either at or near the seafloor in contact with less radiogenic pore fluids, presumably deeper in the sediment. In contrast, samples from all the other areas are characterized by more radiogenic Sr values, suggesting that the seep fluids in contact with more radiogenic terrigenous material such as basinal brine and/or meteoric water.

High-throughput Analysis of Eco-toxicity of Nano-TiO_2 to Model Bacteria under Simulated Environmental Conditions

TIEZHENG TONG[1]*, CHU THI THANH BINH[2], JOHN J. KELLY[2], JEAN-FRANÇOIS GAILLARD[1], AND KIMBERLY A GRAY[1]

[1] Department of Civil and Environmental Engineering, Northwestern University, Evanston, USA, tiezhengtong2014@u.northwestern.edu
[2] Department of Biology, Loyola University Chicago, Chicago, USA

Introduction

Nano-TiO_2 (n-TiO_2) is among the most common engineered nanomaterials (ENM) and is applied in a diverse array of industrial and commercial products from sunscreens and disinfectants to catalysts. Due to its extensive applications and rapid growth of production, n-TiO_2 is inevitably released into natural environment, which has led to growing concerns on its potential environmental and health consequences. However, little is known about the effects of n-TiO_2 on bacteria under environmental conditions. In this study, we tested the toxicity of four types of commercialized n-TiO_2 to model bacteria *E. coli* and *B. subtilis* under simulated environmental conditions, with the help of the high-throughput screening technique.

Experimental design and results

Water collected from Lake Michigan was used as the solution matrix and a xenon arc lamp that provides simulated sunlight was used as the light source. Cell viability was evaluated with the BacLight Kit and reactive oxyten species (ROS) production was determined with carboxy-H_2DCFDA. Results confirmed a strong dependence of n-TiO_2 toxicity on the type of n-TiO_2 and illumination conditions. With broad spectrum illumination from the xenon arc lamp, Degussa P25 and two anatase exhibited significant toxicity to both bacteria while rutile caused no obvious toxicity. Under dark condition n-TiO_2 toxicity was almost negligible. Optic filters were used to assess the effects of light wavelength on n-TiO_2 toxicity. With exposure of Degussa P25 to light of above 400 nm, the viability of bacteria was similar to that under dark conditions, while exposure to light above 320nm produced cell mortality similar to that seen with broad spectrum illumination, indicating the importance of wavelengths between 320-400nm for n-TiO_2 toxicity. Suwannee River fulvic acid (SRFA) was used to assess the effects of natural organic matter (NOM) on n-TiO_2 toxicity. In contrast with the traditional assumption that NOM would enhance n-TiO_2 toxicity by reducing the size of n-TiO_2 aggregate, SRFA was found to decrease n-TiO_2 toxicity, probably due to its absorbance of light within UV region. Our study also suggests that photocatalytic activity of n-TiO_2, which is known to produce ROS, played an important role in bacterial inactivation. A correlation was observed between the decrease of bacterial viability and the increase of ROS production.

Significance

Environmental conditions determine the transport, fate and toxicity of n-TiO_2. Therefore, the simulated environmental conditions employed in our study makes our results more representative of the real scenario in the nature environment. Our study provides critical first steps in understanding the potential ecological effects of ENM.

Provenance, weathering and comminution ages of late Quaternary Weddell Sea sediments

A. TORFSTEIN[1,*], J. MCMANUS[1,2], S. HEMMING[1,2]

[1] Lamont-Doherty Earth Observatory, Columbia University, USA, adi.torf@ldeo.columbia.edu (* presenting author)
[2] Department of Earth and Environmental Sciences, Columbia University, USA, jmcmanus@ldeo.columbia.edu, sidney@ldeo.columbia.edu

The location and geometric setting of the Weddell Sea, one of the large marginal seas of Antarctica, make it a sensitive recorder of the input of subglacial erosion products from Antarctica over glacial-interglacial time scales.

We present a study of Pb, Sr and Nd isotopic compositions, U-decay series, and trace element concentrations of siliciclastic sediments deposited over the last ~250 kyrs in the East and North Weddell Sea (EWS and NWS, respectively). Each sample was separated into three grain size fractions of carbonate free material (>20um, 20-2um, <2um).

Significant differences are observed between sediment compositions between both studied regions as well as between grain size fractions within each sample. Lead isotopic compositions show a clear distinction between both sites with $^{206}Pb/^{204}Pb$ ratios in the EWS and NWS ranging between 17.958-18.307 and 18.655-18.939, repsectively. The isotopic composition of Sr is generally similar in both sites, 0.7152-0.7231, except for <2um particles from the NWS that significantly higher values between 0.7256 and 0.7338. The latter also display the strongest ^{234}U-depletion with ($^{234}U/^{238}U$) ratios typically ranging between 0.766-0.850.

These observations imply that the clay fraction in the NWS originates from a distant region, most likely East Antarctica, and that it was exposed to more intense weathering relative to the coarser particles. Hence, secular variations in $^{87}Sr/^{86}Sr$ and ($^{234}U/^{238}U$) ratios provide a sensitive recorder of changes in the combined effect of the sediments comminution ages (i.e., their time of transport between source and sink) and the intensity of weathering processes they were exposed to. Additional acid leaching experiments provide quantitative constraints on the effects of chemical weathering compared to the preferential loss of ^{234}U through recoil and will be discussed in the context of determining the sediments' comminution ages, which are closely connected to the history of the Weddell Gyre and Antarctic glacial weathering processes.

Uranium isotopic variations as a tracer of environmental contamination in sediment cores

R. TORTORELLO[1*], E. WIDOM[1], AND W. RENWICK[2]

[1] Department of Geology & Environmental Earth Science, Miami University, Oxford, Ohio, USA, tortorrd@muohio.edu (*presenting author)

[2] Department of Geography, Miami University, Oxford, Ohio, USA, renwicwh@muohio.edu

This study investigates potential environmental uranium contamination from the Fernald Feed Materials Production Center (FFMPC) located in SW Ohio. In 1951, the FFMPC site was established to process high purity uranium products from natural uranium ore and recycled recoverable residues, including enriched (EU) and depleted uranium (DU). The facility is estimated to have inadvertently released 200,000 to 1 million pounds of uranium into the environment during its operation from 1952 to 1985 [1]. Previous studies conducted in proximity to the FFMPC site have found elevated uranium concentrations in sediment cores [2] and non-natural uranium isotopic signatures indicative of an anthropogenic source in local tree bark [3].

This study tests the utility of lake sediment as a proxy for the temporal and aerial extent of uranium contamination, as well as to constrain the sources of uranium. A sediment core 80 cm in length was collected from an impoundment located 6.7 km south of the FFMPC site. The core was divided into 2 cm sections, resulting in forty sediment samples. Three samples that span the length of the core (top, middle and bottom) were analyzed using gamma spectrometry to determine ^{210}Pb and ^{137}Cs ages. The relative ^{210}Pb excess and the lack of measurable ^{137}Cs in the deepest sample suggest that it dates to the early 1950's and thus may pre-date any FFMPC activity.

Forty samples representing the entire sediment core were analyzed by ICP-MS, and were found to have U concentrations ranging from 0.33 to 1.33 ppm. Most samples exhibit a strong positive correlation between U and Th concentration. However, anomalously elevated U concentrations were found in nine consecutive samples from immediately above the base of the core (62 to 78 cm depth). In order to determine whether the elevated U was due to natural or anthropogenic sources potentially related to the FFMPC, twenty-one samples were analyzed for U isotopic composition by TIMS. The deepest sample, inferred to have been deposited in the early 1950's, has a natural ^{235}U/^{238}U signature and no measurable ^{236}U, consistent with this sediment pre-dating FFMPC activity. Furthermore, the samples with anomalously high U concentrations have variable ^{235}U/^{238}U ranging from DU to EU signatures (0.00645-0.00748), and all contain measurable ^{236}U with ^{236}U/^{238}U ranging from 2.1×10^{-6}–3.6×10^{-5}. Samples in the upper 0 to 40 cm of the core display natural ^{235}U/^{238}U signatures, but measurable ^{236}U/^{238}U, suggesting a continued presence of contaminant uranium in the local environment.

H_2CO_3 and its Anions and Oligomers: Updates on Experimental and Theoretical Studies

JOHN A. TOSSEL[1,*]

[1] George Washington University, Department of Chemistry, 725 21st Street, Washington, DC 20052, tossell@gwu.edu (* presenting author)

Most chemistry textbooks assert that H_2CO_3 is the dominant species in aqueous carbonic acid. Yet, geochemists know that H_2CO_3 is present at only very low concentration in aqueous solution of carbonic acid, which is instead dominated by hydrated CO_2. H_2CO_3 has recently been characterized in cryoscopic environments and a species which is probably H_2CO_3-HCO_3^- has been created and characterized in aqueous solution. The dianion $(HCO_3^-)_2$ has been characterized as an impurity in calcite. All the oligomeric carbonate species are stabilized by H-bonding. Oligomeric H_2CO_3 has been suggested as a form in which anthropogenic CO_2 can be sequestered. Recent quantum studies on the structures and properties of these species will be presented.

Primordial mantle heterogeneities revealed by coupled ^{182}W and ^{186,187}Os investigations

M. TOUBOUL[1*], J. G. LIU[1], J. O'NEIL[2], I. S. PUCHTEL[1] AND R. J. WALKER[1]

[1]Department of Geology, University of Maryland, College Park, MD, 20742 USA, mtouboul@umd.edu (* presenting author), gobyliu@umd.edu, ipuchtel@umd.edu, rjwalker@umd.edu

[2]Observatoire de Physique du Glode de Clermont-Ferrand, Clermont-Ferrand, France, joneil@dtm.ciw.edu

Subtle W isotope anomalies within the Earth's mantle have been recently evidenced by high-precision measurements for 3.8 Ga Isua rocks [1], and the 2.8 Ga Kostomuksha komatiites [2]. These samples have ~15 ppm ^{182}W excesses, which are similar to the isotope composition of the mantle prior to the arrival of late accreted materials, as estimated assuming that the highly siderophile elements (HSE) present in the silicate Earth today were derived entirely from this HSE-rich extraterrestrial contribution. However, the mantle source of the Kostomuksha komatiites had total HSE abundances ca. 80% of those estimated for the modern mantle. These observations are inconsistent with Kostomuksha komatiites being derived from a pre-late accretionary mantle reservoir. Instead, their mantle source, also characterized by coupled ^{186,187}Os excesses [3], must have contained a primordial component, which is argued [2] to have formed during the lifetime of ^{182}Hf (<60 Myr after Solar System formation) via either magmatic differentiation or metal-silicate equilibration. These processes were modeled [2] to have resulted in development of high Hf/W, Pt/Os, and Re/Os ratios.

Here, we report new high-precision W isotope data for ~4.3 Ga rocks from the Nuvvuaggittuq supracrustal belt (Northern Quebec, Canada). These results, coupled with Os isotope and HSE abundance data, as well as published ^{142}Nd data [4], are used to further constrain the timing and the nature of processes involved in the generation of ^{182}W heterogeneities. Four samples analyzed show ^{182}W anomalies of ca. +16 ppm, whereas the other two have W isotope compositions that cannot be resolved from that of the modern mantle. Samples with positive ^{182}W anomalies have total HSE abundances between 45 and 60% of those estimated for the modern mantle. Assuming that their HSE abundances are representative of their source HSE composition, the data would indicate that a substantial proportion of the late accreted materials were delivered to Earth prior to ~4.3 Ga. This would imply that the ^{182}W anomalies of some Nuvvuaggittuq rocks must have been produced by an early mantle differentiation process and provide further evidence that geochemical heterogeneities were created in the Earth's mantle while accretion was still ongoing, most likely prior to the giant impact and the formation of the Moon at ~4.50 Ga. These mantle domains were preserved until at least the late Archean. Preservation of early differentiation products during accretion events may suggest that the Earth's mantle has never been completely homogenized and/or entirely molten.

The chemistry of pore water and its controlling mechanisms are important properties of clayrocks being considered as host rocks for long-term storage of radioactive waste. Ionic strength, pH and redox potential are key parameters for assessing the speciation and thus the mobility of radionuclides under storage conditions. Porewater-controlling mechanisms must also be known to predict the evolution of the artificial and natural barriers foreseen in storage concepts. Since pore waters in clay-rich rocks cannot generally be sampled directly from rock samples, their chemistry must be estimated using geochemical modelling constrained by laboratory-measurable properties of core samples. In parallel to modelling work, considerable efforts have been made during the last ten years to obtain pore water samples from specially equipped boreholes in Underground Research Laboratories (URLs). Some of these experiments aim at obtaining water samples with minimal perturbations in order to enable comparisons with pore water geochemical modelling. Others obtain samples under disturbed conditions (e.g. bacterial, alkaline, redox, thermal perturbations) which can be used to assess the effectiveness of predicted controlling mechanisms.

Current modelling concepts of porewater composition will be reviewed together with their ability to explain key features in experimental results from the Bure (France) and Mont-Terri (Switzerland) URLs. We will show that pH and ionic strenght as well as major solutes concentrations (Na, K, Ca, Mg, Cl, SO_4, *etc.*) are adequatly predicted in undisturbed conditions, but that redox potential remains a difficult modelling issue. Controlling mechanisms for trace metal concentrations and their impact on radionuclides retention will be also discussed. Hereafter, we will show how the knowledge on solute parameters controls enables predicting the evolution of storage-material under various perturbation scenarios. Model uncertainties and limitations (*e.g.* thermodynamic database accuracy and completeness, kinetic controls, etc.) will be discussed in order to better emphasize the significance of long-term predictive modelling of storage-material evolution.

Recent studies have suggested that CH_4 emissions in urban areas may be underestimated, probably because most regional models to estimate CH_4 fluxes are based largely on agricultural emissions factors [1]. Other studies have proposed that increased extraction and use of natural gas, specifically from shale formations, may increase total methane emissions from fossil fuel sources [2,3]. In this presentation, we will demonstrate the use of stable isotopes (^{13}C and D) and radiocarbon (^{14}C) as tracers of sources of CH_4 in Los Angeles, California [4]. As expected, measurements of the $\delta^{13}C$ and δD of CH_4 from discrete sources showed separation between fossil fuel-derived sources, such as vehicle emissions, power plants, oil refineries, landfills, and sewage treatment plants and biological sources like cows, biofuels, landfills, sewage treatment plants, and cattle feedlots. We also implemented high-altitude monitoring of well-mixed air using continuous tunable laser spectroscopy measurements of CH_4 concentration combined with isotope analyses (^{14}C, ^{13}C, and D) of discrete samples. Our data, particularly variation of δD and (to a lesser extent) $\delta^{13}C$ with CH_4 concentration, indicate that the major source of excess CH_4 in Los Angeles is leakage of fossil fuels, such as from geologic deposits, natural gas pipelines, oil refining, and/or power plants. This is in contrast to some previous studies that have shown that landfills and waste treatment are the dominant source of CH_4 in urban areas. California state inventories currently lack urban emissions factors. More research is needed to constrain fluxes of this "fugitive" CH_4 from gas distribution and refining, as this flux may increase with greater reliance on natural gas and biogas for energy needs. The combination of high-resolution tunable laser concentration measurements and precise stable isotope measurements made via mass spectrometry is a very promising and powerful tool for verifying reductions in greenhouse gas emissions and constraining regional-scale emissions inversion models.

This presentation will include an overview of methods for using isotopes for source apportionment for atmospheric methane, a discussion of previous studies that have successfully applied these methods, and potential applicability to studies of shale gas extraction.

Major element incorporation into apatite: implications for thermometery

DUSTIN TRAIL[1*], LESLIE A. HAYDEN[2], E. BRUCE WATSON[1], NICHOLAS D. TAILBY[1]

[1]Department of Earth and Environmental Sciences & New York Center for Astrobiology, Rensselaer Polytechnic Institute, Troy, NY 12180, USA.

*traild@rpi.edu (presenting author).

Apatite is a ubiquitous accessory mineral that crystallizes in a wide variety of melts from basaltic to granitic. Apatite may also grow in low temperature (~40°C) aqueous solutions and during metamorphism. Crystals incorporate a variety of trace (e.g., rare earth elements [REEs], Sr, U, Th), minor (e.g., Mn) and major (e.g., Fe, Mg, Si) elements that may be used to trace the evolution of rocks, including magma volatile contents [1-4]. It is widely accepted that the incorporation of elements into minerals is at least sensitive to temperature [3]. Therefore, understanding and interpreting the chemisty of apatite crystals (e.g, REEs, U, Th, F, C, OH, Cl, S) may be extended by knowledge of the crystalization temperature.

We report synthesis experiments of apatite crystals grown in melts from 800 to 1200 °C and pressures of 1 and 2 GPa. Synthetic and natural silicate mixes (including SUNY MORB e.g., [5]) were doped with excess moles of CaO, P_2O_5, F, ±Cl, ±S to ensure apatite saturation. Major and minor element concentrations in apatites and co-existing phases (including quartz, diopside, augite, tremolite, and glass) were characterized by electron microprobe. Preliminary data suggest that some major rock forming elements (e.g. Si, Fe, Mg) correlate with temperature when a phase is present that buffers the activities of system components containing these elements. In experiments that contain only apatite and glass, major element concentrations are still demonstrably sensitive to temperature, though component activities are not well constrained.

Elements which are structurally accommodated by the apatite lattice, coupled with component activities that are 'buffered' by other assemblages – in nature and in laboratory experiments – are likely to be the most promising candidates for apatite thermometry. As an example, the activity of SiO_2 in most (silicate) melts can usually be constrained. However, application of apatite Si contents as a thermometer may be hindered because the entry of Si into the P site requires charge compensation with other elements (e.g., trivalent REEs satisfy this requirement). Other elements such as Mg and possibly Fe, for example, may be better candidates that require fewer assumptions. Nevertheless, an apatite thermometer will require an estimate of component activities for application.

Titan aerosol analogs from aromatic precursors: Comparisons to Cassini CIRS observations in the thermal infrared

MELISSA G. TRAINER[1*], JOSHUA A. SEBREE[1], CARRIE M. ANDERSON[1], AND MARK J. LOEFFLER[1]

[1]NASA Goddard Space Flight Center, Greenbelt, MD USA, melissa.trainer@nasa.gov (* presenting author)

Background

Since Cassini's arrival at Titan, ppm levels of benzene (C_6H_6) and possibly polycyclic aromatic hydrocarbons (PAHs) have been detected in the atmosphere.[1] Aromatic molecules, photolytically active in the ultraviolet, may be important in the formation of the organic aerosol comprising the Titan haze layer even when present at low mixing ratios. Yet there have not been laboratory simulations exploring the impact of these molecules as precursors to Titan's organic aerosol.

Observations of Titan by the Cassini Composite Infrared Spectrometer (CIRS) in the far-infrared (far-IR) between 560 and 20 cm^{-1} (~18 to 500 μm) have been used to infer the vertical variations of Titan's aerosol from the surface to an altitude of 300 km.[2] Titan's aerosol has several observed emission features which cannot be reporoduced using currently available optical constants from laboratory-generated Titan aerosol analogs [2,3,4], in particular a broad far-IR feature centered approximately at 140 cm^{-1} (71 μm).

Analog Studies

There is a need to revisit the infrared spectrum of laboratory-produced aerosol, particularly in the far-IR. We speculate these features may be a blended composite of low-energy vibrations of two-dimensional lattice structures of large molecules, such as PAHs or nitrogenated aromatics. Such structures do not necessarily dominate the composition of analog materials generated from CH_4 and N_2 irradiation.

We are performing studies forming aerosol analogs via UV irradiation of several aromatic precursors – with and without nitrogen heteroatoms – to understand how the unique chemical architecture of the products influence observable aerosol characteristics. The optical and chemical properties of the aromatic analog will be compared to those formed from CH_4/N_2 mixtures [5,6], with a focus on the as-yet unidentified far- and mid-IR absorbance features. These studies show that the aerosol formed from aromatic precursors have distinct chemical composition as compared to previously studied analogs, which has implications for the optical properties of Titan's aerosol.

Calcite farming in Florida caves: Calibrating modern calcite $\delta^{18}O$ and $\delta^{13}C$ to ventilation and *in situ* air temperature

D. M. TREMAINE[1*], B.P. KILGORE[1] AND P. N. FROELICH[2]

[1]Florida State University; NHMFL – Geochemistry; Tallahassee, FL, USA; (*presenting author: tremaine@magnet.fsu.edu)
[2]Froelich Education Services, 3402 Cameron Chase Drive, Tallahassee, FL, 32309-2898, USA, pfroelich@comcast.net

Stable isotope records ($\delta^{18}O$ and $\delta^{13}C$) in cave speleothems are typically interpreted as climate changes in rainfall amount and source, cave air temperature, atmospheric CO_2, and overlying vegetation. But these records are difficult to interpret without *in situ* calibrations between cave microclimate (e.g., ventilation) and contemporaneous calcite isotopic composition. In this study at Hollow Ridge Cave (HRC) in Marianna, Florida (USA), cave dripwater and modern calcite (farmed *in situ*) were collected in conjunction with continuous cave air pCO_2, temperature, barometric pressure, relative humidity, radon-222 activity, airflow velocity and direction, rainfall amount, and drip rate data [1, 2]. We analyzed rain and dripwater isotopes, dripwater [Ca^{2+}], pH, $\delta^{13}C$ and TCO_2, cave air pCO_2 and $\delta^{13}C$, and farmed calcite $\delta^{18}O$ and $\delta^{13}C$ to examine the relationships among rainwater isotopic composition, cave air ventilation, cave air temperature, seasonal calcite growth rate and timing, and calcite isotopic composition. Farmed calcite $\delta^{13}C$ decreases linearly with distance from the front entrance to the interior of the cave during all seasons, with a maximum ventilation-induced entrance-to-interior gradient of $\Delta\delta^{13}C$ = -7‰. Farmed calcite $\delta^{18}O$ exhibits a +0.82 ± 0.24‰ offset from values predicted by both theoretical calcite-water calculations and by laboratory-grown calcite (Figure). Unlike calcite $\delta^{13}C$, oxygen isotopes show no ventilation or evaporation effects and are a function only of temperature. Combining our data with other speleothem studies, we find a new empirical relationship for cave-specific water–calcite oxygen isotope fractionation across a range of temperatures and cave environments: **$1000\ \ln \alpha = 16.1(10^3\ T^{-1}) - 24.6$** (light blue dashed line in the Figure).

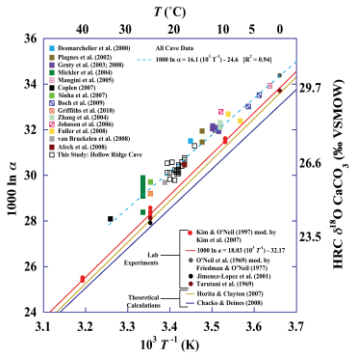

Figure: 1000 ln α vs. $10^3\ T^{-1}$ for HRC calcite (black open squares) plotted with other modern cave studies (solid & crossed squares), laboratory inorganic precipitation values (circles), and theoretical calc-ulations (solid lines). The red line is the best-fit line from [3] as modified by [4]: 1000 ln α = 18.03 ($10^3\ T^{-1}$) - 32.17.

During the Iron Age, the Gaulish *Arverni* and *Lemovices* influence extended well beyond Auvergne (Central France), into the Mediterranean regions owing to extensive agricultural activities and silver mining. Recent discoveries showed that gold mining in the area of Haute-Combraille (Auvergne) may also has contributed to the wealth of these communities. Gold was possibly extracted as well during the first two centuries AD. at the onset of Roman occupation.

Our project (MINEDOR) aims to study from an interdisciplinary and diachronic point of view these ancient gold mines, traditionally attributed to the Gaulish period, discovered in large numbers at the fringes of the *Arverni* and *Lemovices* territories, in the area of Upper Combraille (Puy-de-Dôme). Our goals are 1) to accurately identify the mines through fieldwalking and aerial surveys, analysis of vertical aerial photographic coverage and localization by dual-frequency DGPS, 2) to assess their environmental impact using palaeoenvironmental (palynology, microfossils) and geochemical (heavy metals, trace elements, stable lead isotopes) analyses in wetlands, and 3) to date transient phases of exploitation.

Here we present high-resolution peat core analyses from the Haute-Combraille highlands (900-1000m) that allow to evidence gold mining operational phases since the Iron Age through vegetation cover changes and the release of lead (Pb) from mining activities. These new data highlight important features of the ancient economy of the Massif Central and the transient environmental impact of mining operation on watershed quality.

Advances in MC-TI-MS for precise and accurate Ca isotopic analysis

ANNE TRINQUIER[1*], CLAUDIA BOUMAN[1], NICHOLAS LLOYD[1], MICHAEL DEERBERG[1], AND JOHANNES SCHWIETERS[1]

[1]Thermo Fisher Scientific, Bremen, Germany, anne.trinquier@thermofisher.com (* presenting author)

Ca isotopes have proved to be powerful isotopic tracers in a number of disciplines within Geosciences, including Paleoceanography, Geochronology and Biogeochemistry, and Cosmochemistry, where minute anomalies relative to Earth are a key to deciphering the origin of Earth and the terrestrial planets. However, accurate and precise Ca isotope analysis is highly challenging, due to, both, the extreme range of relative Ca isotopic abundances - ^{40}Ca alone representing 97% of Ca isotopes - and the extreme mass dispersion of the Ca isotope array of 20%. These limiting features have prevented optimized multicollection (MC) analysis of all Ca isotopes, and introduced uncertainties due to ion beam instabilities and inferior counting statistics for the minor Ca isotopes. Precision and accuracy can be improved by optimizing sample loading and double spike techniques, but ultimately, there is a need for improved mass spectrometry performance in order to improve the state-of-the-art for Ca isotopic analysis.

The TRITON *Plus* offers new solutions to address these analytical challenges:

[1] An extended mass dispersion provides *simultaneous collection of all Ca isotopes*, without the requirement of applying a zoom to deflect the Ca ion beam. Peak-jumping mode is no longer required for Ca isotope analysis, thus saving acquisition time and limiting the potential detrimental effects of Ca ion-beam instabilities on precision and reproducibility.

[2] Different gain current amplifiers (10^{10}, 10^{11} and 10^{12} Ohm) can be combined. The 10^{12} Ohm amplifiers provide a factor of 2-3 improvement in the signal/noise ratio relative to a classical 10^{11} Ohm amplifier, and can be associated to the cup(s) collecting the minor Ca isotope(s). Additionally, a 10^{10} Ohm amplifier can be connected to the cup collecting ^{40}Ca, and hence increase the dynamic range by a factor of 100. Amplifier switching to any cup is supported by the tried and tested relay matrix already equipping TRITON instruments. The combination of these current amplifiers ultimately contributes to enhancing Ca isotope in-run precision through improved ion counting statistics and by application of more precise instrumental mass fractionation correction as the normalizing ratio ^{42}Ca/^{44}Ca can be determined at 10 times higher beam intensities.

[3] The new TRITON *Plus* Ca package consists of 2 special cups: an extended cup attached on the high mass side of the focal plane that accomodates acquisition of the heaviest Ca isotope (^{48}Ca); and an oversized cup on the low mass side of the focal plane for the high intensity ^{40}Ca beam.

Indonesia's Merapi volcano is one of the most active and dangerous on the planet, characterized by long periods of dome growth and intermittent explosive pyroclastic events. Merapi currently degasses continuously through high-T fumaroles (>200°C), and has recently erupted mainly crystal-rich basaltic-andesite that contains a large range of igneous and calc-silicate crustal inclusions. To evaluate mechanisms that trigger explosive eruptions, we sampled lavas, inclusions (xenoliths), and gas from active fumaroles. We also experimentally established a time-integrated reaction series of crustal assimilation at Merapi under magmatic conditions.

Merapi lava contains abundant, complexly zoned plagioclase crystals that show variations in anorthite (An) content between 40 and 95 mol% across resorption surfaces. A negative correlation between An content and other indicators of magmatic fractionation, such as MgO and FeO, has been observed. Moreover, *in-situ* Sr isotope analysis of discrete zones in plagioclase yields $^{87}Sr/^{86}Sr$ values that notably exceed those of the host lavas. Zones with the highest An content tend to also show the highest radiogenic Sr values, and, by contrast, low MgO, consistent with a Ca-rich, MgO-poor crustal contaminant. Abundant metamorphosed crustal limestone xenoliths contain compositionally identical feldspar to the lavas (up to An_{95}), demonstrating that magma-crust interaction is a significant process at Merapi.

Carbon isotope ratios of fumarole CO_2 sampled during quiet periods form a baseline of $\delta^{13}C_{2001\text{-}2006}$ = -4.1‰. The notable exceptions are the 2006 values, sampled during the eruption and after the 6.4 magnitude Yogyakarta earthquake, which show elevated $\delta^{13}C$ values up to -2.4‰. Notably, the rise in $\delta^{13}C$ values coincided with an increase in eruptive intensity and volcano seismicity by a factor of 3 to 5 for several weeks after the earthquake. This is consistent with a late-stage, crustal volatile component added to purely mantle and slab-derived volatile sources, arguing for extensive and ongoing magma-crust interaction beneath the volcano, especially during eruptive and/or seismic events.

High P-T experiments show that interaction between Merapi magma and limestone can rapidly liberate crustal CO_2 on a timescale of only seconds to minutes in our experiments [1]. We therefore expect vigorous CO_2 bubble nucleation and growth on a scale of perhaps hours to days in nature. Late volatile input could therefore accelerate or trigger explosive eruptions independently of magmatic recharge and fractionation by sudden over-pressurization of the upper parts of the magma system. Such an event would provide shallow seismic warning signals only and these would be temporally very close to an erratic, CO_2-driven, eruption crisis.

Paleo-environmental characterization of the Pelusiac branch of the Nile (Egypt)

HERVÉ TRONCHÈRE[1*], ALAIN VÉRON[2], JEAN-PHILIPPE GOIRAN[1], IRENE FORSTNER-MULLER[3]

[1]CNRS UMR 5133 Archéorient, Maison de l'Orient et de la Méditerranée, Lyon, France, herve.tronchere@mom.fr (*presenting author), jean-philippe.goiran@mom.fr
[2]CNRS UMR 7330 CEREGE, University Aix-Marseille, Aix en Provence, France, veron@cerege.fr
[3]Austrian Archaeological Institute, Cairo, Egypt, irene.forstner_mueller@oeai.at

The paleo-Pelusiac branch of the Nile delta once housed Avaris, the capital city of the Hyksos kings during the 2nd millenia BC. The now defunct Pelusiac branch also was one of the seven largest diffluents of the Nile and therefore offers the opportunity to investigate paleo-environmental changes in the delta according to hydrological fluctuations and anthropogenic activities.

The Nile has three main affluents that connect in Sudan, the White Nile, the Blue Nile and the Atbara river, more than 2.500km south of the apex of the delta. These three rivers drain much dissimilar geological basins, from the plutonic rocks of the White Nile to the effusive rocks of the Blue Nile. The heavy metals load carried by the Nile reflects this diversity along with dust deposition from Saharan plumes and local discharge from anthropogenic activities. Lead (Pb) and its stable isotopes are known to efficiently trace the geological diversity of sediment particles and to discriminate anthropogenic sources leached into natural reservoirs thanks to the specific imprint of metallic ores [1]. Here we propose to use these isotopes measured from cores collected in the Pelusiac branch to resolve (1) changes in sediment source dynamics and (2) local human activities during the 2nd millenia BC. into the Nile delta.

Lead isotopes, luminescence datings and sediment analysis allow to correlate fluctuations of the delta hydrosystem to regional climate shifts such as the transition from late Pleistocene deposits to more recent Holocene alluvia. Pb isotopes in sediments deposited prior to the onset of the Hyksos city display non contaminated imprints spread between several natural sources. This distribution illustrates transient changes in the Nile hydrodynamics and prevailing climatic settings. Here are also presented anthropogenic signals identified during the Bronze Age in the Eastern Nile delta.

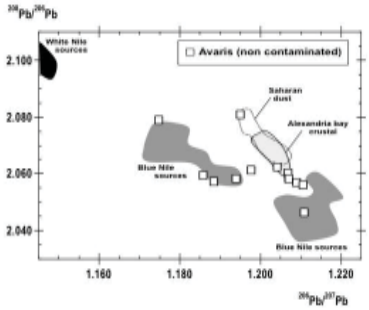

Figure 1: Distribution of the natural Pb isotope imprints at Avaris

Magnesium isotopic fractionation in arid Hawaiian soils

KYLE D. TROSTLE[1*], LOUIS A. DERRY[2], NATHALIE VIGIER[3], OLIVER A. CHADWICK[4]

[1]Cornell University, Ithaca, USA, kdt42@cornell.edu (* presenting author)
[2]Cornell University, Ithaca, USA, lad9@cornell.edu
[3]CRPG, Nancy, France, nvigier@crpg.cnrs-nancy.fr
[4]UC Santa Barbara, Santa Barbara, USA, oac@geog.ucsb.edu

Sampling and Methods

Soil, streamwater, and parent material samples were taken from the arid leeward coast of the Kohala Volcano on the Big Island of Hawaii to investigate the fractionation of magnesium isotopes within the weathering environment. Soil samples were taken from both the Pololu (~350 ka) and Hawi (~170 ka) lava flows, and streamwaters were taken from streams under different discharge conditions. Soils were characterized on site and with x-ray diffraction techniques in order to determine horizonation and mineralogy. These samples were then processed via a sequential extraction to isolate carbonate, exchangeable, and soil organic matter fractions, and will be further processed to isolate noncrystalline phases, poorly crystalline phases, kaolin, and residual materials. Major element chemistry of these extractions was determined, and samples were processed according to an ion exchange method developed by Bolou-Bi et al. (2009) [1] in order to isolate monoelemental solutions of magnesium from each. These were run on a Thermo-Fisher Neptune multi-collector inductively coupled plasma mass spectrometer (MCICPMS) at the Centre de Recherches Petrographiques et Geochimiques (CRPG) in Nancy, France, using standard-sample bracketing techniques to determine δ^{26}Mg with respect to the standard DSM3.

Results and Conclusions

The δ^{26}Mg isotopic composition of soil carbonates (n=7) ranged considerably from -1.05 ± 0.32 per mil to -2.31 ± 0.16 per mil, whereas the magnesium isotopic composition of the exchangeable fraction (n=7) consistently averaged -1.12 ± 0.21 per mil, in both the Pololu (~350 ka) and Hawi (~170ka) soils. The variation in carbonate magnesium isotopic composition may be due to a variety of factors, including depth, age, and phase, but with only seven carbonate samples analyzed, further work is needed to confirm trends within the data. Both of the soil carbonate and exchangeable reserviors of magnesium, in both the Pololu and Hawi soils, are isotopically lighter than the primary sources of magnesium to Hawaiian soils, which include precipitation at a value of -0.8 per mil and basalt at -0.3 per mil [1]. The streamwaters (n=5) measured fall inbetween the isotopic values of precipitation and basalt, with an average value of -0.54 ± 0.20 per mil, although this consistency in magnesium isotopic composition within the streamwaters may be the result of groundwater influence. A magnesium budget for these soils has been created to interpret these findings.

Abstract

Acid rain reduces plant diversity, growth, and population size. Anthropogenic activities that release SO_2 and NO_x produce acid precipitation, and cause to groundwater acidification. This experiment tested the ideal soil mixture for *Lolium multiflorum* (ryegrass), when exposed to low concentrations of acid rain. Using different mixtures of sphagnum peat moss, montmorillonite, and quartz sand, 21 different soils were created. For each, 48 *L. multiflorum* seeds were planted individually, and watered with an average of 10 mL/day of deionized water. Plants were grown in controled conditions under artificial light and were rotated regularly to ensure equal light intensity reaching each plant over a seven day period. On Day 19, each group was split in half, with one half continuing to receive 10 mL/d water, while the rest subsequently received 10 mL/d of 0.0001 M of H_2SO_4 at pH = 3.62. Plant heights were measured and health was monitored via leaf number and general appearance daily. After 35 days, biomass production was measured. Sprouting percentages, mean growth rates, and mean longevity were calculated for each group. In the absence of acid, the sprouting percentage is highest for soils with ≤ 20 vol% sand, ≤ 60 vol% peat moss, and ≤ 80 vol% montmorillanite, while the mean plant heights were tallest for soils with 40 vol% sand, 20 vol% peat moss, and 40 vol% montmorillanite after 35 days. If exposed to acid, the plants grew tallest in soils with 40 vol% peat moss and 60 vol% clay, but plant longevity was highest for soils with 20 vol% peat moss, 20-60 vol% sand and 20-60 vol% montmorillanite. Biomass production was highest for plants exposed to water when their soil averaged 20-40 vol% clay, but for plants exposed to acid, biomass production was highest if their soil had 40-60 vol% clay. Therefore, for ryegrass exposed to acid, growth will be improved, if clay concentrations in their soil are higher than for plants exposed to water alone. Nonetheless, pH of 3.62 did not dramatically affect potential growth for *L. multiflorum.* Thus, it might make a suitable species to use for reme-diation in areas with clay-rich soils and acidified groundwater. Future experiments will examine the ions leached from the soil under these conditions.

Figure 1. Mean plant heights on Day 35 for plants growing in the acidic groundwater (above) and in water lacking acid (below).

Intriduction

The Lopingian of late Permian carbonate platform margin developed in Northeastern Sichuan,China,which located at the west part of Upper Yangzi Platform tectonically，that contain a peculiar and widespread microbial facies, but have received little attention. The microbial facies have been reported from PTB limestone from southeastern China and Japan and have been placed in the basal Griesbachian *Hindeodus parvus* zone (Sano et al.,1997; Kershaw et al., 2002).But the microbial structures developed below that horizon here and also influenced the evolution of carbonate platform margins. The study area in Daba mt.offers a few locations where the Late Permian carbonate platform margins can be studied along the continuous outcrops. Some very good exposured outcrops of Changxing Fm. provide detailed information on the platform margin evolution.

Facies architecture and Evolution

Three stages of the platform margin have been identified:1)ramp stage developed at the first and second member of Changxing Fm. , the thin dark micrite bed with small sponge mounds deposited with about 150 m in thickness. This stage was in the high stand system tract;2)microbial mound rimmed margin developed at the lower part of third member of Changxing Fm. with about 210 m in thickness,and the transgressive system tract developed at this time. The microbial mound shows three internal growth phases vertically including sponges-thrombolite, thrombolite-tubiphytes and thrombolite.The sponges-thrombolite developed in the lowest part of the microbial mound with lower topography and gentle slope,then,the thrombolite-tubiphytes and thrombolite， are the main contributors to mounds, developed quickly and made the rimmed margin to showing higher topography and steep slope gradually. The microbial mound structures play a key factor controlling the progradational geometry of the platform margins;3.oolitic and arenitic shoal stage ,which developed in the high stand system tract, distribute at the upper part of third member of Changxing Fm. with about 46 m in thickness. The evolution of the microbial structures as well as the final demise of late Permian reefs followed by microbial mound without true metazoan reefs may reflect the characteristics of the Late Permian biological crisis.

Conclusion

The evolution of the Late Permian platform margin here was mainly controlled by relation sea-level oscillation, microbial facies architectures, other control factors such as tectonic subsidence, synsedimentary faults may play the subordinate actions.

Sea floor methane emissions in high-latitude continental shelves and the role of anaerobic methane oxidation

IANA TSANDEV[1*], PIERRE REGNIER[2], ANDY W. DALE[3]

[1] Faculty of Geosciences, Utrecht University, Utrecht, the Netherlands i.tsandev@uu.nl (* presenting author)

[3] Helmholtz-Zentrum für Ozeanforschung Kiel (GEOMAR), Kiel, Germany, adale@geomar.de

The melting of submerged permafrost and increases in temperature in high latitude sediments have brought the Earth's methane gas hydrate reservoir closer to destabilisation which is a subject of great concern. Fluxes of methane from sea floor gas hydrates are a potential key forcing of Earth's climate; for example the abrupt environmental change of the Paleocene Eocene Thermal Maximum (PETM) has been linked to methane release from destabilized gas hydrates [1].

If the released methane is oxidized aerobically, such as in a ventilated water column or the surface oxidized layer of the sediment, it results in an increase in dissolved inorganic carbon (DIC), no change in alkalinity (ALK) and thus $CaCO_3$ dissolution. The effect can be opposite if anaerobic oxidation of methane takes place (eg. throughout the reduced part of the sediment column) as this process releases two equivalents of alkalinity per mole of methane oxidized and, thus, induces carbonate precipitation.

In this communication we explore the benthic geochemical dynamics following hydrate melting in high-latitude shelf environments typical of the W. Svalbard coast that are recognised areas for hydrate destabilization [2]. Benthic fluxes were calculated using the 1-D reaction-transport model, BRNS, after imposing an upward flux of methane based on hydrate dissolution estimates. Anaerobic methane oxidation (AOM) significantly reduced the efflux of methane to the overlying water and led to accumulation of DIC and ALK inventories in the sediment porewaters, favouring carbonate precipitation. This also resulted in increased effluxes of DIC and ALK to the overlying seawater.

The magnitude of AOM is, however, very sensitive to the assumed rate constant for this process. We therefore modulated the rate of AOM with microbial biomass growth dynamics [3] and observed a transient response of the microbial community to the upward methane flux. The microbial ecosystem was slow to respond to the fast methane supply leading to a transient loss of methane from the sediment into ocean waters.

Geochemical trends across the Palaeoproterozoic Kuruman and Griquatown BIFs, Transvaal Supergroup, South Africa, and implications for the GOE

HARILAOS TSIKOS*[1], LINDI FRYER[1], HELEN WILLIAMS[2], SIMON POULTON[3], AND ADRIAN BOYCE[4]

[1]Geology Department, Rhodes University, Grahamstown, South Africa h.tsikos@ru.ac.za
[2]Department of Earth Sciences, Durham University, UK
[3]Civil Engineering & Geosciences, Newcastle University, UK
[4]Scottish Universities Environmental Research Centre, UK

The Transvaal Supergroup on the Kaapvaal Craton of South Africa contains one of the thickest (up to ~1000m), most complete, and best preserved sequences of banded iron-formation (BIF) of early Palaeoproterozoic age (~2.5-2.4 Ga). The stratigraphically lower Kuruman BIF exhibits typical microbanded textures dominated by chert and magnetite, with lesser siderite and Fe silicate; it is conformably overlain, through a gradual facies transition, by the granular to microbanded, siderite-Fe silicate-rich Griquatown BIF.

We have carried out a reconnaissance (generally one sample every 10-15m) geochemical study of both the Kuruman and Griquatown BIFs. Our key objective was to test whether these BIFs stratigraphically record geochemical signals of potential relevance to the evolution of the atmosphere-ocean system leading to the Great Oxidation Event (GOE) at *ca.* 2.4Ga. Our sampling focused on two complementary drillcore intersections located approximately 60 km NW of the town of Kuruman. The two drillcores together capture the entire BIF stratigraphy, which in this specific area measures ~400m thick. The Kuruman BIF is stratigraphically underlain by the Klein Naute black shale that overlies the Campbellrand carbonate sequence at the base of the Transvaal Supergroup, whilst the Griquatown BIF is overlain conformably by the Makganyene diamictite.

Our sample suite captures essentially all major sub-lithofacies of the Transvaal BIFs as described previously [1]. Geochemical results show a number of broad stratigraphic trends: (i) bulk carbonate $\delta^{13}C$ data range between -6 and -11 per mil, and fluctuate in concert with corresponding fluctuations in the non-ferrous carbonate component of the samples; (ii) Fe and Mn speciation data record a general upward increase in the Mn:Fe ratio of carbonate (and bulk-rock); and, (iii) bulk $\delta^{57}Fe$ data range between -2.7 and 0.9 per mil, with lower values generally corresponding to samples with high modal siderite relative to magnetite, as seen particularly in the Griquatown BIF.

We regard the stratigraphic increase in the Mn:Fe ratio and attendant decrease in bulk $\delta^{57}Fe$, as possible precursor signals to the stratigraphically higher, manganiferous and ^{57}Fe-depleted Hotazel Formation, itself thought to have formed prior to the GOE in a highly evolved – chemically and isotopically – stratified marine basin. Mass balance considerations also suggest that C and Fe isotope variations in the BIFs may record primary precipitation from a chemically and isotopically stratified water column, rather than isotopic fractionation related entirely to biogeochemical redox processes during diagenesis.

Kinetic theory of crystallization from meta-stable phases

K. TSUKIMURA[1]*, M. SUZUKI[1], Y. SUZUKI[1], T. MURAKAMI[2]

[1]AIST, Geological Survey of Japan, Tsukuba, Ibaraki 305-8567, Japan
[2]University of Tokyo, Tokyo 113-0033, Japan

Abstract

Various kinds of meta-stable phases are formed on the Earth's surface. Most of these phases are amorphous or poorly crystallized nano-particles. These phases can contain various kinds of harmful elements. When we discuss the behavior of these harmful elements contained in the meta-stable phases, we need to estimate the lifetime of the meta-stable phases because these meta-stable phases are transformed to crystalline stable phases. This paper describes a kinetic theory of the crystallization from a metastable phase [1]. The theory assumes that a crystal nucleates only on the surface of a meta-stable phase, the crystal stops growing at a certain size, and the concentration of metal ion in solution is close to the solubility of the meta-stable phase. On the basis of these assumptions, we have derived integral equations for $R(t)$ (crystal ratio as a function of time). We have solved the integral equations with a successive approximation method. When time t is less than t_{inflec} ($=r_{max}/G$, r_{max}: maximum radius of crystal, G: growth rate of crystal), $R(t)$ is close to fourth power of time; when t is larger than t_{inflec}, $R(t)$ is close to an exponential-type function. The kinetic theory has been applied successfully to the transformation of ferrihydrite nanoparticles to goethite or hematite crystals (Fig. 1), and the crystallization of TiO_2 and ZrO_2. The theory shows that the nucleation rate of crystal essentially determines the crystallization rate, and that induction period is observed when the growth of crystal is slow.

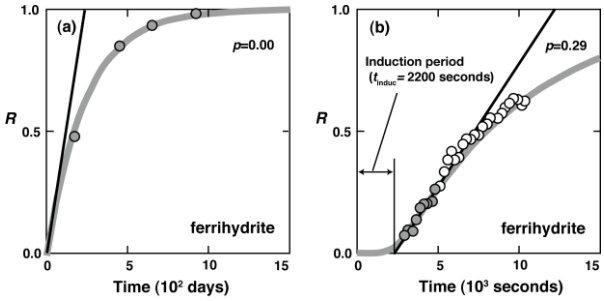

Figure1: Relation between observed and calculated values of R [1]; (a) the transformation of ferrihydrite at pH 6 and 297 K [2] and (b) the transformation of ferrihydrite at pH 10.7 and 361 K [3]. Circles denote experimental data points and solid curves calculated values based on the present theory. Data points in grey symbols were used for the determination of parameters p and t_{inflec} ($=4/3\ t_{induc}$) .

Tailings pond mixed species biofilm gives metal precipitates

RAYMOND J. TURNER[1] *, SUSANNE R. GOLBY[1], HOWARD CERI[1]

Biofilm Research Group, Department of Biological Sciences, University of Calgary, AB, Canada, turnerr@ucalgary.ca (*presenting author)

Background

Our group has been interested in metal ion resistance and tolerance of bacteria growing as a biofilm compared to that of their free-swimming planktonic state [1]. As expected overall bacteria growing as a biofilm are more tolerant to metals. Recently we have moved from single model species to environmental community isolates. This study utilized the Calgary biofilm device (CBD) as a microscale reactor to cultivate mixed species biofilms directly from Alberta oil sands tailings pond sediments, under a variety of different culture conditions [2]. This approach revealed that the organisms within the biofilms strongly represented the indigenous population in the tailings used as the inoculum and contained over 10 different genera per biofilm including organisms belonging to *Pseudomonas, Thauera, Hydrogenophaga, Rhodoferax* and *Acidovorax* [2].

New results

Subsequently we have been challenging these organisms to salts of metals known to be present in the tailings ponds and at other mining sites including Cu, Pb, Cr, V, Ni, Zn, and Sr as well as Ag, due to its strong microbial biocidal activity. We observed that the mixed species biofilms showed higher tolearance to metal ion stress than a monospeci biofilms isolated from the community. The highest tolerance was to Pb and Sr. The metals Cu, Ag, Pb and Sr were found in deposits on, and within, the biofilms suggesting that the organisms in the biofilm community were seeding the crystal formation not seen in monospecie biofilms (example see Figure 1).

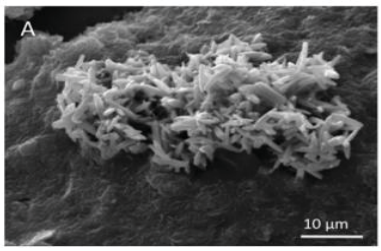

Figure 1: Scanning electron microcrosopy image of biofilm exposed to 1000 mg/L $CuSO_4$. Crystals shown to be Copper by energy dispersive spectrometry.

Summary

A process of growing mixed species biofilms directly from environmental samples has been established. This growth method demonstrated biogeochemical transformation of several metal ions to preciptiates on and within the biofilm.

Mantle flow, slab-surface temperatures and melting dynamics in the north Tonga arc – Lau Basin

S.TURNER[1*], J. CAULFIELD[1], R. ARCULUS[2], C. DALE[3], N. KELLER[4], J. PEARCE[5] AND C. MACPHERSON[3]

[1]Department of Earth and Planetary Sciences, Macquarie University, Australia, simon.turner@mq.edu.au*
[2]Research School of Earth Sciences, ANU, Australia
[3]Department of Earth Sciences, University of Durham, UK
[4]Institute of Earth Sciences, University of Iceland, Iceland
[5]School of Earth and Ocean Sciences, Cardiff University, UK

The Fonualei Spreading Centre is a nascent series of en échelon ridges that extend north from near Fonualei volcano, on the Tonga arc front, to the Mangatolu Triple Junction in the northeastern Lau Basin. Fresh basaltic glasses dredged from these ridges afford an excellent opportunity to evaluate geochemical changes with increasing depth to the slab. Here we augment previously published major and trace element data with new Sr, Nd, Pb, Hf and U-Th-Ra isotope data for selected Fonualei Spreading Centre samples as well as present new Hf isotope data from boninites and seamounts to the north of Tonga. The Pb and Hf isotope data are used to appraise interpretations of the extent and distribution of Samoan plume mantle beneath the Lau Basin based on He and Pb isotope data. If elevated ^{208}Pb and lowered Hf isotope ratios in lavas from Niuafo'ou Island and the Mangatolu Triple Junction reflect a Samoan plume influence this is not visible in He isotopes. The boninite and seamount data indicate that the tear in the northern end of the slab may not extend east as far as the boninite locality. Mantle flow is inferred to be oriented to the southwest. In the Fonualei Spreading Centre lavas, Ce/Pb, $^{87}Sr/^{86}Sr$ and $^{208}Pb/^{204}Pb$ increase, whereas U/Th, Th/Nb and $^{143}Nd/^{144}Nd$ decrease, with increasing distance from the arc front. These changes are accompanied by increasing slab surface temperatures (725-940 ºC) as inferred from decreasing H_2O/Ce ratios. Consistent with experimental data, the geochemical trends are interpreted to reflect changes in the amount and composition of wet pelite melts and aqueous fluids derived from the slab under appropriate conditions. With one exception, all of the lavas preserve both ^{238}U excesses and ^{226}Ra excesses. Ba-Yb, Na_8-Fe_8 and U-series isotope systematics suggest that lavas from the Fonualei Spreading Centre and Valu Fa Ridge reflect fluid-fluxed melting. However, there is a change to decompression melting in lavas from the East and Central Lau Spreading Centres where slab surface temperatures reach ~ 900-1000ºC. A similar observation is found for the Manus and East Scotia back-arc basins and may reflect the absence of lawsonite in the subducted basaltic crust.

Evaluating permeability change due to altered pore geometry in CO_2 sequestration systems

BENJAMIN M. TUTOLO*, ANDREW J. LUHMANN, XIANG-ZHOU KONG, MARTIN O. SAAR, WILLIAM E. SEYFRIED, JR.

Department of Earth Sciences, University of Minnesota Minneapolis, MN, USA
(*presenting author: tutol001@umn.edu)

Background

Experimental, numerical, and field investigations of CO_2 injection into deep saline aquifers indicate alteration of formation mineralogy and permeability in CO_2-affected regions. Permeability typically increases in carbonate-hosted systems with the formation of preferential flow pathways and typically decreases in feldspar-rich systems due to formation of secondary clay minerals.

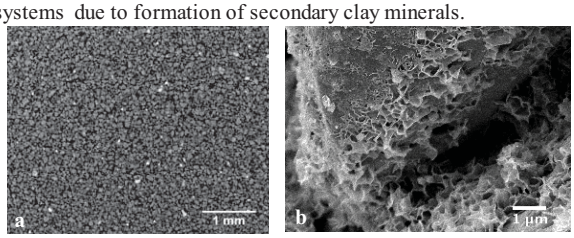

Figure 1 a: XMT image of packed arkosic sediment core
b: SEM image of alteration minerals on feldspar grain surface

Approach

With X-ray Microtomography (XMT, Fig. 1a) and Scanning Electon Microscopy (SEM, Fig. 1b) images of cores before and after they are subjected to CO_2-saturated water/brine experiments at elevated temperatures and pressures, we observe pore-scale alteration of flow path geometry. The reconstructed XMT images are thresholded to separate pore space from solids and divided into Representative Elementary Volumes (REVs, Fig. 2) to calculate permeability fields over large sections of the core with lattice-Boltzmann methods. Real-time monitoring of core permeability and geochemical modeling of core mineralogy and sampled solution chemistry yield additional, vital data to observe the rates and characteristics of mineral and permeability alteration throughout the experiment.

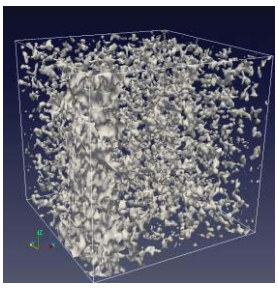

Figure 2: REV reconstructed from XMT images.

Results

This combined experimental and numerical approach is used to characterize and predict permeability modification resulting from CO_2 injection for several rock types, including arkose, dolostone, and basalt. This approach avoids bulk porosity-permeability relationships commonly used in reactive transport modeling to predict permeability changes and instead focuses on physical changes due to chemical alteration at the pore scale.

Assessing the importance of extracellular iron scavenged on phytoplankton cells with synchrotron x-ray fluorescence microscopy

BENJAMIN S. TWINING[1*]

[1]Bigelow Laboratory for Ocean Sciences, W. Boothbay Harbor, USA, btwining@bigelow.org (* presenting author)

Iron is an essential micronutrient for phytoplankton, and it has been shown to limit primary production in large swaths of the ocean with low external inputs. Dissolved iron occurs primarily as Fe(III) in the oxic surface waters of the ocean, and ferric iron is nearly insoluble under these conditions. Thus iron is prone to precipitate and scavenge onto particle surfaces. Oceanographers have long considered that a non-negligible fraction of iron associated with ocean plankton may be extracellularly adsorbed rather than associated with intracellular biological moieties. A number of studies have been conducted to investigate the behavior of this iron, and several operationally-defined chemical rinses have been developed and utilized to remove this extracellular fraction prior to elemental analyses. I have analyzed numerous plankton cells from both natural open-ocean environments and laboratory cultures with synchrotron-based hard x-ray fluorescence (SXRF) microprobes, occasionally in conjunction with the above-mentioned rinses. By and large, the spatial distributions of iron and other bioactive elements in these cells suggest that the extracellular adsorbed fraction is only a minor component of cellular iron contents. I will present data from both lab and field studies in support of this observation, discuss reasons for its occurrence, and suggest ways to reconcile these observations with geochemical evidence for Fe scavenging in the ocean.

Enriched mantle source for the Cretaceous alkaline lamprophyres from the Catalonian Coastal Ranges (NE Spain)

TERESA UBIDE*, CARLOS GALÉ, ENRIQUE ARRANZ, MARCELIANO LAGO, PATRICIA LARREA, PABLO TIERZ, AND TOMÁS SANZ

University of Zaragoza, Department of Earth Sciences, Spain, tubide@unizar.es (* presenting author)

During the Cretaceous, the opening of the Bay of Biscay led to a widespread alkaline magmatism in northeast Iberia [1]. This magmatism is recognised in the Pyrenees [2] and in the Catalonian Coastal Ranges [3]. In the latter sector, it is represented by lamprophyre sills, classified as camptonites. They are hypocrystalline porphyritic rocks composed of large mafic crystals (clinopyroxene, kaersutite, olivine pseudomorphs and opaque minerals) set in a fine-grained groundmass. Most of the groundmass consists of microlites of feldspars and kaersutite; apatite is a common accessory phase.

The lamprophyres are basic and ultrabasic rocks enriched in incompatible elements (10 to more than 100 times over the primitive mantle). They show a Ti/V ratio over 50, similar to OIB-type rocks. In order to obtain petrogenetic information from the incompatible trace elements, only the most primitive samples (MgO > 7 wt. %) were considered. In addition, rocks with high volume fractions of large crystals were dismissed as their composition is strongly influenced by the accumulation of the crystals [4].

The primitive mantle-normalised multi-element patterns are very similar to each other, suggesting a common magma source. $(La/Lu)_N$ values (14.9-17.3) indicate highly fractionated patterns. All the samples show positive anomalies for Nb-Ta and smaller ones for Ba; some of the samples also present a negative anomaly in Pb. These data point to an astenospheric enriched mantle source similar to EM-1 [5]. Small differences are observed for K, which correlate with the proportion of kaersutite in the samples. Slight differences in P are probably related to the presence of apatite.

The εSr values define a wide variation range (-11.7 to +14.9). Given that these variations do not correlate with the SiO_2, MgO or Sr contents, crustal contamination can be ruled out. Therefore, a heterogeneous mantle source is inferred, as previously reported for the Permian and Triassic magmatisms in the Pyrenees [6].

In contrast, the εNd values (+3.1 to +4.4) and the Pb isotopic ratios ($^{206}Pb/^{204}Pb$: 19.06–19.46; $^{207}Pb/^{204}Pb$: 15.65–15.70; $^{208}Pb/^{204}Pb$: 39.28–39.82) show small variations. The low Pb ratios discard the involvement of a HIMU-type component. The Sr-Nd-Pb isotopic values support a heterogeneous, astenospheric mantle source with the involvement of an EM-1 component [5].

The obtained T_{DM} ages are very consistent (0.55-0.60 Ga). They may reflect a Cadomian fractionation event in the mantle.

Photodissociation origin of Archean S-MIF and dynamical sulfur cycling under highly reducing atmosphere

YUICHIRO UENO[1]*, SEBASTIAN DANIELACHE[1], YOSHIAKI ENDO[1], MATTHEW JOHNSON[2], NAOHIRO YOSHIDA[3]

[1]Department of Earth & Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan. ueno.y.ac@m.titech.ac.jp

[2]Copenhagen Center for Atmospheric Research, Department of Chemistry, University of Copenhagen, Denmark.

[3]Department of Environmental Sciences and Technology, Tokyo Institute of Technology, Yokohama, Japan.

Mass-independent fractionation of sulfur isotopes (S-MIF) demonstrated that Earth's atmosphere was virtually oxygen-free in the Archean [1], and is a key to understand chemistry of atmosphere and ocean before the rise of oxygen. However, the mechanism and factor controlling the S-MIF signal have been poorly understand yet. We newly determined higher resolution UV absorption cross sections of not only $^{32}SO_2$, $^{33}SO_2$ and $^{34}SO_2$ but also $^{36}SO_2$ within the two absorption bands: (1) 190 – 220 nm and (2) 250 – 320 nm. These data together with chemical reaction model allow us to predict isotopic compositions of photochemical product. The calculated photochemical fractionation pattern assuming broadband solar UV flux reproduce our previous work [2], though the effect of UV shielding by each atmospheric species including SO_2 itself differ from previously estimated trend. Nonetheless, almost all of the simulations result in $\Delta^{36}S/\Delta^{33}S$ ratio of -0.9 ~ -1.1, generally reproducing those observed in Archean sedimentary rocks. Thus, we conclude that photodissociation of SO_2 was a primary MIF-yielding reaction in the Archean atmosphere. Our simulation predict, however, the remaining SO_2 after UV photolysis acquires positive $\Delta^{33}S$ as opposed to widely-accepted previous model where H_2SO_4 ($-\Delta^{33}S$) and S_8 ($+\Delta^{33}S$) aerosols carried "opposite" MIF signals into ocean and sediment [4,5]. We speculate the possibility that almost Archean sulfide deposits were produced by sulfate reduction. The new model requires relatively innert reducing form of sulfur reservior. If the atmosphere was strongly reducing and contained high level of CO or CH_4, photolytically produced SO was finally transferred into OCS [2] or organo-sulfur compounds [6], respectively, which remained in the atmosphere and were not readily converted into sulfide. Occasional oxidation of the reducing sulfur pool enhanced sulfate concentration and deposited rare sulfate minerals with negative $\Delta^{33}S$. The new dynamical sulfur cycle model may explain observed heterogeniety of S-MIF records in the basin to microscopic scale. If correct, this implies more reducing Archean atmosphere than previously thought.

Petrological Exploration of podiform chromitite by using of detrital spinel, Sangun Zone, southwest Japan.

TOMOYUKI UMEDA[1*] AND ICHIRO MATSUMOTO[1]

[1] Department of Education, Shimane University, Matsue, Japan, umedatomoyuki@gmail.com (* presenting author) chromim@edu.shimane-u.ac.jp (second author)

Sangun zone ultramafic rocks and chromitite

Many ultramafic complexes some of which have chromitite bodies are exposed in the Sangun zone in central Chugoku district, Southwest Japan. All complexes are harzburgite-dominant, and dunite is various in amount on each complex and sometimes has small amounts of chromitite in it [1]. A chromitite pod is always enclosed by dunite envelopes and large chromitite bodies are exclusively found in relatively dunite-dominant complexes or portions [1, 2]. Largest chromite mines of Japan that are Wakamatsu and Hirose are exists in the northern part of Tari-Misaka complex.

Detrital chromian spinel as a tool for exploration of podiform chromitite

Exploration of podiform chromitite has been difficult, because its occurrence is usually very irregular in ultramafic complex. Matsumoto and Arai (1997) proposed the petrological exploration of podiform chromitite by using of spinel chemistry and morphology from the rocks from the outcrops [2, 3]. Above study is epoch-making as an investigating method for exploration of podiform chromitite. However, an investigation precision does not go up by this Method. Because it dose not have the good exposure of ultramafic rocks in the Sangun zone. In this research, we observed detrital spinel in bottom sediment of small creek in and around the ultramafic complex. By this method, there is an advantage that can analyze much spinel grain at once. Moreover, it is expected that we can evaluate a large locality (complex) with a comparatively sufficient precision.

Cr# (Cr/Cr+Al) of detrital chromian spinels from the creek around relativery dunite rich ultramafic complex varies from 0.55 to 0.65. In contract to this, from the creek around dunite free or poor ultramafic complex, Cr# of detrital chromian spinels varies from 0.40 to 0.60. And complex with relativery large chromitite show high in Cr# and Mg# (Mg / (Mg+Fe^{2+})) of chromian spinel. Above results are basically same as Matsumoto and Arai (1997). However, it is very significant results for exploration of chromitite that we have calculated the quantitive chromitite's existence rate each ultramafic complex separately. That is northern part of Tari-Misaka complex is the place where most high potenciality of chromitite deposit. This result also concordant with the idea of chromitite formation proses [4, 5].

Microbial characterization at iron-clay interfaces after 10 years of interaction *in situ* in an argillaceous formation (Tournemire, France)

LAURENT URIOS[1*], FRANCOIS MARSAL[2], DELPHINE PELLEGRINI[2], MICHEL MAGOT[1]

[1]Université de Pau et des Pays de l'Adour, IPREM UMR 5254, Equipe Environnement et Microbiologie, IBEAS, F-64013 PAU, France, laurent.urios@univ-pau.fr (* presenting author)
[2]Institut de Radioprotection et de Sûreté Nucléaire (IRSN), DSU/SSIAD/BERIS, B.P. 17, 92262 Fontenay aux Roses Cedex, France, francois.marsal@irsn.fr

Introduction

Microbial activity has been proven to occur in argillaceous formations, as well as the development of exogenous microorganisms within disturbed areas [1]. In the context of a geological disposal of radioactive waste in clayey formations, the consequences of such a microbial activity are of concern regarding the corrosion of metallic materials. In particular, sulfate- or thiosulfate-reducing bacteria may influence localised corrosion processes [2], that may lead to a premature loss of watertightness of containers. Moreover, the passive film, which is formed progressively during the generalised corrosion process and induces a decrease of corrosion rates, may react with iron-reducing bacteria which could thus promote corrosion [3]. The purpose of the present work was to characterise the microbial diversity that may have impacted corrosion processes at the interface between re-compacted argillite and steel coupons after 10 years of interaction under *in situ* conditions inside the Toarcian argillite layer in Tournemire (France).

Results and Conclusion

The characterization of the microbial diversity was carried out using 16S rRNA genes cloning and culture media. More than 630 clone sequences were analyzed and 123 isolates were identified. Altogether, 19 phylotypes and 55 taxa were defined. They were affiliated to only 3 bacterial phyla: *Firmicutes*, *Actinobacteria* and *Proteobacteria*. The biodiversity identified differs depending on the steel type and the location of the sample, indicating the influence of *in situ* physico-chemical conditions. Moreover, isolates and clone sequences have revealed that sulfate-reducing bacteria, iron-reducing bacteria as well as thermotolerant strains able to grow at temperatures up to 75°C could develop in this environment. Different microbial populations can colonize the interfaces between materials in a very short period of time compared with the timescales of a geological disposal. These results should be considered to assess the consequences of microbial activities on the evolution of the metallic disposal components.

Evidence from D/H and volatile abundances of impact melts for a surficial water reservoir on Mars

TOMOHIRO USUI[1, 2*], CONEL M. O'D. ALEXANDER[3], JIANHUA WANG[3], JUSTIN I. SIMON[1] AND JOHN H. JONES[1]

[1]ARES, Johnson Space Center, NASA, Houston, TX, USA. tomohiro.usui@nasa.gov (* presenting author)
[2]Lunar Planetary Institute, Houston, TX, USA.
[3]DTM, Carnegie Institute of Washington, Washington DC, USA.

Martian surface morphology implies that persistent liquid water once existed on its surface and played a significant role in the formation of weathered regolith. In order to study this surficial water we measured volatile abundances (H_2O, CO_2, S, Cl, F) and H isotopes of impact melts (IMs) and maskelynite (shocked plagioclase) in geochemically enriched (LAR 06319 [LAR06]) and intermediate (EETA79001 [EETA79]) shergottites by ion microprobe analysis. Early studies of inert gases contained in IMs from EETA79 match the relative abundances of modern Martian atmosphere.

IMs in LAR06 contain lower H_2O (~150ppm), CO_2 (~20ppm) and S (100-400ppm) but higher F (10-30ppm) and Cl (40-80ppm) than IMs in EETA79 (~300ppm H_2O, ~300ppm CO_2, 3200ppm S, <3ppm F, ~30ppm Cl). The major element compositions of IMs are probably derived by partial melting of primary plagioclase and pyroxene. Likewise, the halogen abundances could possibly reflect the incorporation of primary phosphates. On the other hand, the much higher H_2O/CO_2 ratios than that of the Martian atmosphere ($<10^{-3}$) imply the presence of another water source.

In a previous study [1] based on olivine-hosted melt inclusions we showed that the primary magma of the geochemically depleted shergottite (Yamato 980459 [Y98]) had a chondritic low-δD value of 275‰, whereas that of LAR06 had a very high-δD value of 5079‰. In contrast with such extreme δD differences, matrix phases in Y98 and LAR06 both have moderate δD values. Groundmass glasses (GGs) in Y98 exhibit a slightly greater δD variation of 200-1600‰, but still much less extreme than the range exhibited by the melt inclusions. The δD values of the Y98 GGs rise with increasing water contents, implying mixing of two components: near-surface moderate-δD and magmatic low-δD components. On the other hand, IMs and maskelynites in LAR06 exhibit lower δD values of ~1000-3000‰ than the primary LAR06 melt (5079‰), although mixing calculations suggest that these matrix δD values could have been modified by contamination of <30ppm terrestrial water (δD~-200‰). IMs in EETA79 also have a moderate δD value of ~1600‰.

This study shows that the matrix phases (GG, IM and maskelynite) in all three shergottites have a relatively limited range of δD values regardless of the distinct δD of their magmatic sources. A [δD *vs.* $1/H_2O$] mixing diagram shows a convergence among the matrix δD values, which could be attributable to the impact-induced addition of a common near-surface water with a moderate δD value (~1200-2000‰). The origin of this surficial water reservoir remains unresolved: (1) it may be derived from the Martian atmosphere, but its moderate δD values are distinctly lower than the widely-accepted atmospheric δD value of ~4000-5000‰, and/or (2) it could originate from the addition of a weathered soil/dust component enriched in volatile elements. Natural variations of uranium isotopes in uranium ore minerals

YULIA A. UVAROVA[1], KURT KYSER[1*], MAJDI LAHD GEAGEA[1], AND DON CHIPLEY[1]

[1]Queen's University, Kingston, Canada, kyser@geol.queensu.ca (* presenting author)

Introduction

Recent studies have shown significant variations in $^{235}U/^{238}U$ and $^{234}U/^{238}U$ ratios in geologic materials. We have investigated the uranium isotopic compositions of natural ores from various uranium deposit types with the use of MC-ICP-MS to better understand mechanisms and processes for fractionation of uranium isotopes in different geologic conditions.

Results

The $\delta^{235}U$ and $\delta^{234}U$ values of uranium minerals from various types of deposits worldwide show variations of 1.8 and 500‰, respectively, measured relative to NBL CRM 129-A. Higher $\delta^{235}U$ values are generally recorded by magmatic- or metasomatic-related U mineralization or deposits that have igneous rocks as a source of uranium (Fig. 1). High-grade unconformity type deposits have $\delta^{235}U$ values around -0.9‰. Vein-type, sandstone-hosted, most unconformity-type deposits, and uranium mineralization in the Beaverlodge area have lower $\delta^{235}U$ values (Fig. 1). $\delta^{234}U$ values for most samples analyzed are around 30‰ and record secular equilibrium. Some samples have $\delta^{234}U$ values much lower or higher than 30‰ associated with addition or removal of ^{234}U during the past 500 Ka.

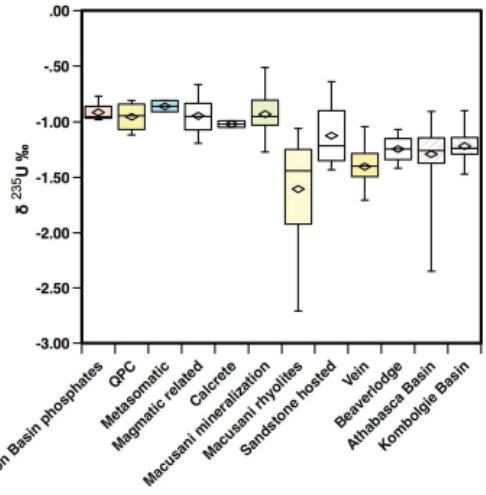

Figure 1: $\delta^{235}U$ values for studied samples

Discussion

The $\delta^{235}U$ and $\delta^{234}U$ values recorded in uranium ores from different types of deposits indicate that there are at least two different mechanisms responsible for $^{235}U/^{238}U$ and $^{234}U/^{238}U$ fractionation. $^{234}U/^{238}U$ disequilibria ratios indicate fluid alteration of the uranium minerals or rocks and postdepositional migration of ^{234}U. Fractionation of ^{235}U and ^{238}U as a result of nuclear volume effects results in enrichment of the heavy isotope in reduced insoluble species relative to oxidized mobile species. Therefore, isotopic fractionation effects should be reflected in $^{235}U/^{238}U$ ratios in U ore minerals formed either by reduction of U^{6+} to UO_2 or chemical precipitation in the form of U^{6+} minerals. $\delta^{235}U$ values of uranium ore minerals from a variety of deposits are controlled by isotopic signature of the U source, the efficiency of U precipitation, and later fluid-produced alteration of the ore.

Climate extremes and volcanic eruptions: Trace elements, isotopes and U-series geochronology recorded by a [1]Late Quaternary stalagmite

I. TONGUÇ UYSAL[1*], EMMA J. ST PIERRE [1], AND JIAN-XIN ZHAO[1]

[1] University of Queensland St Lucia, QLD, 4072, AUSTRALIA, t.uysal@uq.edu.au (*presenting author)

Documenting the timing of large volcanic eruptions is critical in climate change research because volcanic gas and ash spreading globally from equatorial eruptions can cause a significant change in global temperatures [*1,2,3,4*]. Cave carbonate deposits provide an unprecedented opportunity to reconstruct climate changes, volcanic eruptions, and recurrence patterns of paleo-seismic events [*5*]. Through high-precision U-series dating and micro-chemical analysis, speleothems are capable of providing tandem records of climate and environmental change, and thus can offer new insights into the complex interplay of seismic, volcanic and hydrological processes.

We investigated a stalagmite sample from a cave in a volcanically active region in Indonesia by a high-resolution micro-sampling, high-precision U-series dating combined with trace element, C, O, and Sr isotope analysis. The stalagmite contains several dark laminas that record major volcanic eruption cycles and/or episodic climatic shifts. A sharp increase in the trace element abundance, which correlates clearly with increasing $\delta^{18}O$ and $\delta^{13}C$ values and a drop in $^{87}Sr/^{86}Sr$ values, is conspicuous in the black layers. Strikingly, the pattern of $^{87}Sr/^{86}Sr$ values of the investigated stalagmite sample parallels their U/Th age spectra. Voluminous CO_2 emission due to phreatic eruptions and/or a sudden turnover to dry climate episodes are interpreted as leading to carbonate growth hiatuses before the precipitations of black layers. More future studies of millimetre to submillimetre-scale geochemical investigations and precise age dating of speleothems from volcanically active regions will provide detailed insight into interplay among volcanic cycles, fluid flow events and climate changes.

Phosphorus sorption properties of surface sediments in the northeastern Baltic Sea

ANU VAALAMA* AND KAARINA LUKKARI

Marine Research Centre/Finnish Environment Institute, Helsinki, Finland
anu.vaalama@ymparisto.fi*, kaarina.lukkari@ymparisto.fi

Introduction

Hypoxia weakens water ecosystem's health by reducing habitats for living resources and altering the biogeochemical cycle of nutrients. In the Baltic Sea, hypoxia has been present intermittently since the excistence of the sea but its spatial extent and intensity has increased due to anthropogenic nutrient loading [1]. The Gulf of Finland is one of the most eutrophied basins in the Baltic Sea and receives hypoxic near-bottom water from the Baltic Proper.

Oxygen depletion further feeds eutrophication by promoting release of phosphorus (P) from reducible iron(oxyhydr)oxides in sediments. However, P is released from sediments also in oxic conditions, for example, as a result of organic matter decomposition and bioturbation. In addition, P adsorption onto iron(oxyhydr)oxides is at least partly reversible [2,3] and can result in P release also from oxidized particle surfaces. Significant spatial variation in the sediments' P storages and their chemical composition in the Gulf of Finland [4] suggests variation also in P sorption ability of the sediments.

We investigated P sorption-desorption behaviour in occasionally hypoxic surface sediments in the open Gulf of Finland and the northern Baltic Proper by equilibrating oxidized sediments with artificial sea-water of varying P concentrations. In addition, we determined physico-chemical characteristics of the sediments, such as specific surface area, amount of organic matter, total P, as well as iron, aluminium, manganese and their (oxyhydr)oxides, to find out, whether these factors explain the P sorption behaviour.

Results and Conclusions

According to our preliminary results, P sorption behaviour varied among the study sites. P sorption was efficient in sediments with high organic matter and low ambient oxygen concentration in the bottom-water. In these sediments, iron-bound P was probably released during hypoxia but there was enough iron to regenerate good P sorption capacity when samples were oxidized again. The low concentration of easily desorbable P in these sediments and, in contrast, high easily desorbable P in sediments with poor P sorption ability, supported this conclusion.

Sorption-desorption behaviour of P at the sediment-water interface is a dynamic phenomenon. In addition to prevailing oxygen conditions, other physico-chemical characteristics describing the sorption environment are important in explaining the behaviour of P. These results suggest that the iron-rich, poorly oxygenated sediments in the open Baltic may bind P efficiently if oxic conditions return.

17 c. Laser ablation ICPMS for trace-element, isotope and imaging applications in geochemistry

LA-ICP-MS represents suitable analytical tools for elemental mapping minor and trace elements in geological samples. The advantages consists in low limits of detection and sufficient lateral resolution.

We present possibility of elemental mapping by means of LA-ICP-MS. The presented elemental maps were obtained by laser ablation of granitoids from Bohemian massif what represents sufficient heterogenous samples. The new lab-made software was used for creation of elemental maps (Fig.1).

The second part is focused on quantification procedures for elemental mapping – total sum of signals of isotopes and external calibration with internal standard normalization. Their advantages and drawbacks in quantification of heterogeneous samples will be discussed.

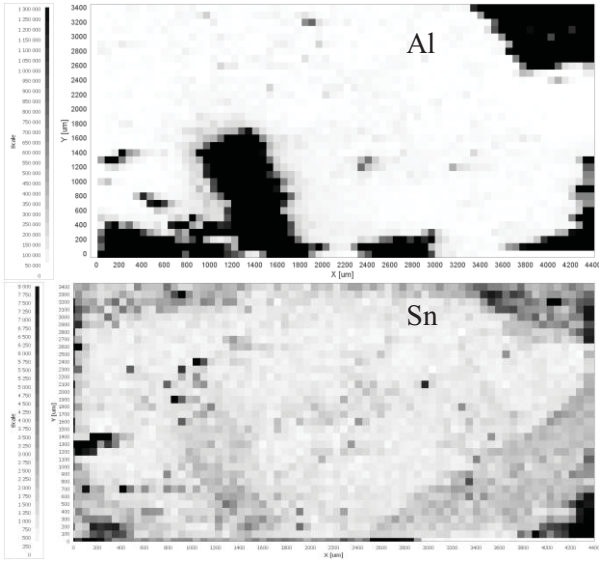

Figure 1: Elemental map of aluminium and tin in granitoid sample from Bohemian massif

Oxygen Isotope Geochemistry of Zircon

JOHN W. VALLEY [1*]

[1]Department of Geoscience, University of Wisconsin, Madison, WI 53706, USA, valley@geology.wisc.edu

In situ analysis by SIMS and LA-ICP-MS allows correlation of multiple geochemical systems within single sub-domains as small as 1 μm^3 of a zircon crystal. Such data have provided detailed records of igneous, metamorphic and sedimentary events in the crust of Earth and elsewhere.

Igneous zircons with $\delta^{18}O$ values outside of the "mantle-equilibrated" range (5.3±0.6‰ 2sd) indicate crustal input to parent magma. These values are preserved by slow diffusion rate in non-radiation-damaged zircon even through granulite metamorphism and anatexis (1). Zircon growth zoning can thus record magma contamination or mixing during sucessive tectonic events. In contrast to radiogenic isotope systems that evolve with time and trace elements that fractionate due to different degrees of incompatibility, $\delta^{18}O$ fractionates largely in response to low temperature exchange with fluids. Each system contributes complimentary information.

High values of $\delta^{18}O$ in igneous zircons (>6‰) are not in equilibrium with primitive mantle and provide a clear indication of magmas that contain a significant crustal component. This crustal signature provides a means for sorting U-Pb age and εHf data, when correlated *in situ* for sub-domains in zircon, to distinguish quantities of recycled crust and identify mantle extraction events (2).

The range of $\delta^{18}O$ in igneous zircons has increased since the end of the Archean with maximum values of 7.5‰ throughout the Archean increaseing to ~12‰ in the Phanerozoic (3). This secular trend of $\delta^{18}O_{max}$ started at ~2.5 Ga due to increased recycling of high-$\delta^{18}O$ supracrustal material into melts. Clay-rich mudstones are the largest high-$\delta^{18}O$ reservoir on Earth today, but were less common in the Archean suggesting that zircons document increased continental weathering after 2.5 Ga due to expansion of continents and epeiric seas, and oxygenation of the atmosphere.

Low $\delta^{18}O$ igneous zircons (<4.5‰) are most common in young rocks, but this has been argued to result from poor preservation of near-surface environments (3). The absence of a secular trend in minimum values of $\delta^{18}O$(Zrc) is high-lighted by zircons with $\delta^{18}O$ as low as -26‰ at 2.4 Ga (4).

In contrast to the relatively restricted variability of $\delta^{18}O_{max}$ for igneous zircons, values of $\delta^{18}O$ for metamorphic zircons are generally more variable and range up to 25.5‰ in detrital (probably Tertiary) metamorphic zircons (5) and 10.4‰ at 2.6 Ga (1). Thus higher $\delta^{18}O$ metasediments existed *locally* throughout the rock record and the apparent absence (scarcity?) of such elevated $\delta^{18}O$ igneous zircons indicates homogenization of larger *regional* domains by magmatism. Metamorphic zircons thus preserve unique evidence of smaller-scale environments that may be key to understand the larger transitions on Earth.

Background

Nanotechnology has the potential to revolutionise modern life, but has also been linked with concerns about the potential toxicity of newly created materials. This is because on the nanoscale, common materials can take on entirely new chemical, physical and biological properties, offering new unique technological opportunities, but also leading to unpredictable and potentially harmful biological or environmental effects. A substantial body of research now exists on the potential toxicity of nanomaterials, but many of these studies have been limited by difficulties in detecting nanoparticles in biological or envioronmental media, at appropriate concentrations. Often, the concentrations that make an experiment environmentally relevant are so low that the identification of nanoparticles containing elements already present at elevated concentrations (e.g. of Cu or Zn) in the environment and/or biota is not feasible.

.

Results and Conclusions

Here, we are reviewing the results from a number of very recent studies on isotopically modified CuO and ZnO [1,2,3] which have successfully demonstrated the application of this labelling method in *in vivo* experiments with environmental relevance. We are also considering the challenges in the synthesis of labelled particles and speculating about where the method of stable isotope modification has potential to go in the future, including in a life-cycle context. We are finally reviewing the importance of appropriately designed experiments, in which a thorough understanding of the behaviour of nanoparticles in experimental media can be established, specifically in terms of aggregation, dissolution and complexation and how labelling can also contribute to improvement of experimental designs.

Rhenium-Osmium dating of black shales from the Neoproterozoic Shaler Supergroup, Victoria Island, Canada

DAVID VAN ACKEN[1*], DANIELLE THOMSON[2], ROBERT H. RAINBIRD[3], AND ROBERT A. CREASER[1]

[1]University of Alberta, Edmonton, Canada, vanacken@ualberta.ca (* presenting author), rcreaser@ualberta.ca
[2]Carleton University, Ottawa, Canada, dthomso2@connect.carleton.ca
[3]Geological Survey of Canada, Ottawa, Canada, rrainbir@nrcan.gc.ca

The Neoproterozoic Shaler Supergroup from Victoria Island, Canada, is a diverse sequence of sandstone, carbonate, evaporite and shale that was deposited in an intracontinental basin within the supercontinent Rodinia. The ~ 4km-thick succession was intruded by diabase sills and dykes of the ca. 720 Ma Franklin igneous event, which provide a minimum depositional age for the Shaler Supergroup. Its maximum depositional age, from detrital zircon geochronology, is about 1000 Ma. The Shaler Supergroup has been used as a reference section for global $^{87}Sr/^{86}Sr$, $\delta^{13}C$ and biostratigraphic correlation of Neoproterozoic sedimentary successions, notably with the Canadian Mackenzie Mountains Supergroup and the Australian Bitter Springs Formation.

Whereas global chemostratigraphic correlations are better established in the late Cryogenian and Ediacaran, precise age information for the late Tonian and early Cryogenian Periods that encompass the Shaler Supergroup is scarce. The Wynniatt Formation of the Shaler Supergroup has been correlated to the ~830 Ma Gillen Member of the Bitter Springs Formation in Australia based on lithostratigraphy and matching low $^{87}Sr/^{86}Sr$ from carbonates.

Recent advances in Re-Os geochronology allow for direct dating of black shales as a tool for chrono-stratigraphic correlation of sections where other chronostratigraphic and biostratigraphic information are lacking. In order to constrain the depositional history of the Shaler Supergroup, Re-Os analyses were obtained from core and outcrop samples of black shale from the Wynniatt and Boot Inlet formations collected from the Minto Inlier of Victoria Island.

Black shales from the Wynniatt Formation, several hundred meters below the contact with ~720Ma basalts that mark the top of the Shaler Supergroup, yield preliminary Re-Os ages around 770 – 790 Ma. Samples from the Boot Inlet Formation, about 1 km stratigraphically below the Wynniatt Formation, yield Re-Os ages around 900-920 Ma. These ages provide additional valuable anchor points for the Neoproterozoic timescale.

Old and new geochemical proxy evidence for deciphering the southern high latitude 'doubthouse'

T. VAN DE FLIERDT[1] AND EXPEDITION 318 SCIENCE PARTY

[1]Imperial College London, London, UK, tina.vandeflierdt@imperial.ac.uk

Antarctica is the least explored continent on our planet Earth, largely due to today's massive ice cover on the continent, reaching a thickness of 4500 m in places, leaving only 0.3% of the land area uncovered. This ice sheet, however, was not always in place, and its inception ~34 million years ago at the Eocene-Oligocene boundary marked one of the most fundamental climate transitions in recent Earth history: the transition from the greenhouse world of the Cretaceous and early Paleogene to the icehouse world we are currently living in.

Global climate in the greenhouse world seems to have been characterized by low latitudinal temperature gradients and subtropical temperatures at high latitudes. Atmospheric CO_2 levels were probably well in excess of 1000 ppm, and it is hypothesised that there was no or only very little ice on the poles. A range of geochemical proxies have been used over the years to characterize baseline conditions as well as rapid climate excursions during the 'doubthouse' (ca. 144 to 34 Ma).

Here I will provide a summary and critical evaluation of some of the proxies that can shed light on the interrelationship between Earth's cryosphere, ocean chemistry and temperature, and the carbon cycle. I will pay particular attention to the early Paleogene in the southern high latitudes and to evaluating the use of radiogenic isotope systems (i.e., Hf, Nd, Pb isotopes). I will furthermore highlight some of the spectacular initial results obtained from material recovered during IODP Expedition 318, which sailed in January to March 2010 to the Wilkes Land coast, East Antarctica. Seven sites were drilled along an inshore to offshore transect, yielding ~2000 m of middle Eocene to Holocene sediment. At Site U1356, a partial record of the early Paleogene was retrieved (Expedition 318 Scientists, 2011), offering the rare opportunity for detailed geochemical studies on a marine section from the southern high latitudes during this time.

Tracing seawater-rock interaction in slow spreading oceanic crust: precise chlorine measurements in MORB by microprobe

F.M. VAN DER ZWAN[1*], J. FIETZKE[1], C.W. DEVEY[1], R.R. ALMEEV[2] AND K.M. HAASE[3]

[3]GeoZentrum der Friedrich-Alexander Universität Erlangen-Nürnberg, Erlangen, Germany

Chlorine is a key element in tracing present and past interaction between magmas/rocks of the oceanic crust and seawater due to the large differences in concentration between magmas derived from the asthenosphere and seawater.

Processes, such as assimilation of hydrothermally altered oceanic crust by mid ocean ridge magmas, which lead to higher magmatic chlorine concentrations, have been demonstrated for fast spreading ridges [e.g. 1, 2]. Similar features have, up to present, not been observed at slow spreading ridges, partly because their intrinsically low chlorine contents made this work analytically challenging and variations in concentrations could not be explored with conventional methods.

To change this situation we have developed a new method to measure chlorine in basaltic glass by electron microprobe. Using a combination of mapping and standard-sample bracketing techniques, chlorine can be measured at very low detection limits (10's of ppm's) with a precision of 1-2 ppm standard deviation. With this, the very low chlorine concentrations in Mid Ocean Ridge Basalts from slow spreading ridges can be explored, and the new method enables us to reveal variations that could not be observed before.

We have used this method to examine a sample set of basaltic glasses from the Southern Mid Atlantic Ridge at 7-10 °S, for which large variations in depth of last equilibration with a mafic mineral assemblage have previously been shown [3]. We find chlorine concentrations which decrease from about 200 to 60 ppm with this crystallisation depth. However, several samples,have much higher chlorine contents which are independent of depth (>300 ppm).

The chlorine variations observed may have multiple causes: 1) hydrothermal interaction, related to the present spreading, and subsequent assimilation of altered crust, 2) alteration of the rocks at the seafloor, or 3) a mantle anomaly, which potentially can be related to melting processes and/or older interaction of the ocean with the magmatic system. With the aid of other trace elements the nature of the observed chlorine enrichment will be determined and a distinction between the causes made.

Polymict eucrite NWA 5232: composition of clasts

KATRINA VAN DRONGELEN[1,2*], KIM TAIT[1,2], MIKE GORTON[1], AND IAN NICKLIN[2]

[1]University of Toronto, Dept. of Geology, k.vandrongelen@geology.utoronto.ca (* presenting author)
[2]Royal Ontario Museum, Dept. of Natural History, ktait@rom.on.ca

Northwest Africa (NWA) 5232 is an 18.535 kg polymict eucrite, a member of the Howardite-Eucrite-Diogenite (HED) meteorite group, which are interpreted to come from the asteroid 4 Vesta [1]. NWA 5232 is comprised of four main constituents: eucrite (lithic) clasts, CM clasts, melt clasts, and matrix. A Petrographic microscope and JEOL JSM-6610LV scanning electron microscope at the University of Toronto were used to examine textures and mineral constituents of these phases. Clast sizes typically range from less than 0.5 mm to 3 cm and are variable in their distribution and angularity. The matrix is very fine- to coarse-grained, making up a significant proportion of this matrix-supported breccia. Various shock features were identified in the clasts and matrix, including bent pyroxene lamellae and pervasive fractures. The eucrite clasts show various textures, primarily subophitic, of varying coarseness and range in size from <0.5-30 mm, averaging 5 mm. Distinguishing basaltic and cumulate eucrite clasts on the basis of texture alone is problematic as both groups may be medium- to coarse-grained, have pyroxenes with exsolution lamellae, and consist of the same major mineral phases (pyroxene and plagioclase). Minor and accessory phases include SiO_2, ilmenite, chromite, Fe,Ni-metal, and troilite. A Horiba LabRAM Aramis confocal Raman spectrometer with SWIFT mapping stage at the Royal Ontario Museum was used to identify terrestrial weathering phases using the 532 nm laser. Pervasive fractures have been filled with calcite during terrestrial weathering.

Eucrite clasts were analyzed with a Cameca SX50 electron microprobe (EMP) with a 1 µm beam, an accelerating potential of 15 keV, and beam current of 15 nA at the University of Toronto. Eucrite clast pyroxenes have a Fe/Mn (afu) of 31.1 ± 2.3 n=329 (within the characteristic range of HED meteorites [2]) and of the 30 eucrite clasts analyzed with EMP, only one plotted on a pyroxene quadrilateral outside of the basaltic eucrite field as a cumulate eucrite [3]. Plagioclase compositions are within those expected for eucrites (An_{79-91}, avg $An_{87} \pm An_{1.8}$, and K (afu) = 0.003 ± 0.001 n=94) [3].

Two matrix samples and ten eucrite clasts were analyzed with INAA (Instrumental Neutron Activation Analysis) at the University of Toronto and generally show a ~5 x CI REE pattern with a LREE (La) depletion. The high $(Yb/La)_{CI}$ values (average 4.03 ± 1.24) may be due to dissolution of REE-rich phosphates during weathering [4]. The relatively high Co, Ni, and Ir contents of matrix samples (*e.g.* 27, 390, 0.032 ppm, respectively for a sample with mass of 229 mg) are consistent with the contribution of a chondritic component [4].

NWA 5232 is a polymict eucrite comprised of eucrite, CM, and melt clasts in a heterogenenous matrix. Lithic clasts are primarily basaltic eucrite clasts and no diogenite material was identified.

Beyond Henry's Law: Interpreting element signatures in oxide minerals at high concentrations

VINCENT VAN HINSBERG* AND BERNARD WOOD

Earth Sciences, University of Oxford, Oxford, United Kingdom, V.J.vanHinsberg@gmx.net (* presenting author), Bernie.Wood@earth.ox.ac.uk

The compositions of minerals are frequently used to estimate the compositions of the fluids and melts from which they formed. For major elements, concentrations in a coexisting melt or aqueous solution are readily estimated from mineral solubility data, and partition coefficients enable calculation of trace element contents. Intermediate concentrations are more difficult to constrain, however, because the impact of minor elements on solubility is commonly poorly known, and such concentrations exceed Henry's Law behaviour required for a partitioning approach. This is a problem, as this concentration range is of key interest, especially in ore formation, where it traces enrichment of the ore element. Moreover, knowledge of the changing element content in the fluid can reveal clues about the mechanisms of enrichment and ore formation.

Here, we experimentally explored the distribution of a suite of trace elements between mineral and melt at increasing concentrations of a dopant. We used perovskite ($CaTiO_3$) as our model mineral and doped with either La, Nd or Yb from 500 ppm to 5 wt%. The other REE + Mg,Sr,Ba,Li and Na were added at ~100 ppm to act as passive tracers of the impact of the dopant. Experiments were run in a 1 atm furnace, cooling a Ca-Ti-Si-O melt suspended from Pt wire from 1450°C to 1370°C at 1°C/hr, followed by 80hr equilibration.

Results show an abrupt change in REE distribution behaviour as a "Henrian limit" is encountered in agreement with earlier work [1]. Below this limit, a characteristic partition coefficient (D) describes the mineral-melt REE distribution, and the mineral concentration can be directly translated to a REE content in the melt. In contrast, above this limit, the REE distribution depends on the dopant concentration, and the REE content of the melt is strongly underestimated when using the Henrian D value. This change in behaviour is due to exhausting the inherently available vacancies in the perovskite structure. The change in REE behaviour is mirrored by the 1+ trace elements, which show an *increase* in D value with increasing dopant level beyond the "Henrian limit". We link this increased incorporation of the 1+ elements in perovskite to charge compensation for 3+ dopant uptake. In contrast, the 2+ trace elements can substitute isovalently, and, as therefore expected, are unaffected by increasing dopant concentration. Moreover, the systematics in element distribution among isovalent trace elements remain unchanged.

We conclude that mineral-fluid/mineral-melt distribution of elements at elevated concentrations differs strongly from that at low concentrations, even for elements that are at trace levels, which can lead to both under- and overestimation of fluid concentrations. However, the systematics among an isovalent suite of elements, such as the REE, are preserved and minerals therefore remain an accurate tracer of the REE pattern of their host fluid.

Type Section Heading Here [bold, 9pt font size]

X-ray absorption near-edge structure (XANES) spectroscopy provides new interpretations of Ni speciation in sulfidic Ni processing, particularly with respect to soluble Ni in workplace aerosol samples collected at the Copper Cliff nickel smelter and refinery. Typically, Ni speciation is identified using a sequential extraction developed by the Ni industry for determining workplace exposures. However, as this technique and its variants become more widely applied, there is evidence that the method may not always accurately report soluble and metallic Ni. Because of the importance of exposure reconstruction to the determination of carcinogenicity classification of Ni compounds, we have begun to evaluate alternative speciation methodologies for Ni. Here we present the results of a study comparing Ni speciation results obtained using XANES spectroscopy and sequential extraction along with complementary SEM, EDX, and XRD results.

Biomineralization can be used as ground improvement method, for a wide range of geo-engineering applications, like mitigation of liquefaction and associated damage, improving the stability of dikes, dams, levees and slopes, reducing the permeability of underground leaking structures or stopping or diverting subsurface transport of contaminants by forming impermeable or reactive barriers. Most studies on applied biomineralization involve the precipitation of calcium carbonate, in particular by urea hydrolysis. In this process urea hydrolyzing bacteria are introduced in the subsurface and supplied with urea and calcium chloride. By hydrolyzing urea, the bacteria produce ammonium and carbonate. The carbonate precipitates with calcium carbonate and remaining ammonium chloride is removed. The calcium carbonate crystals form a binding cement between the soil particles while (partly) filling up the pore space, which increases the strength and stiffness of the soil and reduces the permeability. Using an empirical approach the feasibility of MICP by urea hydrolysis as ground improvement method has been demonstrated at full scale using conditions and techniques as used in practice, both as single point injection or over a horizontal distance using screens of injection and extraction wells. Engineering parameters correlated well with $CaCO_3$ content or dry density [1]. At the same time, a more fundamental approach was used to improve our understanding of the MICP process that involved multiple components including bacteria and multiple chemical species that are subject to both kinetically controlled and equilibrium reactions over multiple phases, undergoing transport in porous medium with changing porosity and permeability. Understanding of these processes was required to enable control of the *in situ* distribution of bacterial activity and reagents and the resulting distribution of $CaCO_3$ and related engineering properties. The combined approach of theory, experiments, modeling and monitoring has resulted in the first field applications in which biomineralization was used to cement gravel layers in order to improve borehole stability during horizontal directional drilling [2].

$^{40}Ar/^{39}Ar$ cooling dates and deformation history on the southern flank of the Thor-Odin dome BC: tectonic implications of overlapping compressional and extensional regimes in the Paleocene-Eocene.

D. VAN ROOYEN[1]* AND S.D. CARR[1]

[1] Ottawa-Carleton Geoscience Centre, Dept. of Earth Sciences, Carleton University, Ottawa, ON, Canada K1S 5B6 (*dvrooyen@connect.carleton.ca)

The southern flank of the Thor-Odin dome comprises an ~12 km thick S-dipping panel of amphibolite to granulite facies rocks, the lower half of which is migmatitic. Throughout the structural section the rocks have a pervasive composite transposition foliation, with rootless folds, folded by syn- and refolded by post-metamorphic NE verging folds. Metamorphism and the youngest stages of ductile deformation are Late Cretaceous to Eocene and young progressively down section. On the basis of cross cutting granitoids dated by U-Pb studies, transposition and folding had ceased by: (i) 73 Ma at the highest structural levels (e.g. in the southern part of the study area near Whatshan Lake and west of the dome at Joss Mountain); (ii) 64 – 62 Ma (in the central section west of Arrow Park lake); (iii) ~58 Ma on the upper margin of the dome at Cariboo Alp; and, (iv) ~56 – 54 Ma within the dome. Cooling from the thermal peak of metamorphism to ~300°C occurred between 62 and 52 Ma on the basis of $^{40}Ar/^{39}Ar$ cooling dates. Thor-Odin dome and its southern flank lie in the footwall of the ~55 Ma and younger, E-dipping Columbia River normal fault. Proposed models for the exhumation of the dome and overlying rocks on the southern flank include extension, extrusion or diapirism (with an erosional contribution).

$^{40}Ar/^{39}Ar$ cooling dates on hornblende, muscovite and biotite from 80 samples at all structural levels were studied in order to place constraints on the timing of the exhumation over a temperature range of ~600 to 300°C. Hornblende $^{40}Ar/^{39}Ar$ cooling dates (calculated closure temperatures from 500 - 600°C) are ~62-58 Ma at the top of the panel, ~57-56 Ma in the middle, and ~55-53 Ma near the upper margin of the dome. Hornblende $^{40}Ar/^{39}Ar$ data from migmatites in the dome are disturbed and do not produce meaningful dates. Biotite cooling dates (280 - 350°C) are ~52-51 Ma throughout the 12 km thick structural section, including the dome. Since rocks from all different structural levels cooled through ~300°C at the same time the structural section was tilted prior to cooling or cooling rates were extraordinarily high. 51-50.5 ± 0.2 Ma muscovite dates from greenschist-facies muscovite intergrowths in extensional structures in the dome, grew below their closure temperature and date late stage extension.

The downward younging progression of deformation and the thermal history are consistent with that of a highly strained crystalline sheet that was deforming progressively as it overrode a basement ramp, the Monashee ramp imaged in Lithoprobe seismic reflection profiles 6, 7 and 8. Exhumation and cooling as a result of syn-convergent extension in the upper part of the structural section was ongoing during the last stages of transposition and folding in the dome in the Late Paleocene to Early Eocene. By ~51 Ma, extensional structures were active at all structural levels reflecting crustal scale extension and exhumation via normal faulting linked to continuing motion on the Columbia River and possibly the Okanagan Valley extensional fault systems.

[4]Institut für Metallurgie, TU Clausthal, Germany

The lunar magma ocean (LMO) model [1,2] remains the starting point for most models of early lunar differentiation. Petrologists have studied LMO crystallisation sequences [3,4], and numerical thermochemical convection models have been developed to study the evolution of layered cumulate piles formed during MO crystallisation [5-7]. These models generally take into account changes during differentiation in major element composition and density of the minerals involved.

Here, we give an overview of our recent progress on combining mineral and melt density measurements [8-10], experimental studies of the distribution of trace elements during and after LMO crystallisation, and numerical models of lunar interior thermal evolution. Recent experimentally determined mineral-melt partitioning data [11,12] show that the interior distribution of the main heat-producing elements K, U and Th is highly heterogeneous in the aftermath of LMO crystallisation and differentiation. This has significant effects on the thermal evolution of the lunar interior after solidification - effects that are missed if partitioning of heat-producing elements is ignored.

In the Moon, K, U and Th are concentrated in late-crystallising, dense ilmenite/cpx-rich cumulates. Thermochemical convection models show that sinking of these cumulates towards the lunar core, and increased levels of heat production associated with their trace element chemistry lead to (a) the formation of a thermal blanket on the core which could play a role in the recently proposed extreme longevity of lunar dynamo activity [13] (b) prolonged interior mantle dynamics consistent with the young ages of some surface lava flows derived from crater density analysis [14]. These results illustrate the value of combining experimental and numerical approaches to planetary interior evolution.

Isotopic tracers of metal cycling in the oceans and sediments

D. VANCE[1*], S.H. LITTLE[1], V. CAMERON[1], D. M. SHERMAN[1], S. WESTERMANN[1], A. MATTHEWS[2] AND T.W. LYONS[3]

[1]School of Earth Sciences, University of Bristol, Bristol, UK, d.vance@bristol.ac.uk (* presenting author)

[3]Department of Earth Sciences, University of California, Riverside, USA, timothy.lyons@ucr.edu

The emerging isotopic systems of the transition metals potentially have much to tell us about sources of metals to the oceans, their biogeochemical cycling within the oceans, and the nature of the output processes to sediment. With respect to the latter, it has been the redox-sensitivity of the outputs, and the variability of the isotopic fractionations involved in different output pathways, that has attracted most attention. For example, the isotopic composition of Mo in marine sediments has already been used as a monitor of ancient water-column redox conditions. Here, we introduce the isotopic systems of other transition metals (Cu, Zn, Ni), systems that are much less developed, and assess their potential for providing complementary paleoceanographic information to Mo.

Isotopic data for seawater and Fe-Mn crusts reveal that the light isotope of Cu, as with Mo, is preferentially removed from the seawater solution under fully oxic conditions. In contrast, Zn isotopic compositions of Fe-Mn crusts are heavier than Zn in the dissolved phase in the deep ocean, by about 0.5 ‰ for $^{66}Zn/^{64}Zn$. Sorption experiments for Cu to Mn oxide reproduce the sense of the natural fractionation, but the magnitude of the latter is slightly greater than in the experiments. For Zn, by contrast, the fractionation seen in the Mn oxide experiments is opposite to that in nature. This could be due to complexing of Zn in the natural seawater solution, or to the superimposition of other biological effects on Zn isotopes in the oceans.

In contrast to the oxic output discussed above, and in a developing picture that looks qualitatively very similar to Mo, it appears that both Cu and Zn undergo little or no isotopic fractionation as a result of removal from seawater solution under anoxic conditions. For example, in the most euxinic sediments from the Black Sea and Cariaco Basin, enrichments of Cu and Zn are associated with isotopic compositions that are identical to (Zn) or likely very close to (Cu) the local deep ocean.

We are at an earlier stage in the development of Ni isotopes. It is clear that seawater is homogeneous at $\delta^{60/58}Ni_{SRM986}$ = 1.44±0.1 ‰. In common with both Cu and Mo this is distinctly heavier than the riverine input (at about 0.8 ‰ based on the discharge-weighted mean of 7 large and small rivers), while rivers themselves, again in common with Cu and Mo, are heavier than rocks (0.1-0.2 ‰). These observations imply fractionation of Ni isotopes in both the weathering and marine environment. In the case of Ni it appears that it is not the oxic sink that removes the light isotope to push seawater to heavy values, as analyses of Fe-Mn crusts suggest that they are significantly heavier than seawater at 1.7-1.9 ‰.

Zinc isotopic data from the NE Pacific reveals shallow recycling

D. VANCE[1*], YE ZHAO[1], J. CULLEN[2], AND M. LOHAN[3]

[1]School of Earth Sciences, University of Bristol, Bristol, UK, d.vance@bristol.ac.uk (* presenting author), y.zhao@bristol.ac.uk

[2]School of Earth and Ocean Sciences, University of Victoria, Victoria, Canada, jcullen@uvic.ca

[3]School of Geography, Earth and Environmental Sciences, University of Plymouth, Plymouth, UK, maeve.lohan@plymouth.ac.uk

Isotopic data for biologically-active trace metals can elcuidate their sources to seawater and their biogeochemical cycling within the oceans. Here we present new dissolved-phase Zn concentration and isotopic data for depth profiles along a transect (Line P, around 50°N) from the North American continental margin to the open ocean in the NE Pacific, with 10-25m depth resolution in the upper 100m of the water column.

Zn concentrations increase with depth, with surface or near-surface concentrations as low as 0.05 nM and concentrations at 2000m at 10-11 nM. There are two distinct differences between the new dataset and the only previous study of Zn in the NE Pacific of similar geographical scope [1]. Firstly, concentrations at 10m depth increase gradually from 0.09 nM at the marginal station to 0.65 nM at the open ocean station, a reversal of findings for samples collected in 1999, and showing a closer coupling to Si. Secondly, at some stations the shallow sub-surface (at 50-100m at the marginal station) is characterised by a distinct bulge in the concentration depth profile.

The isotopic data for the deep ocean, for Zn concentrations ≥ about 7 nM (beneath 200-600m, depending on the station), are very homogeneous, with $\delta^{66}Zn_{Lyons\text{-}JMC}$ = 0.52±0.10 ‰ (2 SD, n = 15). The upper ocean is much more variable. Firstly, the immediate sub-surface (50-100m at the marginal station) is characterised by distinctly light Zn isotopic compositions, down to $\delta^{66}Zn$ = -0.4 ‰. This feature persists along the transect but the depth range over which this light isotope value is found shallows oceanwards. Above the thin isotopically light layer, the surface ocean has heavier isotopic compositions at very low Zn concenttrations, by 0.5-0.8 ‰ and with the shift occuring over a depth range of 10m or less.

The three features described above – a homogeneous deep ocean, an isotopically light layer in the immediate sub-surface, and a return to variably heavy values in the photic zone – are proving to be common to Zn isotope depth profiles in the ocean in a small but building database. But they are particularly clear in the NE Pacific, perhaps partly because of a highly-stratified water column. Moreover, only here is the sub-surface isotopic feature associated with recognisable features in the concentration profile. The new isotopic data shed light on the biogeochemical cycling of Zn in the upper ocean that are not readily apparent from concentration data alone. In particular, the anomalously light isotopic compositions are most likely to be explained by the very shallow recyling of a pool of light Zn sequestered into phytoplankton cells [2] in the photic zone.

Evaluating Changes in Sources and Pathways of Trace Metals Over Time Using Lake Sediment

VANNIER, RYAN G.[1*], LONG, DAVID T.[1], ROBINSON, AMANDA M.[1], YOHN, SHARON, S.[2]

[1]Michigan State University, East Lansing, MI, USA, milakes@msu.edu (* presenting author)

Abstract

Environmental regulation has reduced the loadings of metals to the environment since the advent of the Clean Air and Water Acts in the 1970's. Reducing emissions may have changed transport pathways since this legislation targeted major sources of metals which influenced the environment on a regional scale. Watershed-scale processes may now provide the significant contribution to metals loadings. Thus, our working hypothesis is that the reduction of major emission sources has allowed local influences and watershed features to affect metal transport pathways. If true then there should be differences in watershed attributes/influences (e.g., %urban, population density) changed the pathways of metals transport of these metals. In this study we examine Pb, Cu, Zn, and Ni because these metals 1) build from previous studies, 2) exhibit similar environmental behaviour but separate pathways, 3) represent various degrees of contaminant enrichment. To test this hypothesis, sediment accumulation rates of these metals at decadal intervals were compared to selected watershed attributes. Sediment cores were collected from the deepest portion of 35 inland lakes representing diverse land uses. Cores were sectioned; microwave digested, and analyzed using mass spectrometry. Sedimentation rates, ages and sediment focusing were determined via 210Pb/137Cs/stable Pb profile analysis. Similar to the previous work, the data show regional sources of the metals studied to subside upon introduction of environmental legislation in the 1970's. However, watershed-scale sources provide a more significant portion contaminant loading in nearly all lakes studied, preventing lakes from reacquisition of reference condition values. When compared to landscape attributes, these patterns provide some insights into the causes for the continued contaminant loading. Population density and percent urban provide excellent predictors for recent metals loadings. Lead also showed excellent correlation with slope percent. Unexpectedly all metals showed a change in watershed attributes influencing accumulation rates between the two decades, even though some have not had a significant atmospheric transport pathway or contaminant loading. The reasons for this are subject to further study.

Introduction and Project Goals

Numerous chemicals containing cationic amine functional groups, such as antibiotics, herbicides, and antidepressant drugs, have been detected in surface and ground waters, and some of these pose risks to humans and ecosystems. Understanding and predicting the extent of sorption under a wide range of environmental conditions is key to anticipating potential contamination of groundwater by these chemicals. Cation exchange, the primary mechanism for cationic amine sorption has been well studied. However, there is a lack of knowledge about potential secondary mechanisms of sorption that may result in non-linear sorption isotherms and about the soil characteristics that may facilitate secondary, intermolecular interactions between amines sorbed to the surface and adjacent amines in solution. By examining the sorption of a series of model compounds that represent important sub-structures of antibiotics and pesticides, this study addresses three significant gaps in current understanding of cationic amine fate: (i) the influence of compound structural criteria on amine cation sorption, (ii) secondary interactions mechanisms that contribute to non-linearity in sorption phenomena, and (iii) effect of soil properties on sorption linearity and non-linearity.

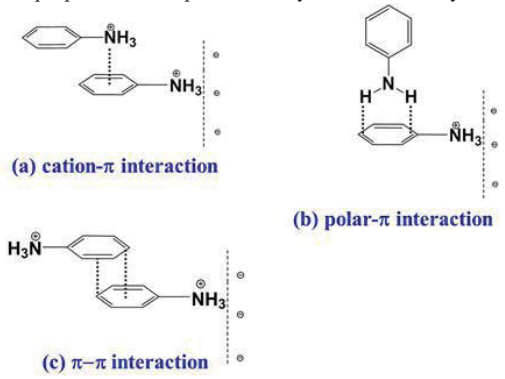

Figure 1: Hypothesized intermolecular interactions contributing to sorption isotherm non-linearities.

Results and Conclusions

On evaluating the sorption of several substituted anilines, benzylamines and cyclohexane methyl amine to Ca- and Na-montmorillonite, we established that the primary sorption mechanism, cation exchange, is influenced by the charge density on the amine moiety and compound hydrophobicity. In addition, we found that the presence of a π system, orientation of the molecule on the surface, and electron density at the center of the aromatic ring influenced the extent of intermolecular interaction between a sorbed amine and an adjacent amine. Furthermore, on evaluating cation amine sorption to a wide range of soils, we established that soils with higher density and closer proximity of negatively charged sites (i.e., soils with high cation exchange capacities) may facilitate secondary intermolecular π interactions.

Evolution of the Strange Lake pluton: Insights from melt and fluid inclusions

O.VASYUKOVA* AND A.E.WILLIAMS-JONES

Department of Earth and Planetary Sciences, McGill University, Montreal, QC, H3A 2A7, Canada, olga.vasyukova@mcgill.ca

The Mid-Proterozoic Strange Lake pluton (Québec-Labrador, Canada) hosts economic rare earth element (REE) and high field strength element (HFSE) mineralization. The richest zones are confined to the most altered areas within subsolvus granite and associated pegmatites. The main HFSE mineral, the zirconosilicate, gittinsite, is commonly accompanied by armstrongite, kainosite-(Y), bastnäsite, gagarinite-(Y), monazite, pyrochlore and gadolinite.

Previous data on fluid inclusions from quartz pseudomorphs after elpidite and narsarsukite, quartz veins and pegmatitic quartz [1] revealed the importance of late Ca-metasomatism for the REE/HFSE mineralization of the Strange Lake pluton. Two fluids were found to contribute to the mineralization, a high salinity magmatic aqueous liquid containing a reduced carbonic component [2], and a Ca-rich meteoric fluid. Fluid mixing caused oversaturation of the fluid with fluorite and its precipitation, which triggered precipitation of Zr, Y and REE minerals as a result of decreased ligand concentration.

This study reports the results of observations of fluid and melt inclusions characterising progressive stages of the melt-to-fluid evolution. Quartz phenocrysts contain melt inclusions trapped during the very early stage of formation of the Strange Lake granites and pegmatites. A later population of magmatic quartz hosts melt inclusions representing more evolved magmas. Early fluorite included in late magmatic quartz and late arfvedsonite contains two types of inclusions, devitrified melt inclusions and NaCl-and possibly $FeCl_2$-rich fluid inclusions. This association presents evidence of the timing of exsolution of fluid from the magma. The next stage of melt-to-fluid evolution is preserved in quartz from miarolitic cavities, which contains abundant aqueous inclusions of variable salinity. The final stage of hydrothermal activity, which is associated with REE/HFSE mineralization, involved Ca-rich aqueous fluids, which were trapped as primary fluid inclusions in late hydrothermal fluorite and secondary inclusions in pegmatitic quartz.

The study of melt and fluid inclusions is permitting reconstruction of the melt-to-fluid evolution of the Strange Lake pluton from the very earliest magmatic stage to the latest stage of mineralization, thereby providing a deeper understanding of the REE/HFSE mineralizing processes at Strange Lake.

The Quebec government has recently launched an ambitious program to quantify the Province's groundwater resources. In this framework, a multi-isotopic study involving noble gases, U and stable isotopes and major elements was initiated in the Bécancour River catchment basin, Central Québec, with the goal of dating groundwater and identifying flow paths. This basin is particularly interesting because this same area is a target for shale gas exploitation. This basin extends from the Appalachian Mts. down to the St. Lawrence River. Unconfined and partially confined sandy aquifers of Holocene age (Champlain sea) are mainly recharged in the mountains but also receive some local recharge in the plain.

A preliminary survey using noble gases along with stable and U isotopes was carried out along two transects, one parallel to the main flow direction, the second perpendicular to it. A plot of $^{20}Ne/^{4}He$ vs. $^{3}He/^{4}He$ ratios clearly points to the occurrence of three water bodies with distinct helium isotopic signatures.

Modern waters from shallow wells (5-7 m depth) show nearly atmospheric He and Ne concentrations ($^{20}Ne/^{4}He$ = 3.5) as well as $^{3}He/^{4}He$ ratios close to 1.1 Ra, where Ra is the atmospheric $^{3}He/^{4}He$ ratio. These waters are extremely young, with ages ≤10 years. Groundwater localized in the north-eastern border of the basin shows tritiogenic ^{3}He excesses up to $1.80x10^{-13}$ ccSTP/g. Using the Ottawa tritium decay curve from IAEA, which is valid for central Québec [1] and measured ^{3}He content in groundwater, leads to a first-order estimation age of ~19-21 yrs old.

The third water body contains large amounts of radiogenic ^{4}He, up to $4.48x10^{-5}$ ccSTP/g. These amounts are three orders of magnitude higher than the atmospheric background. A simple *in situ* U-Th-^{4}He age model [2] yields ages varying between 2 and 22 Ma, an age range that is older than the age of the aquifers themselves. The well with the highest ^{4}He content is located in the proximity of the recharge area and U and stable isotopes as well as major elements suggest freshly recharged water. A possible mechanism for water ageing is related to vertical transport of radiogenic ^{4}He by: (1) a diffusive crustal basal flux; (2) upward advection of ^{4}He-rich fossil brines from the basement through fault pathways; or (3) upward degassing of methane from the Utica shales carrying ^{4}He.

[4]Environmental Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN USA, brookssc@ornl.gov

Soils and sediments, where mercury (Hg) can exist as Hg sulfide minerals (HgS), represent major reservoirs of Hg in aquatic environments. Due to their low solubility, primary and authigenic HgS (eg. cinnabar and metacinnabar) have historically been considered insignificant sources of soluble Hg(II) to the environment. Recently however, HgS solubility was shown to be greatly enhanced in the presence of a natural microbial consortium [1]. Mechanisms for this enhanced solubility have yet to be assessed. Further, bacteria capable of colonizing HgS surfaces in the environment have not been identified, yet their association with the mineral makes them likely key players in effecting chemical changes that can impact dissolution.

To this end, we assessed the microbial diversity on HgS surfaces in the Hg-contaminated sediments of the East Fork Poplar Creek (EFPC) in Oak Ridge, TN and examined the effect of these communities on HgS solubility. Mineral sections of metacinnabar, the dominant Hg species in EFPC sediments, were incubated 4 cm below the sediment surface in the creek channel and bank. Cinnabar and other metal sulfides were also incubated to distinguish mineral structure and host metal effects on the colonizing community.

Bacterial community composition and diversity were determined after 6 weeks of incubation via pyrosequencing targeting the 16S rRNA. Metacinnabar colonization was dominated by sulfur-oxidizing bacteria. Specifically, members of the genus *Thiobacillus*, *Sulfuricurvum* and *Sulfuricella* were among the most abundant community members. Members of these genera are known to use reduced sulfur compounds as electron donors during growth.

Following field incubation, oxidation rinds were observed on metacinnabar. Synchrotron-based X-ray microprobe mapping and X-ray absorption spectroscopy reveal the incubated metacinnabar interior contained pyrite inclusions, and the rind was enriched in Fe(III). Oxidation was not observed on cinnabar where, interestingly, sulfur-oxidizing bacteria were not dominant community members.

Microbial enrichments obtained from field-incubated sulfides were incubated in the presence of HgS in the lab. Both metacinnabar and cinnabar solubility were significantly enhanced in the presence of these consortia. The extent, rate, and mechanisms of HgS dissolution by the consortia and, in particular, sulfur-oxidizing bacteria are currently under investigation. The results from this study may have important implications on the role of microbial communities in the dissolution of HgS phases and hence Hg mobility in the environment.

Abiotic U(VI) reduction by biogenic mackinawite

HARISH VEERAMANI[1*], NIKOLLA P QAFOKU[2], RAVI KUKKADAPU[2], AMY PRUDEN[1], MITSUHIRO MURAYAMA[1], NIVEN MONSEGUE[1] AND MICHAEL F HOCHELLA JR[1,2]

[2] Pacific Northwest National Laboratory (PNNL), USA

Biostimulation of dissimilatory metal and/or sulfate reducing bacteria (DMRB and DSRB) has been extensively researched as a remediation strategy for mitigating subsurface uranium [U(VI)] contamination. These bacteria derive energy by reducing oxidized metals as terminal electron acceptors by utilizing organic substrates as electron donors. Iron [Fe(III)], an abundant subsurface element, represents a substantial sink for electrons from DMRB, and the reduction of Fe(III) leads to the presence of dissolved Fe(II) and/or reactive biogenic Fe(II)- and mixed Fe(II)/Fe(III)- mineral phases. Likewise, reduction of other electron acceptors such as sulfates by DSRB leads to the formation of sulfide-bearing minerals in subsurface environments. Thus, when evaluating the potential for *in-situ* uranium remediation in heterogeneous subsurface media, it is important to understand how the presence of alternative electron acceptors such as Fe(III) and sulfate affect U(VI) remediation and the long term behavior and reactivity of reduced uranium. Consequently, abiotic U(VI) reduction by reactive forms of biogenic Fe(II) and sulfide-bearing minerals will be a potentially important process for uranium immobilization.

In this study, amendment of Fe(III) and sulfate to a culture of *Shewanella putrefaciens* CN32 (DMRB) bacterium, resulted in the production of biogenic mackinawite, a Fe(II)-bearing sulfide mineral. This biogenic mineral was systematically characterized by X-ray powder diffraction (XRD), electron microscopy (SEM, TEM, HRTEM) and Mössbauer spectroscopy. Batch experiments involving biogenic mackinawite and U(VI) were carried out at room temperature under strict anoxic conditions. Following complete reduction of uranium (determined by ICP analysis), the biogenic mackinawite was analyzed by a suite of analytical techniques including X-ray absorption spectroscopy (XAS), SEM, HRTEM and Mössbauer spectroscopy to determine the speciation of uranium and concomitant phase transformation(s) with respect to mackinawite. SEM and selected area electon diffraction (SAED) analyses showed reduction of U(VI) to nanoparticulate UO_2 on the surface of biogenic mackinawite. These findings are consistent with XANES analysis that indicate reduction of U(VI) to U(IV) and μXRF analysis that was used to map iron and uranium in the sample. Determining the speciation of uranium is critical to success of a remediation strategy. The present work elucidates abiotic molecular scale redox interactions between biogenic mackinawite and uranium.

Extreme microbial sulfur isotope fractionation in a Mars analogue environment at Rio Tinto, SW Spain

Sulfur isotopes are likely to be a key tool for the detection of past or present life on Mars, where abundandt sulfate minerals are present. To investigate the link between the activity of sulfate reducing microortanisms and sulfur isotope fractionation, we incubated sediments from a modern hyper-acidic, Fe-rich subareal environment at Rio Tinto, SW Spain.This site has frequently been used as a geochemical anologue of Mars.

Sediments were sampled from the upper part of the Rio Tinto (Marismilla) as well as the estuary (Moguer). Laboratory incubation were carried out at 30° C using an artificial input solution with sulfate in excess and following techniques developed by Stam et al. [1]. The experiments were performed with an input solution at pH 7 and pH 3 and electron donors were provided by the natural substrate. Duplicate reactors were incubated for a total of 10 weeks. Initial data indicate moderate sulfate reduction rates of between 5 and 90 nmol cm^{-3} h^{-1} in Marismilla and between 5 and 45 nmol cm^{-3} h^{-1} in Moguer, independently of the inflow solution pH. Outflow solutions showed pH close to 7, regardless of inflow pH of 3 or 7, suggesting buffering within the sediments. Sulfur isotope fractionation was extreme in the Moguer estuary, extending beyond the maximun of 47‰ as predicted by the starndard Rees model [2] of microbial sulfur isotope fractionation, suggesting that additional fractionation is possible [3] or indicating multiple cycles of reduction and oxidation of sulfate within the reactors. These data indicate that sulfur isotopes may have a potential to be sensitive indicators of biotic activity on Martian sulfate minerals.

Potential impacts to ecosystem health and water quality from Marcellus Shale drilling

DAVID J. VELINSKY*, PAULA ZELANKO, FRANK ANDERSON, RICHARD J. HORWITZ, AND JERRY V. MEAD

Academy of Natual Sciences of Drexel University, Patrick Center for Environmental Research, Philadelphia, USA (* presenting author) velinsky@ansp.org

Pilot Study

As drilling for natural gas in the Marcellus Shale increases, so do the concerns for the welfare of the surrounding environment. In a July 2010 pilot study, biological and chemical indicators were used to assess the potential effects of gas extraction on streams in north eastern Pennsylvania. Sites ranged from streams draining areas with high well density and known violations to sites with no wells. Density of natural gas wells within a watershed was the main test variable (gradients in potential covariates such as land cover were controlled for). Stream health indicators were regressed against well density to determine possible impacts. Several stream health indicators had significant ($p<0.10$) negative (macroinvertebrates family, Shannon-Wiener diversity index of macroinvertebrates) or positive (water conductivity) correlations with well density. Multiple t-tests among groups of sites with high, low and no wells found that the correlations resulted from differences between sites with high well density and those with low density or no wells. Significant differences were not found between low density and reference sites.

Figure 1: Field team taking stream measurements (left), collecting benthic samples (middle), and collecting water (right).

Expanded Study

During summer and fall of 2011, 60 sites with varying well densities were sampled for water quality analysis. Wastewaters produced from drilling activities in the same region were also tested to identify a "produced water" signature. This signature, consisting of a particular combination of cations and anions, are being compared to samples from the 60 sites. Preliminary data, plotted as Stiff diagrams, suggests three sites have a produced water fingerprint. Two sites had documented spills, while the third site had the highest well pad density. In addition, concentrations of chloride ions increased with well density.

Future Research

Biota samples were also collected at 30 of the water quality sites. As in the pilot study, stream health analysis will be applied to this data in the near future. In 2012, previous sampling sites will be re-visited and new sites added for water quality and biota sample collection. Time transgressive sampling will provide additional information on the potential impacts of Marcellus drilling activities throughout the region.

High resolution aerosol sources and anthropogenic impacts in Central Europe during the Holocene

ALAIN VÉRON[1*], MARTIN NOVAK[2], EVA BRIZOVA[2] AND GAËL LE ROUX[3]

[1]CEREGE, CNRS UMR7330, University Aix-Marseille, Aix en Provence, France, veron@cerege.fr (* presenting author)
[2]Czech Geological Survey, Prague, Czech Rep., martin.novak@geology.cz, eva.brizova@geology.cz
[3]Ecolab, CNRS-University of Toulouse, Castenet Tolosan, France, gael.leroux@ensat.fr

Aerosol transport and deposition is a well-known indicator to assess environmental impacts due to climate changes (erosion, droughts…) and/or human activities (deforestation, quarries, mining…). In particular, sudden climate shifts have become a key issue to develop and test models dealing with recent and forthcoming climate change. Meanwhile, transient and rapid environmental fluctuations in landlocked continental regions cannot be resolved by means of the sole remote ice and marine (generally poorly discriminated at the scale of the Holocene) cores. Because ombrotrophic peatlands are fed by atmospheric deposition only they can archive a full suite of proxies (such as dust, pollens, carbon, trace elements including metals) to resolve climate uncertainties at a high temporal resolution during the Holocene [1]. They also uniquely trace human activities and its environmental effects [2].

Here we present proxy's imprints recorded from a 13,000 years old peat bog collected in Central Europe (Czech Rep.). The well-known Younger Dryas cold interval is clearly characterized with increased dust fluxes at 11.5-12.7 ky BP, a period that compares well to other continental records of this event. Another significant dust episode is identified at 9.3-8.8 ky BP while the marine 8.2 ky BP circum North Atlantic event is not detected. Other major multi-century dust episodes are recorded at 6.0 ky and 3.3-2.9 ky BP that fit cold events from Greenland ice cores and German tree rings. Pollen records are consistent with these findings and show the transition from Late Glacial to Boreal and Atlantic climate zones. In order to verify aerosol sources during these events and to better define successive identified dust peaks we have measured stable Pb isotope ratios that are key markers for the diversity of aerosol sources. We could clearly differentiate aerosol from various regions including the Gobi and Saharan deserts, the Chinese loess, the Scandinavia shield, and the local Czech Bohemian bedrock.

Pb enrichment and specific isotopic ratios could also indicate a long-range transport of pollutant Pb from the Mediterranean regions as early as 5.2 ky BP. This invasion of warmer Mediterranean airflows could explain the advent of warm deciduous species (hazel, elm, oaks) in our peat as also observed in German mires during the same climatic optimum. Mixed imprints of local bedrock and Bohemian ores are observed between 4.4 and 1.7 ky BP that demonstrate well-established regional mining activities.

Ore origin of Middle-Bronze Age copper artefacts from Sidon

ALAIN VÉRON[1*], GAËL LE ROUX[2], DAVID BAQUÉ[2], ANDRÉ POIRIER[3] AND CLAUDE DOUMET-SERHAL[4]

[1]CEREGE, CNRS UMR7330, University Aix-Marseille, Aix en Provence, France, veron@cerege.fr (* presenting author)
[2]Eco-Lab, ENSAT, Toulouse, France, gael.leroux@ensat.fr
[3] GEOTOP-UQAM, Science de la terre et de l'atmopshère, Earth and Planetary Sciences, Montreal, Canada, poirier.andre@uqam.ca
[4]British Museum, University College, London, England, claude.lbfnm@binternet.com

Over one hundred burials dating from the Middle Bronze Age (2000-1550BC) have been excavated in Sidon since 1998 under the direction of The British Museum and the Department of Antiquities [1]. These excavations led to the discovery of copper (Cu) artefacts (named "bronzes" according to the regional archaeological terminology) that could provide unique indication on the origin of metal used to manufacture them, and therefore help elucidate trade relations between the Levantine coast and the rest of the Mediterranean. These artefacts included weapons (daggers, knife, arrow head, spear head), jewels (torque, belt) and some miscellaneous (pin, fish hook). Our goal was to determine the geographic origin of the mines from which Cu were extracted by means of stable lead (Pb) isotopes that are efficient tracers of Cu, Pb and Ag ore sources [2] [3].

Lead isotope ratios from twenty-eight Bronzes were compared to well-known antique Cu and Pb ore body isotope signatures from Crete, Greece, Turkey, Oman, Sardinia, Spain, Italy, Cyprus, Egypt, Southern Levant, Iran-Iraq and Syria. Both Cu and Pb ore imprints from the same geographic area generally overlap except in the Taurus region and Egypt. The three most common possible geological origins for these bronzes were located in Cyprus, Crete, and, more unexpectedly, in the Cu rich Oman Gulf region. Only one artifact could be related to the abundant Southern Levant Cu mines in spite of its geographic proximity to Sidon and none to Egypt or any other location in the Western Mediterranean basin. Silver (Ag) artifacts from two burials were attributed to Turkish sources. No clear pattern between provenances, as determined by Pb isotopes, burial's chronologies and objects could be established. Trace element analyses were used to resolve source uncertainties associated with mixed/recycled ores and corrosion.

This archeometric approach confirmed archaeological findings about possible networks bewteen the Aegean, Cyprus, Turkey and Sidon more than three thousands years ago. The Gulf of Oman is less likely reliable as a trade partner, but could not be denied on the basis of Pb analyses only.

Earthworm secreted calcium carbonate – a new palaeothermometer?

EMMA A. A. VERSTEEGH[1*], MARK E. HODSON[1] AND STUART BLACK[2]

[1]University of Reading, Soil Research Centre, Reading, UK, e.a.versteegh@reading.ac.uk (* presenting author), m.e.hodson@reading.ac.uk
[2]University of Reading, Scientific Archaeology, Reading, UK, s.black@reading.ac.uk

Oxygen and carbon isotope ratios of calcium carbonate skeletons, produced by a range of aquatic and terrestrial organisms, have often been found to be useful proxies for environmental variability [1]. Although they do not form skeletons, many earthworm species are true biomineralisers, secreting granules of intricately zoned calcite [2]. These granules are frequently found in archaeological finds and buried soils. We are currently investigating the utility of stable isotope compositions of earthworm secreted calcite granules for reconstructing past environments.

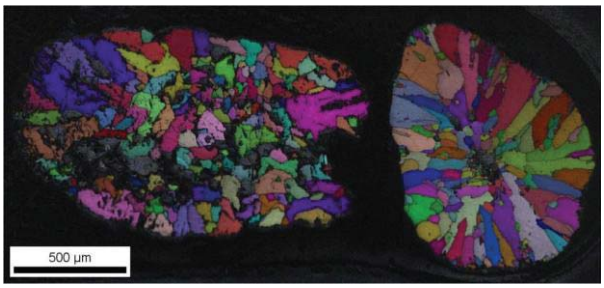

Figure 1: Electron Backscatter Diffraction (EBSD) orientation contrast maps of two Pleistocene earthworm granules highlighting their polycrystalline microstructure. Image by Martin Lee, School of Geographical and Earth Sciences, University of Glasgow.

Experiments were designed in which individual earthworms (*Lumbricus terrestris*) were kept in bags of soil for up to four months. Two different types of soil (C3 and C4 vegetation) were used, which were air-dried and then moistened with three isotopically different types of mineral water. The experiment was performed at three different temperatures. $\delta^{13}C$ and $\delta^{18}O$ values were measured for the soil organic matter, soil pore water, food (manure), soil air, earthworm tissues and $CaCO_3$ granules. Preliminary results show that the $\delta^{18}O$ values of the granules accurately reflect those of the pore water, in a similar way as for inorganically precipitated calcite. $\delta^{13}C$ values appear to reflect those of food offered to the earthworms.

In combination with U/Th dating, the stable isotope composition of earthworm secreted calcite granules can likely help in the reconstruction of past temperatures, vegetation and soil organic matter composition. As such it provides a much needed new terrestrial proxy for the reconstruction of past environments in archaeological and geological contexts.

Micron-scale intrashell $\delta^{18}O$ variation in cultured planktic foraminifers

LAEL VETTER[1*], REINHARD KOZDON[2], CLAUDIA I. MORA[3], STEPHEN M. EGGINS[4], JOHN W. VALLEY[2], BÄRBEL HÖNISCH[5], AND HOWARD J. SPERO[1]

[4]Research School of Earth Sciences, The Australian National University, Canberra, ACT, Australia
[5]Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, 10964, USA

Introduction

Recent studies have used *in situ* analyses via Secondary Ion Mass Spectrometry (SIMS) to document $\delta^{18}O$ heterogeneity within the shell walls of planktic foraminifers and shell microstructures [1,2] that may result from ontogenetic, ecologic, or diagenetic controls. Here we show that the rate of precipitation of shell calcite in the extant planktic foraminifer *Orbulina universa* is sufficiently rapid that 12h calcification periods in ^{18}O-labeled seawater can be resolved and accurately measured using SIMS with a 3 µm spot. *Orbulina universa* secretes a large, spherical shell that thickens over the course of 3-5 days. Live *O. universa* were collected via scuba diving and maintained at constant temperature (22°C). These individuals calcified continuously while they were transferred every 12h between ambient seawater ($\delta^{18}O_w$ = -0.4‰ VSMOW), and seawater with enriched barium (4x ambient seawater) and $\delta^{18}O_w$ = +18.6‰ VSMOW. Transfers produced geochemically distinct layers of calcite that were enriched in both Ba and ^{18}O, separated by layers precipitated in ambient seawater. We quantified the position of the Ba-spiked calcite in the shell wall of *O. universa* specimens via laser ablation ICP-MS depth profiling of trace element ratios, and then measured intrashell $\delta^{18}O$ in the same specimens using SIMS with a 3 µm spot and an average precision of 0.6‰ (±2 SD).

Results and Conclusion

Measured $\delta^{18}O_{calcite}$ values in *O. universa* shell layers are -2.0±0.5‰ VPDB (n=5) for ambient calcite and +16.4±0.4‰ VPDB (n=3) for ^{18}O-labeled calcite. These values agree well with predicted values of -2.2‰ and +16.8‰, respectively, computed using empirical $\delta^{18}O$-temperature calibrations from live culture of *O. universa* [3]. Elemental and oxygen isotope data show that LA-ICP-MS and SIMS measurements can be cross-correlated within the spatial resolution of the two analytical techniques. Precipitation of ^{18}O and Ba seawater tracers in planktic foraminifer shell calcite appears to be synchronous, with no measurable spatial offsets. These results demonstrate the capability of SIMS to resolve diurnal growth increments in foraminiferal shells, and highlight the potential to address paleoceanographic and biomineralization questions.

Development of the MultiGAS for determining fumarole gas chemistry in geothermal systems

VIGOUROUX, NATHALIE[1]*, WILLIAMS-JONES, GLYN[2], RODRIGUEZ, CAROLINA[1], YEHIA, RON[1], BONA, PAOLO[1], HICKSON, CATHERINE[1]

[1]Alterra Power Corp., Vancouver, Canada, nvigouroux@alterrapower.ca (* presenting author)
[2]Simon Fraser University, Burnaby, Vancouver, glynwj@sfu.ca

Geothermal exploration relies on the gas geochemistry of fumaroles, bubbling/boiling springs and steaming ground to offer insight into the nature of the fluids at depth, procceses affecting them when rising to the surface, and provide estimates of the temperature of last equilibration of the gases within the reservoir. Traditional measurements involve direct sampling of the gases in pre-evacuated Giggenbach glass bottles before being sent to the lab for chemical analysis. Gas component analysis, combined with the isotope ratios of certain components (e.g., CO_2, He), provides insight into the proportion of magmatic, crustal, meteoric and atmospheric components in the fluid, and the state of equilibrium and temperature of these fluids at depth.

The Multi-component Gas Analyzing System (MultiGAS) was developed by the volcanological community over 10 years ago as a field-portable instrument for in-situ analysis of the major volcanic gas components in diffuse and dilute gas emissions. No two instruments are identical but all consist of various sensor types now capable of simultaneously analyzing for H_2O, CO_2, CO, SO_2 and H_2S.

In high-temperature (volcanic) geothermal systems, surface manifestations are often composed of gas emissions. In some cases, low temperatures and/or low flow rates make traditional sampling of fumaroles difficult, due to rapid vapor condensation and atmospheric contamination. The MultiGAS is best suited to these types of manifestations, providing a tool that can be used at a wide variety of gas emmission styles.

The MultiGAS has been field-tested in a geothermal prospect area characterized by steaming ground and fumaroles at the boiling temperature of water. Results of the MultiGAS analysis ($H_2O/CO_2/H_2S$ ratios) are compared with the equivalent ratios obtained from traditional sampling and analytical procedures, in order to identify the advantages and disadvantages of this new technique, and allow for the characterization of the hydrothermal system from the gas phase. The MultiGAS also allows for the gas/steam ratio of fumaroles to be quickly assessed in the field, which can aid in mapping/targeting of fumaroles in a large field, and the selection of the most ideal fumaroles to sample using the traditional method.

Mass transport experiments in low permeability shale

PETER VILKS[1*] AND NEIL H. MILLER[2]

[1]AECL, Whiteshell Laboratories, Pinawa, Canada, vilksp@aecl.ca (* presenting author)
[2] AECL, Whiteshell Laboratories, Pinawa, Canada, millern@aecl.ca

Introduction

The process of understanding sorption and its role in the transport of radionuclides in Canadian sedimentary rocks under saline conditions requires a combination of batch sorption experiments and mass transport tests to demonstrate that sorption coefficients (K_d) can be applied to explain mass transport. Although sorption in low permeability shale is diffusion dominated, transport tests with induced hydraulic flow are performed using the High Pressure Radioisotope Migration (HPRM) apparatus [1] in an attempt to obtain transport information on a shorter time scale than possible with diffusion tests. Tests are performed on core samples by pumping fluid through the core (along the core axis) using pressures as high as 4.5 MPa. The rock matrix permeability is calculated from the measured pressure differential between the inlet and outlet side of the core, and from the flow rate determined by the volume of eluted water [1]. Mass transport tests are performed by injecting a combination of sorbing and non-sorbing tracers and monitoring their eluted concentrations.

Results and Discussion

Initial tests were performed with a core sample of Queenston Formation. First deionized water was pumped through the sample to remove existing brine from pore spaces so that Cl from the subsequent brine injection could help define porosity. The deionized water was followed by 300 g/L TDS Na-Ca-Cl brine solution, and then same brine solution with uranine dye tracer. The average flow rates of water through the rock sample varied from 0.004 to 0.05 mL/day. The permeability varied from 1.0×10^{-21} to 7.5×10^{-21} m^2 and although the viscosity in permeability calculations was not increased for higher salinity, the resulting permeability values were not significantly affected by fluid composition. The sample pore volume estimated by the initial breakthrough of Cl from the brine injection was 0.22 ± 0.03 cm^3, which is in agreement with the 7 % porosity of a 2.5 cm diameter core with a length of 0.6 cm. In the mass transport test, uranine breakthrough was slower than that of Cl (assumed to be non-sorbing), producing a retardation factor of 1.44 ± 0.31 for uranine. Using a bulk mass density of 2.66 g/cm^3 for Queenston shale, this retardation factor corresponds to a sorption coefficient (K_d) of 0.167 ± 0.036 cm^3/g. This value is in agreement with batch measurements of uranine sorption on dolomite, calcite and quartz in the presence of Dead Sea brine solution [2]. Results of ongoing migration tests in shale using a brine solution containing a mixture of conservative (Li) and sorbing (Ni, Cu, Pb, Bi, Zr, U) tracers will be reported. These tests are aimed at demonstrating the role of sorption in mass transport processes by comparing the derived K_d values to that obtained from the batch sorption tests.

Geochronology and hygrochronology of metamorphic and metasomatic rocks

IGOR M. VILLA[1,2*] AND MICHAEL L. WILLIAMS[3]

[1]Institut für Geologie, Universität Bern, 3012 Bern, Switzerland igor@geo.unibe.ch (* presenting author)
[2]Università di Milano Bicocca, 20126 Milano, Italy
[3]Dept Geosciences, U of Massachusetts, Amherst, MA 01003, USA

Metamorphism, metasomatism, retrogression, and aqueous alteration are based on the same underlying mechanism at the atomic scale; their different names depend on the large-scale context. They all require recrystallization, which can be viewed as nano-scale dissolution/reprecipitation, mediated by an aqueous fluid [1].

What drives compositional or isotopic modification? Even if 19th century chemistry emphasized "diffusion", mass balance arguments made it quicky clear that changes in stoichiometry need a chemically open system, i.e. advection, rather than diffusion. Aqueous fluids are the main control on the formation of metamorphic parageneses [2], and on isotope exchange in minerals [3]. The reason is that the rate constants for fluid-mediated isotope transport are orders of magnitude larger, and activation energies much smaller, than those for diffusion. Recrystallisation is energetically less costly at almost any temperature than diffusive reequilibration [3].

In a companion abstract [4], it is argued that stepwise release and spatially resolved analyses are a decisive tool in understanding the petrologic processes controlling isotope exchange. However, unambiguous constraints can also derive from petrology alone, provided one knows what to look for. Diffusion is detectable against a background of faster transport only when water was absent and P-T-A-X calculations give an "asterisk" (an overdetermined set of independent reaction equilibria, all intersecting in one point) as proof of retrogression-free rocks.

The observations demonstrate that only in rare cases diffusion is the sole promoter of isotope resetting. Further, the observations require a major shift in perspective on the significance of mineral ages. Just as the "diffusionist" view that zircon discordance is due to thermal disturbances [5] was superseded by the petrological understanding that it is due to recrystallization [6], interpretations of intra-mineral age variations in terms of a purely thermal history neglecting the microchemical-petrogenetic context is no longer tenable.

Because fluid-mediated dissolution/reprecipitation depends mainly on water activity and only very loosely on temperature, isotope data provide a geohygrometric but not an unambiguous geothermometric datum.

Spatial resolution, stepwise release: connecting the multi-isotope record with microchemistry and petrology

IGOR M. VILLA[1,2*]

[1]Institut für Geologie, Univ. Bern, 3012 Bern, Switzerland [2]Univ. Milano Bicocca, 20126 Milano, Italy. - igor@geo.unibe.ch

Most metamorphic reactions require dissolution/reprecipitation, i.e. water activity controls petrology in metamorphic minerals, and also the isotope record, as radiogenic isotopes (except ^{4}He) do not diffuse faster than major elements forming the mineral structure [1]. Isotopic inheritance in relicts (i.e. slow diffusion) was observed in zircon, monazite, amphibole, K-feldspar, and micas. However, a priori there could be causes of isotope loss/exchange other than recrystallization. Temperature was proposed to play a role by changing diffusivity in geochronometers [2]. If diffusion has been the factor limiting isotopic (or chemical) closure, the concentration profile is bell-shaped. To ascertain if isotope transport in a sample was controlled by diffusion or recrystallization, spatial information is needed: only bell-shaped gradients are compatible with volume diffusion. So far, in-situ dating *never* described bell-shaped isotope gradients in patchily zoned minerals. On the contrary, patches are certain evidence of fluid-mediated local recrystallization, i.e. a guarantee of petrological, and therefore isotopic, disequilibrium.

The geochronology of mixed diachronous phases is managed by two complementary "SR techniques": spatially resolved analyses and stepwise release. SR techniques have shaped a better understanding of geochronology, as they reveal the elemental & isotopic compositions on the subgrain scale, and allow the recognition and the chemical/ isotopic characterization of relicts and retrogression. In SR techniques, the chemical signature is also measured in the same analysis as the age. Electron microprobe "chemical" geochronology [3] offers the most complete microchemical characterization of intra-crystalline zonations. ^{39}Ar-^{40}Ar analyses yield the concentrations of three elements (K, Ca, Cl) and their ratios to radiogenic ^{40}Ar. Why worry about the Ca/Cl ratio in a mineral, if the age is calculated from the Ar/K ratio? So as to unravel polyphase mixtures by comparing Cl/Ca/K signatures with independent microchemical data. When K-Ar ages of metamorphic minerals are older than we expect, they are brushed off as "excess Ar". Much confusion can arise if we mix up "excess Ar" (^{40}Ar gain) with "inherited Ar" (^{40}Ar loss). Inherited Ar often correlates with Ca/Cl. In addition to just K-Ar, multi-isotope geochronology (Rb-Sr, Lu-Hf, etc) should be used. If Ar and Sr correlate, it's due to Ar and Sr inheritance, not to excess Ar [4]. Overdetermined Rb-Sr isochrons [5] also can reveal inheritance.

Thanks to submicroscopic petrology, isotopic inheritance can be put into context with petrogenetic disequilibria. Analytical advances allow dating of each mineral generation. This opened up a wealth of data on the P-T-A-X-d history of rocks. In the long run, this will improve our ability to develop credible numeric models.

Selenate reduction rates in littoral sediments of a hypersaline lake, the Salton Sea, CA

JUAN FERNANDO VILLAROMERO[1]* AND CÉLINE PALLUD[2]

[1]PMB, University of California, Berkeley, USA;
[2]ESPM, University of California, Berkeley, USA
(*correspondence: villaromero@berkeley.edu)

The Salton Sea is California's largest lake and is located in the Salton Basin of the Colorado Desert. It supports one of the most productive fisheries of the Western hemisphere and more than 400 species of birds, including endangered migratory populations. The Alamo and New Rivers collect agricultural runoff from a 2,250 Km^2 area, and deliver 80% of the annual water inflow along with selenium (Se) and salts to the Salton Sea. Today, Se concentrations reach 10 mg Kg^{-1} in the sediments of the lake, and salinity is expected to further increase from its current value of 48. Such high selenium concentrations and increasing salinity pose a serious threat to the unique avian diversity of the Salton Sea [1]. Selenium naturally occurs in Western U.S. bedrock and can be mobilized through irrigation water as selenate (SeO_4^{2-}) and/or selenite (SeO_3^{2-}). Upon reaching anaerobic sediments in the Salton Sea, Se is microbially reduced to Se(0) and immobilized. Reduced selenium species are expected to remain sequestered in sediments as long as anaerobic conditions persist.

To identify the environmental factors that control selenate reduction rates in the Salton Sea, we measured these rates at salinity 45, along with porosity, bulk density, C:N, and the abundance of selenate-reducing bacteria (SeRB) in littoral sediment samples collected from seven sites. We also measured pH and salinity in water overlying sampling sites.

Higher selenate reduction rates (45.42 nmol h^{-1}cm^{-3}) and a higher abundance of SeRB (4×10^3 cells cm^{-3}) occurred at the site with the lowest C_{org}:N (2.7). Frequent and massive fish die-offs are commonly reported in the Salton Sea and lead to an accumulation of fish carcasses in the littoral potentially explaining such low C_{org}:N. Without nitrogen limitations, and given that selenate was the only terminal electron acceptor provided, SeRB can thus achieve higher abundances and higher selenate reduction rates.

Salinity averaged 48.41 in six out of seven sites; however, it was only 2.97 in a site mapped to the Alamo River delta. Selenate reduction rates and the abundance of SeRB were maximal in this site (223.3 nmol h^{-1}cm^{-3} and 3.5×10^3 cells cm^{-3}, respectively). The low salinity measured in this site may result from the mix between river freshwater and Salton Sea water. Interestingly, salinity is reported to negatively correlate with microbial diversity [2]; also, salinity imposes significant energetic requirements to microbial cells, especially under anaerobic conditions [3]. Finally, higher diversity results in communities more resistant to salinity stress [4]. Consequently, we hypothesize that the sediment exposed to salinity 2.97 supports a more diverse community of SeRB, and this higher diversity may facilitate a better response to salinity stress in experimental anaerobic slurries at salinity 45, detected as higher SeRB numbers and higher selenate reduction rates.

Our preliminary results show that water salinity and sediment C_{org}:N are important factors controlling selenate reduction in littoral sediments of the Salton Sea.

Calcium-(bi)carbonate equilibria in aqueous solutions: a high-accuracy titration-based study

A. VILLEGAS-JIMÉNEZ[1*], R. M. HAZEN,[1] AND D.A. SVERJENSKY[2]

[1]Carnegie Institution of Washington, Geophysical Laboratory, Washington, D.C. 20015, USA
adriano@gl.ciw.edu (* presenting author)

[2]Johns Hopkins University, Earth and Planetary Sciences, Baltimore, MD 21218, USA

A thorough understanding of calcium-(bi)carbonate equilibria in aqueous solutions is key for making accurate predictions of aqueous speciation in Ca-HCO_3-CO_3-H_2O-CO_2 systems and assessing the extent of precipitation (or dissolution) of $CaCO_{3(s)}$ polymorphs in environmental, biological, and industrial systems. Despite earlier determinations of the formation constants of calcium-(bi)carbonate ion pairs in aqueous and seawater-like solutions, recent studies postulating the formation of metastable [1,2] or stable prenucleation $CaCO_3$ nanoclusters [3,4] have triggered new interest on calcium-(bi)carbonate interactions, particularly at near-calcite saturation conditions. Moreover, anomalous pH values and calcium concentrations consistently observed during acidimetric titrations of aqueous calcite suspensions suggest that the chemical equilibria governing the $CaCO_3$-HCO_3-CO_3-H_2O-CO_2 system may not be fully understood [5].

In this study we perform a critical review of the available thermodynamic constants describing the formation of calcium-(bi)carbonate ion pairs and compare these values with constants extracted from new experimental data acquired over fairly broad compositional ranges. Our experimental approach consists of performing high-accuracy titrations of (bi)carbonate solutions in contact with a gas phase but completely isolated from the atmosphere. For the first time in this type of determinations, $CO_{2(g)}$ exchange across the gas-water interface is quantitatively monitored and the chemistry of the solution is fully characterized (analytically overdetermined) through a combination of pH, alkalinity, pCO_2, ΣCO_2 pCa, and ΣCa measurements at each titration point. Data fitting and parameter extraction is made stochastically following a genetic algorithm approach described earlier [6].

Leachate analyses of volcanic ashes from Sakurajima volcano, Japan: insights into the magmatic degassing processes

NICOLAS VINET[1,*], HIROSHI SHINOHARA[2], AND ISOJI MIYAGI[3]

Ash erupted from active vents acts, by adsorption onto its surface in volcanic plumes, as an efficient scavenger of volatile elements such as sulphur (as sulphate, SO_4^{2-}), halogens, and other species present as soluble salts adhering to the particle surface. Analysis of water-soluble ash leachates is a suitable supplement for remote monitoring of volcanic gases at inaccessible volcanoes. The chemical composition of ash leachates is considered as a proxy for volcanic plume chemistry (volatile ratios), and its temporal variations reflect changes in the magmatic conditions, eruptive activity, along with local conduit- and plume-related processes. The importance of ash-leachate analysis also lies in the fact that up to 30-40% of the volatile budget emitted by subduction-related volcanoes are scavenged by such adsorption processes on volcanic ash. This adsorbed component has been generally neglected, resulting in excess degassing underestimated by 30-40%.

In this study, we investigate the temporal variations of the chemical composition of water-soluble leachates from volcanic ashes emitted from Sakurajima volcano, Southern Kyushu, Japan, during the period 1981-2011 (with emphasis on 2010-2011). Pristine ash was collected on-site, ca. 3 km away from the vent, directly after an explosion occurred.

We observe a strong positive correlation between SO_4, F and Cl/SO_4 against Cl, especially in ash leachates from 2008 to 2011, corresponding to the reactivation of Showa vent. Our results also show significant long-term and short-term temporal variations in ash leachate compositions (SO_4, F, Cl, Cl/SO_4, S/F, Mg/Na), reflecting changes in the eruption rate and style. Since ash-gas interactions started at the fragmentation level within the vent, these temporal variations may also reflect changes in the fragmentation mode or the volatile accumulation (adsorption) process onto the ash within the vent. In turn, this is linked to the mean residence time of magma in the upper conduit (including the vent), as a response to magma renewal and/or convection in this part of the volcano system.

In addition to chemistry we also investigate the influence of grain size distribution and texture on ash-leachate analyses over time. This is at present time very preliminary, but if correlations are found in particular between volatile ratios in ash leachates and the grain size and/or texture, it will provide new and valuable semi-quantitative information on the degassing processes in the shallow volcanic conduit.

Improved carbon isotope modeling of biogenic coalbed methane systems: The nature of initial CO_2

DAVID S. VINSON[1*], JENNIFER C. MCINTOSH[1], DANIEL J. RITTER[1], NEAL E. BLAIR[2], AND ANNA M. MARTINI[3]

[1]University of Arizona, Dept. of Hydrology and Water Resources, dsvinson@email.arizona.edu (* presenting author), mcintosh@hwr.arizona.edu, dritter@email.arizona.edu

[2]Northwestern University, Depts. of Civil & Environmental Engineering and Earth & Planetary Sciences, n-blair@northwestern.edu

[3]Amherst College, Dept. of Geology, ammartini@amherst.edu

Carbon isotope signatures (e.g. $\alpha_{CO2\text{-}CH4} = (\delta^{13}C_{CO2}+1000)/(\delta^{13}C_{CH4}+1000)$) for distinguishing acetoclastic methanogenesis vs. CO_2 reduction were investigated in a biogenic coalbed methane (CBM) system, the Powder River Basin (WY/MT, USA). Past studies of this basin present inconsistent isotopic [1,2] and microbiological [3,4] evidence of methanogenic pathways.

Combined gas and groundwater analysis of monitoring and CBM production wells along a 25 km transect indicates several geochemical trends from shallow, basin-edge wells to deeper wells. Broadly, these basinward trends indicate: increasing pH (7.4-8.5), alkalinity (13-33 meq/kg), and temperature (11-28 ºC); increasing $\delta^{13}C_{CH4}$ (-78 to -56‰), $\delta^{13}C_{CO2}$ (-24.7 to 4.7‰), and $\delta^{13}C_{DIC}$ (-11.0 to 16.2‰) values; increasing calcite saturation indices (-0.71 to 0.60); increasing $\delta^{2}H$ (-164 to -129‰) and $\delta^{18}O$ (-21.2 to -17.2‰) values; and decreasing apparent inputs of sulfate from shallow formations. Across this gradient of geochemical and isotopic conditions, *apparent* values of $\alpha_{CO2\text{-}CH4}$ are characteristic of CO_2 reduction (most 1.05-1.07). Given that $\delta^{13}C$ values of residual CO_2 are distinctively >0‰ in closed CO_2-reducing systems, inputs of DIC from microbial respiration (e.g. sulfate reduction) and/or carbonate dissolution would contribute isotopically depleted CO_2 to the reactant pool. This initial CO_2 is modified by methanogenesis. The lower $\delta^{13}C_{CH4}$ and $\delta^{13}C_{CO2}$ values observed in shallower, calcite-undersaturated waters are consistent with possible inputs of alternative electron acceptors (e.g. sulfate) from shallow units. Moreover, subequent reduction of this CO_2 would represent an early stage of methanogenesis yielding depleted $\delta^{13}C_{CO2}$ and $\delta^{13}C_{CH4}$ relative to late-stage methanogenesis, in which more of the CO_2 pool has been reduced [2]. Thus, both the nature of initial CO_2 and the extent of reactant pool consumption can strongly influence observed $\delta^{13}C_{CO2}$ and $\delta^{13}C_{CH4}$.

The potential role of acetate remains undetermined. Low acetate concentrations basinwide (low µM range [3]) imply (1) a depleted acetate pool or (2) steady-state acetate production and consumption. Analysis of compound-specific and intramolecular C isotope ratios of acetate may elucidate acetate's role. The relative importance of methanogenic pathways has implications for understanding subsurface contributions to the C cycle and for the potential stimulation of sustainable gas production from CBM systems.

Abstract

Following the December 2008 rupture of a coal fly ash retaining pond at the Tennessee Valley Authority (TVA) Kingston Fossil Plant near Harriman, Tennessee, a comprehensive monitoring effort was intiated to evaluate the extent of ash deposition in the terrestrial and aquatic environments directly impacted by the release. The chemical characteristics of ash and impacted sediment samples were determined through analysis for a variety of metals using inductively coupled plasma atomic emission spectroscopy (ICP-AES) and mercury using cold vapor atomic absorption spectroscopy (CVAA). In addition, polarized light microscopy (PLM) was utilized for the determination of percent ash of sediment samples. A comparison of the percent ash data to the metals and mercury concentrations revealed a strong correlation between ash content and concentration of some metals constituents (*e.g.*, arsenic, strontium, and selenium). Other metals constituents (*e.g.*, aluminum, boron, and iron) demonstrated weak or no correlation to ash content.

In addition to monitoring associated with the recovery effort, a research team from Appalachian State University evaluated the use of mass magnetic susceptibility (MS) as a potential indicator of ash content. MS was observed to correlate fairly well with ash content in the river bottom sediment samples; however, MS measurements showed a weaker correlation to some elements typically considered to be constituents of coal fly ash (*e.g.*, selenium).

Conclusion

This paper evaluates the correlations among various analytical techniques and potential uses of alternate methods as a cost-savings measure for monitoring. PLM may be useful as an alternate method for estimating metals concentrations based on ash content. In addition, MS may be useful as an alternate analytical method for estimating ash content in bottom sediments in aquatic environments.

Force field for oxoanions in solid state and aqueous solutions

LUKAS VLCEK[1*] AND ARIEL A. CHIALVO[2]

[1]Oak Ridge National Laboratory, Oak Ridge, TN 37631, U.S.A, vlcekl1@ornl.gov (* presenting author),

A delicate balance between ion hydration and crystallization plays a crucial role in natural processes leading to dissolution and precipitation of minerals, and forms the basis of many technological applications, such as nuclear waste separation and storage. Our primary interest is to investigate salt crystallization from mixed electrolyte solutions in porous rocks, but the results also pertain to the rational design of complexation agents used in selective crystallization of homologous series of oxoanions.

A reliable description of molecular and ionic interactions is needed to understand atomic-scale mechanisms underlying the thermodynamics and dynamics of electrolyte solutions. Our goal is to develop a consistent force field for the study of oxoanions including CO_3^{2-}, NO_3^-, and those of general formula XO_4^{2-} (X=S, Se, Cr, Mo, W). While several force fields exist for the description of simple alkali metal and halide ion series [1], and isolated models for selected oxoanions have been published [2], a consistent force field for oxoions suitable for comparative studies is missing.

The choice of an appropriate potential model form is dictated by intended applications, balancing accuracy and computational efficiency. Since adsorption and salt precipitation happen over large time and length scales, the simplicity of the model is of high importance. While most of the concerned ions are highly polarizable, their mineral environment is consistently polar, justifying the use of effective pair potentials. We therefore consider pair potentials represented by a combination of point charges and Lennard-Jones interactions compatible with the SPC/E model of water [3].

The force field is optimized against experimental data including hydration free energy at infinite dilution [4], chemical potential at finite concentration obtained from Kirkwood-Buff equations [5], lattice constant and lattice energy for selected crystals, and diffusion coefficient [4]. The potential parameters (at least 5 for each oxoion) were determined using global optimization based on the coupling parameter technique [6].

Dynamic precipitate formation during Fe(II) oxidation in aerated phosphate-containing water

ANDREAS VOEGELIN[*], RALF KAEGI

Eawag, Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland, andreas.voegelin@eawag.ch ([*] presenting author)

The oxidation of Fe(II) at biogeochemical redox interfaces results in the formation of nanoparticulate Fe(III)-precipitates that act either as immobilizing sorbents or colloidal carriers for contaminants and nutrients. In previous work on Fe(I) oxidation products in neutral aqueous suspensions [1, 2], we concluded that nanoparticulate amorphous Fe(III)-phosphate is the first precipitate that forms during Fe(II) oxidation in the presence of phosphate (P), with a molar P/Fe ratio of the solid of ~0.55 (in absence of Ca). At initial dissolved P/Fe ratios less than ~0.55, the formation of Fe(III)-phosphate is followed by the precipitation of amorphous to poorly crystalline Fe(III)-(hydr)oxides (depending on silicate/Fe ratio). These conclusions, however, were based on the study of precipitates collected after complete Fe oxidation and precipitation (no time-resolution) and covering a limited number of P/Fe ratios.

In onoing work, we explore the dynamics of precipitate formation during Fe(II) oxidation in aerated phosphate-containing solutions (bicarbonate-buffered to pH 7.0) time-resolved and over a larger number of initial P/Fe ratios. We monitor the decrease in filterable (<0.2 μm) element concentrations during Fe(II) oxidation and characterize precipitates collected during and after complete Fe(II) oxidation by a suite of complementary techniques, including X-ray absorption spectroscopy and transmission electron microscopy. To monitor precipitate evolution in-situ, additional experiments are performed using time-resolved UV-Vis spectroscopy.

The results from time-resolved experiments confirm the initial formation of an amorphous Fe(III)-phosphate with a P/Fe ratio of ~0.55 (at the time when dissolved P is depleted). However, our results also suggest that in systems with initial dissolved P/Fe ratios substantially below 0.55, initially formed Fe(III)-phosphate transforms or dissolves during ongoing Fe(II) oxidation in P-depleted solution, resulting in the formation of Fe(III)-(hydr)oxides with higher degree of Fe(III) polymerization to which P is sorbed. From our current results, we conclude that at initial dissolved P/Fe ratios less than ~0.17, initially formed Fe(III)-phosphate is absent in the final product of Fe(II) oxidation at near-neutral pH. These results demonstrate that Fe(III) precipitation during Fe(II) oxidation in aqueous solutions is a highly dynamic process that may involve formation of transient precipitates that are absent in the fresh precipitate after complete Fe(II) oxidation. In future work, we plan to further investigate Fe(III) precipitation dynamics during Fe(II) oxidation and the aging of fresh precipitates, also with respect to implications for the solubility and mobility of co-transformed trace elements.

Oxygen and deuterium stable isotope signals in Northeast Atlantic waters

ANTJE H. L. VOELKER[1]* AND ALBERT COLMAN[2]

[1]LNEG, Unidade Geologia Marinha, Amadora, Portugal, antje.voelker@lneg.pt (* presenting author)
[2]The University of Chicago, Dept. of Geophysical Sciences, Chicago, USA, asc25@uchicago.edu

Material and Methods

A comprehensive study of seawater stable isotope properties in the mid-latitude North Atlantic is still missing [1], especially for the intermediate and deep water masses. To fill this gap seawater samples were collected along various transects in the Northeast Atlantic. During the Atlantic Meridional Transect (AMT) 18 expedition the upper 300 m were sampled between 46.6 and 24.7°N. RV Poseidon cruises P334, P349, P377, and P383 to the Azores Front region (38.3–30°N; 22–20°W) generally yielded samples down to 2000 m. High resolution sampling over the whole water column was performed during the OVIDE 2010 (Portugal to Reykjanes ridge) and KN199-4 cruises. Cruise KN199-4 implemented the section from Lisbon to the Cape Verde Islands of the US GEOTRACES North Atlantic transect. AMT 18 and P cruise samples were analyzed for $\delta^{18}O$ using the Delta E mass spectrometer at the Leibniz Laboratory (Kiel, Germany). Analysis of $\delta^{18}O$ and dD in the OVIDE 2010 and KN199-4 samples was done at the Godwin Laboratory (Cambridge, UK) using the PICARRO L2120 water isotope analyzer. Splits of some of the KN199-4 samples were also analyzed for both isotope ratios at the University of Chicago using a GasBench II linked to a Delta V Plus mass spectrometer.

Results and Conclusions

Along the AMT 18 transect, i.e. in the central basin, a clear boundary is visible with $\delta^{18}O$ values in the upper 100 m of 0.75–1.15 permil north of 38°N and 1.3–1.5 permil south of it. The range narrows in the North Atlantic Central Water (NACW) to 0.9–1.2 permil with the stations in the subtropical gyre, as expected, showing the higher values. In the eastern basin variability in the upper mixed layer (<300 m) is much larger with values ranging from 0.4 to 1.6 permil. The high variability can be attributed to seasonal mixing processes at the Azores Front, upwelling along the Iberian margin and the influence of riverine water at KN199-4 station 1 positioned in the Setubal canyon. Below 300 m the subpolar and subtropical NACW can clearly be distinguished in the isotope profiles. Along with temperature, $\delta^{18}O$ values decrease with depth to generally less than 0.7 permil below 2000 m. Along the Iberian margin this trend is, however, interrupted between 500 and 1500 m due to the Mediterranean Outflow Water (MOW). The different cores of the MOW are clearly visible in the $\delta^{18}O$ and dD (which is highly correlated to salinity) profiles, especially those close to the Iberian margin. Results for many of the OVIDE and GEOTRACES stations are pending and when they are available it will be possible to better define the isotopic properties of the subsurface water masses, especially the North Atlantic Deep Water and the Antarctic Bottom Water.

Carbonate diagenesis in the Pacific Equatorial Age Transect (PEAT) Sites and the preservation of geochemical signals in foraminifera

JANETT VOIGT[1]*, ED HATHORNE[1], MARTIN FRANK[1]

[1]GEOMAR | Helmholtz Centre for Ocean Research Kiel, Wischhofstr. 1-3, Kiel, Germany
jvoigt@geomar.de (* presenting author)

The calcite shells (tests) of foraminifera used for reconstructions of oceanic and climatic conditions in the past can be altered after deposition by a process where the original biogenic calcite is replaced by secondary (inorganic) calcite. It is important to quantify changes in the elemental and isotopic composition of the tests caused by this recrystallisation process and thus the reliability of the proxy data. We present initial results from a multi-component study of recrystallisation in sediments from the IODP Expedition 320/321 Pacific Equatorial Age Transect (PEAT), where sediments of similar age and initial composition have been subjected to different diagenetic histories.

$^{87}Sr/^{86}Sr$ ratios of bulk carbonate leachates and the associated pore waters generally suggest that recrystallisation occurred relatively rapidly as the values are indistinguishable (within 2σ uncertainties) from contemporaneous seawater [1]. Notable exceptions include Site U1336, where pore waters and the bulk carbonates in sediments older than 20.3 Ma have lower $^{87}Sr/^{86}Sr$ ratios than contemporaneous seawater, most likely resulting from the upward diffusion of Sr from older recrystallised carbonates.

Furthermore, the lower Sr/Ca ratios of bulk carbonates from Site U1336, compared to the other PEAT sites, suggest more extensive diagenetic alteration as less Sr is incorporated into secondary calcite. Although the recrystallisation of bulk carbonates is well documented, the fate of foraminiferal chemistry is potentially different. To investigate this, laser ablation ICP-MS element/Ca ratio depth profiles through tests of the planktonic foraminifera *G. venezuelana* from Sites U1336 and U1338 were obtained for two time intervals (13.9 Ma and 15.5 Ma). The depth profiling technique reveals heterogeneity of Mg/Ca and Mn/Ca ratios through the wall of the tests comparable to those reported for modern foraminifera from sediment traps [2]. The Sr/Ca ratios show little heterogeneity and fluctuate around 1.1-1.2 mmol/mol as also observed for modern tests. The Sr/Ca ratios exhibit no systematic difference between the sites and time intervals. Therefore, the intra-test element/Ca heterogeneity suggests that foraminifera react differently to bulk carbonates (nanno-fossils) during diagenetic recrystallisation and much of the original geochemical proxy signal may have been retained.

Boron isotopes as a proxy of primary mineral weathering mechanisms

A. VOINOT[1,2 *], D. LEMARCHAND[1], F. CHABAUX[1], AND M-P. TURPAULT[2]

[1]Laboratoire d'Hydrologie et de Géochimie de Strasbourg, EOST, Université de Strasbourg et CNRS, 1 rue Blessig, 67084 Strasbourg, France (*correspondence: alexandre.voinot@etu.unistra.fr)

[2]INRA UR 1138 Biogéochimie des Ecosystèmes Forestiers, Centre INRA de Nancy, 54280 Champenoux, France

Determining the current state of mineral weathering in soils is a key point to understand and model pedogenic processes. Nevertheless, it remains a real challenge given to the difficulty to get informations on the mineral sites actually active and the non-stoichiometric release of site-forming cations.

Boron has been demonstrated experimentaly to be located in different reactive sites of pure biotite (replacing silicon in tetrahedrons or adsorbed in interfoliar sites) with very contrasted isotopic compositions (up to 80 ‰ difference between interfoliar and lattice sites, Voinot et al., in prep). This huge isotopic partitionning between the different mineral sites allowed to distinguish between transformation and dissolution reactions with an higher sensitivity than classic chemical tracers (K and Si).

To assess the ability of boron to better characterize the current weathering state in soils, quantitative mineralogical analyses have been coupled to boron isotopes in a series of sorted minerals (< 50 µm) with varying weathering rates along an Alocrisol profile developped on a granitic bedrock (Breuil-Chenue forest, France). Distinction has been made between rather transforming (biotite, plagioclases) or dissolving minerals (muscovite, K-feldspars).

For biotite and muscovite, even though deep weathering processes lead to low dissolution and transformation rates, we observe that the bulk B chemical and isotopic compositions seem to rapidly equilibrate with the surrounding soil solution. Shallower soil layers show similar B behavior in fine grain fraction of these two minerals, whereas coarser grains tend to accumulate boron in their structure (up to 4 time the initial boron content). Plagioclases dissolve very quickly in the weathering sequence to be replaced mainly by kaolinite, with a strong concentration increase and still seem to equilibrate isotopically with the soil solution. K-feldspars show no specific weathering mechanisms other than dissolution and this is reflected by a progressive depletion with invarious isotopic composition.

In a second series of samples (from the same site but this time on total soil) we assessed the evolution of these mechanisms in presence of organic matter and close to vegetation (comparison of bulk vs rhizospheric soil subsamples in the < 2 mm fraction) in shallower horizons (0 to 23 cm) under two different tree species (beech and spruce). Very shallow processes (0-3 cm horizon) are characterized by a strong organic matter influence (in both bulk and rhizospheric soils), with contrasted boron isotopic compositions between the two tree species (about 8 ‰). In the 10-23 cm horizon, this influence is greatly disminished and lets place to a more mineralogy-controlled mechanism with similar isotopic signature under spruce and beech.

Oxic-anoxic oscillations driven by infaunal hydraulic activity

NILS VOLKENBORN[1*], LUBOS POLERECKY[2], CHRISTOF MEILE[3], DAVID S. WETHEY[1], AND SARAH A. WOODIN[1]

[1]Department of Biological Sciences, University of South Carolina, Columbia, SC 29208, USA (*presenting author: nils@biol.sc.edu)

[3]Department of Marine Sciences, University of Georgia, Athens, GA 30602, USA

Over the last few years we have investigated some of the most important bioturbating infaunal groups with respect to their hydraulic activity and the related porewater advection and oxygen dynamics. This was done by combining time-lapse photography, porewater pressure sensing and planar optode imaging of oxygen. Despite species-specific traits, the investigated crustaceans, bivalves and polychaetes all engage in hydraulic activities that cause intermittent and bidirectional transport of water away and towards the organisms [1, 2]. As a consequence, the sediment surrounding the burrows, as well as the sediment surface, experience frequent oscillations between oxic and anoxic conditions on the scale of minutes to hours.

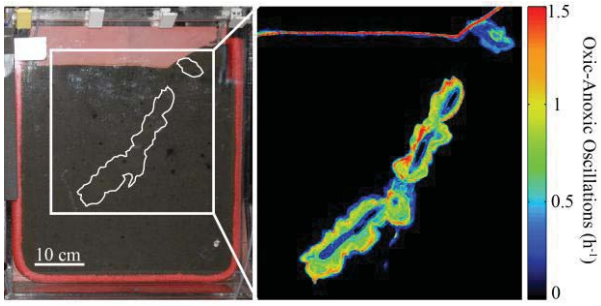

Figure 1: Two-dimensional representation of oxic-anoxic oscillations induced by hydraulic activity of the ghost shrimp *Neotrypaea californiensis*.

The sediment characterized by oscillatory conditions is limited to a thin layer around burrows in muddy environments but can be substantial in intermediate to high permeability sediments. Oscillatory conditions induced by hydraulically active organisms are expected to have significant implications for the distribution of microbial communities, with the durations of oxic and anoxic periods being a crucial determinant of biogeochemcial pathways and rates.

In this talk we will visualize the dynamic nature of geochemical conditions in the presence of hydraulically active organisms, and present quantitative data analysis and reactive-transport model simulations to explore the species- and sediment-specific oscillatory character of bioturbated sediments.

Marine carbonate burial rates at the Phanerozoic mass extinctions

HAUKE VOLLSTAEDT[1*], ANTON EISENHAUER[1], FLORIAN BÖHM[1], JAN FIETZKE[1], KLAUS WALLMANN[1], VOLKER LIEBETRAU[1], JURAJ FARKAŠ[2,3], ADAM TOMAŠOVÝCH[4], AND JÁN VEIZER[5]

[4] Department of Geophysical Sciences, The University of Chicago
[5] Ottawa-Carleton Geoscience Center, University of Ottawa

Several mass extinctions have disturbed the evolution of life during the Phanerozoic Eon. Information about the past environmental conditions and triggers for the extinctions can be inferred from the geological record and in particular from the analysis of different isotope systems (i.e. carbon, sulfur, and calcium) as well as the extinction selectivity [1].

To extend earlier published mass extinction scenarios we measured radiogenic ($^{87}Sr/^{86}Sr$) and stable strontium (Sr) isotope ratios ($\delta^{88/86}Sr$, [1]) simultaneously on globally distributed brachiopod and belemnite samples to constrain changes in Phanerozoic seawater chemistry. This includes quantitative information about the marine Sr output flux, primarily controlled by the burial of marine carbonates, as the precipitation of calcite and aragonite preferentially incorporates the light Sr isotope [2,3], leaving seawater isotopically heavier.

Our Phanerozoic $\delta^{88/86}Sr$ seawater record shows considerable variability from 0.25‰ to 0.60‰ suggesting major changes of the marine carbonate burial fluxes. To quantify our results we developed a numerical box model to reconstruct changes in the inventory and fluxes of seawater Sr, calcium (Ca), and total alkalinity (TA).

The model results reveal severe disturbances in the marine budgets of Sr (0-300 µmol/l), Ca (0-40 mmol/l), and TA (0-30 mmol/l) at the Phanerozoic extinction events, especially at the Permian/Triassic boundary. These changes in the marine carbonate system are explained by processes including carbonate production rates, (shelf) carbonate dissolution, ocean anoxia associated with bicarbonate production by bacterial sulfate reducers (BSR), and shifts in the dominant carbonate mineralogy (calcite/aragonite). The first time geochemical quantification of these processes is a novelty in the field of Paleocanography and will help to identify the causal processes leading to global mass extinctions in the marine realm.

Do mountains withdraw CO_2?

FRIEDHELM VON BLANCKENBURG*[1], JEAN L. DIXON[1]

[1]German Research Center for Geosciences GFZ, Earth Surface Geochemistry, Potsdam, Germany, fvb@gfz-potsdam.de (* presenting author)

Common gospel holds that the rise of mountains in the late Cenozoic has increased global rates of silicate weathering, and, as a consequence, increased withdrawal of atmospheric CO_2. Seawater isotope ratio curves of radiogenic Sr, radiogenic Os, and most recently, stable Li [1] supposedly testify to this change. We challenge this hypothesis on three grounds.

1) A compilation of weathering and denudation rates at both the soil scale and the river catchment scale show that "speed limits" restrict both soil formation (270 t km^2 yr^{-1}, or 0.1mm yr^{-1}) and silicate weathering (135 t km^2 yr^{-1}). Even in high, active mountains, these limits are obeyed. We use a global topographic model to show that due to the combination of weathering speed limit and the small spatial extent of active mountain belts, areas in which erosion exceeds the soil formation speed limit contribute <10% to global weathering fluxes today. In the geologic past, due to the limited range of weathering rates imposed by speed limit, large global changes in uplift and erosion would have resulted in only small changes in global weathering.

2) A reassessment of global and regional erosion rates inferred from global sedimentation rates has shown that a supposed increase in global mountain erosion rates in the late Cenozoic is only an apparent one, and that the underlying increase in sedimentation rates is due to incomplete preservation of sedimentary strata [2].

3) An increasing body of evidence shows that the seawater curves of radiogenic Sr and Os isotope ratios record provenance of these elements [3], or the increasingly glacial contribution to erosion [4] rather than weathering rates. The new stable Li isotope data [1] is intriguing, but we still lack detailed insight into these metal stable isotope systems to attribute their variability with certainty to an increase in terrigenous weathering. In contrast, the ocean $^{10}Be(meteoric)/^{9}Be$ ratio, a weathering proxy that combines an isotope of constant flux with a stable one of weathering-dependent flux, is steady over the last 10My [2]. It is therefore unlikely that changes in CO_2 withdrawal over this period were engineered by silicate weathering.

We conclude that the optimal conditions for CO_2 withdrawal are those where a large fraction of the terrestrial Earth surface is soil covered, and is eroding near soil production speed limit. At lower global denudation rate, global soils will be transport-limited. The consequence of such a low global denudation regime is that the potential for feedbacks between climate, weathering, and CO_2 withdrawal to operate is low. In such a period the Earth system could fail all climate weathering feedbacks.

Development of Flow-Field Flow Fractionation based methods for the characterization of engineered nanoparticles in a complex matrix

S. LEGROS[1], F. VON DER KAMMER[1*], S. WAGNER[1], B. MEISTERJAHN[1], E. H. LARSEN[2], K. LOESCHNER[2], J. NAVRATILOVA[2] & T. HOFMANN[1]

[1]Univ. of Vienna, Dept. of Env. Geosciences, Vienna, Austria
[2]National Food Institute, Division of Food Chemistry, Technical University of Denmark, Søborg, Denmark.
(*presenting author: frank.kammer@univie.ac.at)

Engineered nanoparticles (ENPs) containing consumer products are already on the market. These may release the containing nanoparticles into the environment during their production, use and disposal/recycling. To assess the risk related to this release accurate methods for nanoparticle quantification in a wide variety of matrices are needed. These standardized methods to detect, quantify and characterize ENPs in consumer products are in fact nonexistent.

Field Flow Fractionation (FFF) coupled to specific detectors is one of the most promising techniques for these tasks. To establish robust methods for analyzing ENPs in products, biological media and the environment a systematic approach to thoroughly optimze and validate FFF for certain combinations of ENP and sample matrix is needed. Many parameters like cross flow, carrier composition, membrane type, channel height and injection procedure determine the performance of FFF. The same is true for the sample preparation and the specific particle detection following separation as e.g. by ICP-MS.

The strategy to be adopted depends strongly on the analytical information requested, the type of the ENPs and the nature of the matrix. The examples of nanoparticles of silica-NPs in a food sample (tomato soup) and silver-NPs in food and the environment will be presented.

The sample preparation was performed by several particle/matrix adapted approaches using colloidal extraction, acidic, alkaline and enzymatic attacs. Flow-FFF coupled to online UV-DAD, multi-angle light scattering, dynamic light scatering and ICP-MS were used to characterize compositions and properties of nanoparticles as a function of size. The optimization schemes aimed at maximum recovery, lowest possible influence on peak shape and position, minimum alteration of the original ENP during analytical procedure and pratical applicability (e.g. analysis time). The results show that ENPs can be analyzed in complex matricees with good recovery. Also it is evident how strong FFF results depend on the interplay of sample characteristics and run conditions.

Thoroughly adapted and optimized analytical methods, as those presented here, are essential to investigate the fate of ENPs during the entire life cycle of the consumer product.

Detrital zircon age populations and provenance of the Cape–Karoo succession in South Africa and correlatives in Argentina

CLARISA VORSTER*, JAN KRAMERS, NIC BEUKES, HERMAN VAN NIEKERK

Department of Geology, University of Johannesburg, South Africa, clarisav@uj.ac.za (* presenting author); jkramers@uj.ac.za; nbeukes@uj.ac.za; hermansvn@uj.ac.za

The similarities in litho- and biostratigraphy between the rock successions in the Paleozoic Cape-Karoo basin in Southern Africa and the Sauce Grande basin in Argentina as well as the structure of the Cape and Sierra de la Ventana folded mountain belts that deformed strata of these basins along their southern margins as part of the Gondwanide tectonic terrane, have long been recognized [1, 2]. In order to better constrain the provenance terrains for the two basins, a comparative U/Pb age study of detrital zircon populations was undertaken using LA-ICP-MS . Arenaceous samples were collected in the southwestern Cape region of South Africa, and at Mar del Plata and the Sierre de la Ventana in Argentina. Samples came from the broadly equivalent Ordovician-Silurian Table Mountain and Curamadal Groups, Devonian Bokkeveld and Ventana Groups, uppermost Carboniferous to lowermost Permian glaciogenic Dwyka and Sauce Grande diamictites and greywackes of the lower Permian Ecca and Bonete successions

Results display remarkable similarities but also important subtle diffences in detrital zircon age populations between the two basins, Most characteristic of both areas is the dominance of two major populations of zircons namely late Mesoproterozoic (1200 – 1000 Ma) and late Neoproterozoic to Cambrian (600 – 500 Ma) with perhaps a subordinate late Paleoproterozoic (1900 – 1700 Ma) population in some samples with absolute scarcity or absence of any older zircons. Apart from the glaciogenic Sauce Grande Formation in the Ventana region, all the other formations sampled in this area essentially hold only a late Neoarchean – early Phanerozoic zircon population. In contrast the samples from the western Cape in south Africa are virtually all characterized by both late Neoproterozoic – early Phanerozoic and late Mesoproterozoic age populations. Interestingly a sample of arenite from Mar del Plata along the west coast of Argentina also displays the two major zircon age populations that are characteristic of the correlative Table Mountain arenites in the western Cape. Results indicate that the successions in the Western Cape and eastern part of the Sauce Grande basin were mainly sourced from late Neoproterozoic Pan African/Brasiliano and late Mesoproterozoic Namaqua-Natal metamorphic belts. Rocks in the Ventana area, however, were essentially sourced from Brasiliano terranes. A prominent early Permian zircon population is present in the Bonete Formation of the Ventana region suggesting transport from a juvenile source to the south in the Gondwanide orogen.

The global correlation between bedrock age and the dissolved $^{87}Sr/^{86}Sr$ composition of continental runoff [1] suggests that sufficiently detailed knowledge of spatial distributions of lithological units and runoff fields may allow for more representative predictions of the geochemical nature of continental material exported to the ocean [2]. At the scale of individual drainage basins, however, variations in contributions from geochemically disparate portions of a basin over timescales of weeks to years can cause systematic shifts in the composition of dissolved material exported at different times. In such cases where variability in seasonal hydrology and geochemical "end-members" within a drainage area are significant, predicted geochemical properties must be compared with actual observations at high enough temporal frequency to determine if large-scale modeling approaches can reasonably be applied at the regional or catchment scale.

The Fraser River basin is of intermediate size (232,000 km^2) but possesses stark spatial variability in bedrock geology and precipitation patterns on account of its complex mountainous terrain. Conservative geochemical properties of dissolved constituents (including δD_{H2O} and $^{87}Sr/^{86}Sr$) measured over two years near the Fraser mouth demonstrate a stronger influence during the spring and summer from headwaters with radiogenic $^{87}Sr/^{86}Sr$ and depleted δD. $^{87}Sr/^{86}Sr$ ranges from 0.709 in late winter up to 0.714 in the summer. A mixing model is presented, in which a discharge-weighted average of tributaries is calculated to predict the values of these properties downstream. Strong agreement between the modeled and measured values suggests that such an approach adequately captures the spatial heterogeneity and temporal variability of the Fraser basin. The predicted $^{87}Sr/^{86}Sr$ based on gauging station discharge data agrees well with that based on discharge generated by a global hydrologic model [3], showing promise for extending such an approach to other river systems.

This study provides a framework for further work constraining fluxes and variability of nonconservative constituents (e.g. dissolved organic carbon, nutrients).

In situ silicon isotope analysis of Archean cherts and BIFs by laser ablation MC-ICPMS

P.Z. VROON [1*], H. TSIKOS[2], B. VAN DER WAGT [1], M.J. VAN BERGEN[3], S. EGGINS[4], L. KINSLEY[4]

[1]Dept. of Petrology, FALW, VU University, The Netherlands, p.z.vroon@vu.nl (* presenting author), b.vander.wagt@vu.nl
[2]Dept. of Geology, Rhodes University, Grahamstown, South Africa, H.Tsikos@ru.ac.za
[3]Dept. of Earth Sciences, Utrecht University, Utrecht, The Netherlands, m.j.vanbergen@uu.nl
[4]RSES, The Australian National University, Canberra, Australia, stephen.eggins@anu.edu.au, leslie.kinsley@anu.edu.au

We present results of in situ stable Si isotope measurements on Archean Cherts and Banded Iron Formations (BIFs) from the Pilbara (Western Australia) and Barberton (South Africa) greenstone belts. Samples were obtained from outcrops and drill cores. In this study we used: (1) a Microlas Geolas Laser ablation (LA) system equipped with a 193 nm Excimer laser at the VU Amsterdam (VUA) and an inhouse built LA system with a 193 nm Excimer laser at ANU. Both LA systems were connected to a Thermo Neptune MC-ICPMS. Molecular isobaric interferences of $^{12}C^{16}O^+$, $^{14}N^{2+}$, $^{14}N^{16}O^+$ that are present on masses ^{28}Si, ^{29}Si and ^{30}Si, were resolved with the aid of the medium resolution slit (RP=4000). An ablation pit size of 49 by 300um and with a 5-10 Hz repetition rate and 5 $J.cm^{-2}$ was used on both LA systems. The LA measurements on the VUA and ANU MC-ICPMS were performed with the same setup as described by [1]. To assess precision, accuracy and matrix effects of the LA technique, chert and BIF samples were analyzed that were previously characterized for silicon isotopes by micro-drilling and subsequent liquid chromatographic purification **[1]**. A chemically homogenous chert sample that is well characterized for silicon isotopes by wet chemical techniques and has a $\delta^{30}Si$ of 0.50 ±0.20 (2sd, relative to NIST RM8546) was used as a standard at both the VUA and ANU.

LA silicon isotope results are significantly influenced by the matrix; e.g. in BIF layers with more than 50% Fe_2O_3, we observed a shift of more than 40‰ in $\delta^{30}Si$, compared to values obtained by micro drilling and chemical purification. This shift is highly dependant on the tuning conditions of lasers and MC-ICPMS. It is therefore necessary to carefully match standards and samples, and only if the chemical composition of the samples is relatively constant can accurate data be obtained.

BIFs display significant variations between iron poor and iron rich layers (maximum observed difference ~1.8‰). In all cases the iron rich layers have higher $\delta^{30}Si$ than the iron poor layers. Variations in $\delta^{30}Si$ of up to 1.2‰ were also observed within individual layers on a mm scale. Cherts display variation between black and white bands with a maximum $\delta^{30}Si$ difference of 1.2‰. The data of this study confirm that silicon isotope signatures are not altered by post depositional burial and metamorphism. Therefore, the laser ablation technique opens new possibilities to unravel the depositional mechanisms for Archean BIFs and cherts, provided samples are correctly matrix-matched with standards.

Thiocyanate adsorption onto ferrihydrite and its availability during the aging of ferrihydrite

H. P. VU[1]* AND J. W. MOREAU[1]

[1]University of Melbourne, Melbourne, Australia, hong.vu@unimelb.edu.au (* presenting author)

Thiocyanate (SCN^-) contamination results from many industrial sources such as coal processing and metal separation. Although SCN^- is less toxic than cyanide it is still harmful to aquatic organisms and humans [1]. The use of iron oxides to immobilise contaminants has been shown to be an effective treatment [2] but little is known about the removal of SCN^- by iron oxides.

Adsorption of SCN^- onto the surface of ferrihydrite and the availability of adsorbed SCN^- during the transformation of ferrihydrite were studied using macroscopic techniques complemented with Transmission Electron Microscopy (TEM). The preliminary results show that adsorption of SCN^- decreases as pH increases. Adsorption of SCN^- is strongly affected by the concentration of electrolyte with decrease in concentration of $NaNO_3$ leading to increase in SCN^- adsorption (Figure 1). This indicates that SCN^- adsorbs onto ferrihydrite as outer-sphere complexes.

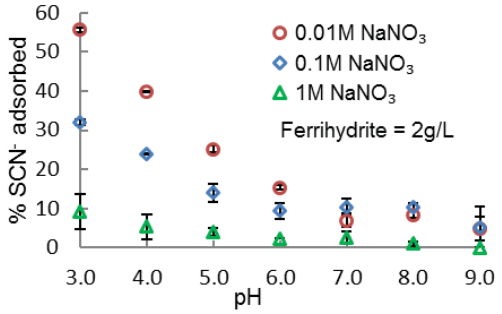

Figure 1: Macroscopic uptake of SCN^- as a function of pH and electrolyte concentration.

The adsorption isotherm reveals that adsorption capacity increases with increases in concentration of SCN^-. Within the studied range of SCN^- concentrations adsorption capacity is linearly proportional to the equilibrated concentration of SCN^- (Figure 2).

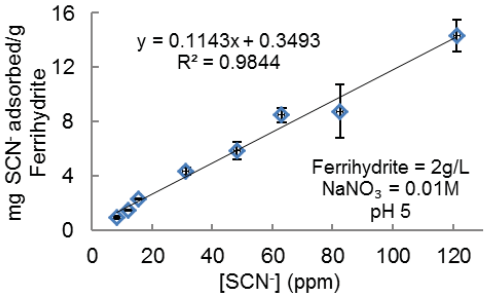

Figure 2: SCN^- adsorption isotherm.

The knowledge of the speciation of coinage metals is a key element of the understanding of their transport in hydrothermal conditions and the formation of metal deposits from geological fluids. In saline brines, the main carrier of silver, solvated as silver cation Ag^+, is the chloride anion Cl^-. Extrapolations from low temperature thermodynamical data, which suggest either $AgCl_2^-$ [1] or $AgCl_4^{3-}$ [2] as the dominant species at high temperature, lead to solubilities of Ag-bearing minerals that differ by two to three orders of magnitudes at elevated temperature. Molecular modelling can help putting constrains on these models. The interaction of silver or other coinage metals with water is, however, more complex than that of simple cations like Na^+ [3]. Moreover, at elevated temperatures, the hydrogen bond network of water is largely broken and its dielectric constant much lower than at ambient conditions, which questions the validity of empirical force-fields. First-Principles Molecular Dynamics (FPMD) makes no a priori assumption about the interactions and enables the description of such complex chemical systems.

We will first briefly discuss the FPMD description of supercritical water, with particular emphasis on the role of long-range dispersion interactions [4]. We will then present results from large scale FPMD simulations of silver solvation in aqueous solutions at ambient and elevated temperature, with various Cl^- contents. Modelled EXAFS signals will be compared to recently obtained experimental data. In agreement with very recent FPMD study using smaller samples [5], we find that $AgCl_2^-$ and $AgCl_3^{2-}$ species are stable at ambient conditions. We also find the $AgCl_4^{3-}$ complex to be stable in our simulations. $AgCl_2^-$ is found to be a linear complex while $AgCl_3^{2-}$ is trigonal planar and $AgCl_4^{3-}$ a distorted square planar complex. The largest complexes are, however, not stable at high temperature where only AgCl and $AgCl_2^-$ complexes are found. These structures appear very fluxional. Transitions between these complexes at ambient temperature and chlorine exchange in $AgCl_2^-$ at high temperature occur on a time-scale of about 10 picoseconds. The role of quadrupolar polarizability of Ag^+ in the stability and dynamics of these structures will be discussed.

Clumped isotopes applied to Silurian brachiopod shells, Gotland/Sweden

ULRIKE WACKER[1*], JENS FIEBIG[1], AXEL MUNNECKE[2], MICHAEL M. JOACHIMSKI[2] AND BERND R. SCHÖNE[3]

[1]Department of Geosciences, Goethe University Frankfurt, Germany (* U.Wacker@em.uni-frankfurt.de; Jens.Fiebig@em.uni-frankfurt.de)

[2]GeoZentrumNordbayern, FAU Erlangen-Nürnberg, Germany (axel.munnecke@pal.uni-erlangen.de; michael.joachimski@gzn.uni-erlangen.de)

[3]Institute of Earth Sciences, Johannes Gutenberg-University, Mainz, Germany (schoeneb@uni-mainz.de)

Several O and C isotope records from the Silurian sequence of Gotland/Sweden are published, which are based on brachiopod shell calcite [1,2], micritic limestones [3] and biogenic phosphates [4]. All recorded isotope curves show similar trends with pronounced shifts in $\delta^{18}O$ and $\delta^{13}C$. Besides, three C isotope excursions are measured globally. Correlation between the C and O isotope signals supports the assumption that the values are of primary origin.

We are applying the carbonate clumped isotope thermometer to brachiopod shells from Gotland to decipher both, temperature and $\delta^{18}O$ of Silurian ocean water. Based on the ordering of isotopes, i.e. on the clumping of ^{13}C-^{18}O within carbonate groups of minerals, precipitation temperatures can be estimated independently of the isotopic composition of the water from which the crystals grew. The measure of temperature is Δ_{47}, which describes the deviation of the 47/44 abundance ratios in CO_2 derived from H_3PO_4 digestions of carbonates from the corresponding stochastic 47/44 ratios.

Due to different pre-analyses of brachiopod shells from Gotland various researchers interpret most of these fossils not to be influenced by diagenesis [1,2], and stable isotope ratios are assumed to be preserved. However, temperatures between 40 and 60°C are estimated from first Δ_{47} measurements, which indicate a diagenetic overprint that affected at least ^{13}C-^{18}O clumping in carbonate groups. It needs to be proven, whether the $\delta^{18}O$ values reflect a pristine signal or had been reset at least in parts, and whether geochemical signatures of these fossils can be used for paleoreconstructions. This will be tested by a comparison of Δ_{47} and $\delta^{18}O$ values of pristin and altered shell sections which were already identified using CL and SEM. Additionally, trace element concentrations were measured.

High resolution sampling along ontogenetic transects of four brachiopods indicate variations in $\delta^{18}O$ of about 1.5‰ within the single shells expressed by a constant trend to lower values with increasing distance to the hinge, but a shift to higher values in the most anterior part. Δ_{47} analyses along growth directions of these brachiopods might provide additional information whether the O isotopic pattern reflects primary fluctuations of temperature or $\delta^{18}O$ during growth of the organisms.

Phosphate reaction with PbS stimulates microbial S oxidation

ALEXANDRA B. WALCZAK[1*], NATHAN YEE[2], LILY Y. YOUNG[2]

[1]Rutgers Univeristy, Microbiology and Molecular Genetics, New Brunswick, USA walczaal@eden.rutgers.edu (*presenting author)

[2]Rutgers Univeristy, Dept. of Environmental Science, New Brunswick, USA nyee@envsci.rutgers.edu, lyoung@aesop.rutgers.edu

Introduction

The reaction of lead (Pb) and phosphorus-containing compounds causes the formation of pyromorphite-type mineral phases [1]. These mineral phases have a low solubility and bioaccessibility, making their formation a viable option for stabilizing Pb contamination in soil and waste rock [1]. In cases where an insoluble mineral such as galena (PbS) is the primary form of Pb the effect of phosphorus amendment on the sulfur speciation and the microbial interactions are still poorly understood.

Methods

Pure culture experiments were set up with *Bosea* sp. str. WAO, an autotroph which is capable of growth on several reduced sulfur sources [2]. Replicate flasks containing 40 mM phosphate buffered growth medium and 2 mM PbS were amended with either live cells (active), killed cells (sterile control), or no cells (background control). Flasks were maintained aerobic by shaking and incubated at 30°C. Periodic samples were taken to measure sulfate, total dissolved sulfur, and Pb in the bulk medium and solid phase.

Results and Conclusions

The addition of phosphate to the growth medium containing powdered PbS caused the abiotic exchange of sulfide for phosphate, producing lead phosphate $Pb_9(PO_4)_6$, and was confirmed by powder XRD. The released sulfide was then available for strain WAO to use as an energy source for growth.

The microbial oxidation of the released sulfide to sulfate was compared to background and sterile controls. Active cultures containing 2 mM PbS produced ~1.7 mM sulfate as measured by IC within 9 days of incubation. No production of sulfate was measured in the background and sterile controls during the incubation period. Metal analysis by ICP-OES measured less than 0.2 mM of Pb in the bulk medium after incubation for active or control, while 2 mM was recovered after acid extraction of the precipitate.

WAO preferentially colonized the PbS mineral surface to gain access to the released sulfide as shown with epifluorescence microscopy on slide cultures of mineral powder. The biomass of strain WAO increased on the mineral surface over time and was also shown to be closely associated using confocal microscopy.

Although the phosphate amendment makes the Pb less bioavailable, it is increasing the availablity of sulfide which can stimulate the growth of sulfide oxidizing organisms and the production of sulfate. In situations where there are high concentrations of these sulfidic minerals the addition of phosphate may increase the microbial S oxidation, an important contributor to acid mine drainage.

Combined ^{182}W, ^{186,187}Os and ^{142,143}Nd Constraints on Terrestrial Differentiation and Mantle Mixing

R. J. WALKER*, M. TOUBOUL AND I. S. PUCHTEL

Department of Geology, University of Maryland, College Park, MD 20742, USA, rjwalker@umd.edu

Collectively applied, the ^{182}Hf-^{182}W, ^{190}Pt-^{187}Re-^{186,187}Os, and ^{146,147}Sm-^{142,143}Nd radiogenic isotope systems are potentially useful for exploring early planetary processes ranging from metal-silicate segregation (via Hf-W and Re-Pt-Os), to crystal-liquid fractionation in silicate domains (via Hf-W, Pt-Re-Os and Sm-Nd). For example, study of the 2.8 Ga Kostomuksha komatiites of NW Russia revealed a mantle source that was ~15 ppm enriched in ^{182}W, relative to ambient terrestrial W [1], and also modestly enriched in ^{186}Os and ^{187}Os [2], relative to chondritic references. However, the ^{142}Nd and ^{143}Nd isotopic compositions of these rocks are generally consistent with those of the contemporary ambient mantle [3,4]. Accounting for these isotopic characteristics is challenging. The necessary magnitude of fractionations of Hf/W, Pt/Os, and Re/Os could have been generated as a result of metal-silicate segregation at high temperatures and pressures. Such process would not have affected the initial chondritic Sm/Nd. Thus, these komatiites may, in part, have tapped a mantle domain that formed within the first ~30 Myr of the Solar System history, as required by the 8.9 Myr half-life of ^{182}Hf. The Kostomuksha komatiite source, however, had abundances of highly siderophile elements (HSE) within the range of estimates for the primitive mantle, so the dominant Os isotopic signature, as well as the HSE abundances, must have been inherited from ambient mantle that had acquired its HSE budget via late accretion. It is equally plausible that the necessary fractionations occurred as a result of crystallization and overturn in transient magma oceans, although the effects of such processes on Pt/Re/Os systematics at present are poorly constrained. Further, diverse, 3.8 Ga rocks from Isua, Greenland [5] have also been shown to have comparable ^{182}W enrichments, yet are also enriched in ^{142}Nd. Consequently, it is clear that there is no single mantle domain that can account for the variations that are now known for ^{182}W, ^{186}Os, ^{187}Os, and ^{142}Nd in ancient rocks. Numerous, important implications can be drawn from these findings. For example, the requirement for very early formation of the sampled mantle domain means that the putative giant impact that led to creation of the Moon > 50 Ma following Solar System formation [6], could not have resulted in the complete melting and mixing of the mantle. In addition, long-term preservation of such early-formed mantle domains means that materials added to the mantle by late accretion might also still be preserved in the mantle and identified by diverse nucleosynthetic signatures. A new era of study of early-Earth chemical geodynamics, utilizing combined short- and long-lived radiogenic isotope systems, has begun.

[3]Old Dominion University, OEAS, Norfolk, USA, gcutter@odu.edu
[4]Old Dominion University, OEAS, Norfolk, USA,psedwick@odu.edu

Introduction

Each year a significant amount of coal fly ash enters the environment, where it can potentially cause adverse effects by releasing a range of bioactive trace elements. In this context, environmental studies have largely focused on the leaching of trace elements from the coal ash in landfills by rainwater and groundwater, while there has been relatively little study of the release of bioactive trace elements from coal fly ash deposited in natural fresh waters such as rivers and lakes. Furthermore, the batch leaching methods that have been used to study the interaction of rainwater and groundwater with coal ash in landfills are not readily extrapolated to rivers and lakes, where the solution to particle ratio is typically high. To address this problem, we have adapted a flow-through leaching protocol that has been used to estimate the fractional dissolution of trace elements from mineral aerosols in ocean waters. We argue that this rapid leaching technique more closely resembles the interaction of coal ash with fresh waters, thus allowing us to assess the release of coal fly ash constituents into rivers and lakes.

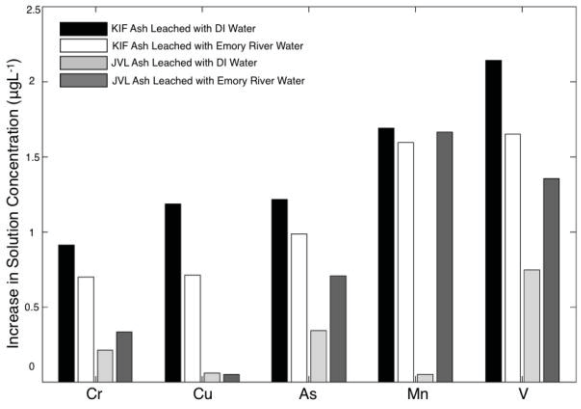

Figure 1. Increase in solution concentration of bioactive trace elements in Emory River water leach solutions.

Results

We have performed a series of flow-through leaching experiments using fresh coal ash and fresh waters collected from rivers and lakes in the southeastern U.S. A suite of bioactive trace elements have been analyzed in the resulting leach solutions and in acid digests of the bulk coal ash, using high-resolution plasma-source mass spectrometry. Our preliminary data (Fig. 1) suggest that significant fractions of a number of bioactive trace elements in coal ash are readily soluble in natural fresh waters.

Age of the Stillwater Complex

COREY J. WALL[1*], JAMES S. SCOATES[1], RICHARD M. FRIEDMAN[1], AND WILLIAM P. MEURER[2]

[1]Pacific Centre for Isotopic and Geochemical Research, Earth and Ocean Sciences, Vancouver, BC, Canada, cwall@eos.ubc.ca*, jscoates@eos.ubc.ca, rfriedman@eos.ubc.ca

[2]ExxonMobil Upstream Research, Houston, TX, USA, william.p.meurer@exxonmobil.com

The Archean Stillwater Complex, a large mafic-ultramafic layered intrusion in the Beartooth Mountains of Montana (USA) and host to the world-class J-M Reef platinum group element deposit [1], may represent a sub-volcanic reservoir through which a substantial quantity of magma was processed [2]. We present U-Pb ID-TIMS results for ultramafic, mafic, and felsic samples from across the exposed max. 8 km-thick intrusion to constrain the age and duration of magmatism associated with this major intrusion. The accepted age for plagioclase-rich rocks of the Banded Series is ca. 2704 Ma with older ages recorded in the basal sills and dikes (2710-2713 Ma) [3]. Our U-Pb results for three mafic samples reveal a small range of weighted $^{207}Pb/^{206}Pb$ ages at ca. 2709 Ma, which we interpret as the age of crystallization of the Banded Series: 2708.80 ± 0.75 Ma (baddeleyite) and 2709.05 ± 0.85 Ma (zircon) for a troctolite from the J-M Reef package in the Lower Banded Series, and 2708.70 ± 0.82 Ma (zircon) for an olivine gabbronorite in the OB3 Zone and 2709.82 ± 0.51 Ma (zircon) for anorthosite from the AN2 Zone of the Middle Banded Series. A preliminary age of 2710.7 ± 1.1 Ma for high Th/U (8-14) zircon from a feldspathic orthopyroxenite at the top of the Bronzitite Zone suggests that the lower Ultramafic Series could be resolvably older than the overlying Banded Series.

Small-volume granophyric and pegmatitic rocks are found throughout the Banded Series and some may represent extreme differentiates [4]. Samples studied include a pegmatitic ksp-qtz core to a gabbroic pegmatoid in the Lower Banded Series (N1 Zone), an alaskite (quartz diorite) and an amphibole-rich reaction zone between the alaskite and anorthosite (AN1 Zone) in the Middle Banded Series, and an amphibole-bearing granophyre from the Upper Banded Series (GN3 Zone). U-Pb dating of zircon from the N1 pegmatite yields a weighted $^{207}Pb/^{206}Pb$ age of 2709.65 ± 0.80 Ma, which is identical to ages from the dated mafic rocks. Zircon grains from the other three samples are strongly metamict and U-Pb results are strongly discordant (12-86%). Stepwise leaching experiments on the GN3 granophyre reveal two distinct Pb-loss events at ca. 2.0 Ga (leachates) and 2.7 Ga (residues). Titanite ages from the pegmatite and the alaskite agree with the U-Pb zircon ages from the mafic rocks (ca. 2708-2709 Ma), whereas titanite from the other two samples exhibits a wide range of discordance (1.5-61%) suggesting multiple stages of Pb-loss. The disturbed titanite U-Pb systematics and identified Pb-loss events reflect the combined thermal and alteration effects produced by a wide range of post-crystallization events, including the emplacement of a regionally extensive granitic batholith (Mouat quartz monzonite), multiple generations of mafic dike swarms, and greenschist facies metamorphism.

Tc(IV) complexation with organic ligands - an overview

NATHALIE A. WALL[1*], AND BAOHUA GU[2]

[1] Washington State University, Pullman, US, nawall@wsu.edu

[2] Oak Ridge National Laboratory, Oak Ridge, US, gub1@ornl.gov

Introduction

^{99}Tc represents a significant environmental contaminant because of its long half-life of $2.1 \cdot 10^5$ y, complex chemistry, and potential high mobility. Although the anionic and highly mobile Tc(VII) is stable under oxic environments, it can be reduced to the sparingly soluble Tc(IV) and reductive precipitation of Tc has been proposed as one of the promising remedial approaches to impede Tc migration offsite. However, at environmentally relevant pH Tc(IV) forms cationic and neutral species, which can complex to soluble organic ligands and induce Tc(IV) solubilization. It is therefore necessary to assess Tc(IV) complexation with relevant organic ligands, including ligands commonly found in nuclear wastes (e.g. EDTA) and those ubiquitous in the environment (e.g. humic acids).

Results and conclusions

The stability constants of Tc(IV) with acetate, citrate, EDTA, and a variety of humic acids were experimentally determined using a solvent extraction method – a summary of these stability constants is presented in **Table 1**. Additionally, the influence of selected organic ligands (EDTA and humic acids) on Tc(IV) solubity was experimentally measured [6]. The addition of 2.5 mM EDTA leads to an increase of Tc(IV) solubility by over two folds, reaching a Tc(IV) concentration of $4 \cdot 10^{-7}$ M at pH 6, in good agreement with modeling calculations performed based on the EDTA stability constants, which predicts a Tc(IV) solubility of $4.6 \cdot 10^{-7}$ M in presence of the same EDTA concentration and at same pH.

Acetate	$\log\beta^0_{1,-1,1} = 2.8 \pm 0.3$	I = 0 M	[1]
Oxalate	$\log\beta^0_{1,0,1} = 7.2 \pm 0.2$	I = 0 M	[2]
Citrate	$\log\beta^0_{1,-1,1} = 7.5 \pm 0.2$	I = 0 M	[3]
Humic acid	$\log\beta_{1,-1,1} = 6.2 \pm 0.6$	I = 0.1 M	[4]
EDTA	$\log\beta^0_{1,0,1} = 20.0 \pm 0.4$ $\log\beta^0_{1,1,1} = 25.3 \pm 0.5$	I = 0 M I = 0 M	[5]

Table 1: Stability constants of Tc(IV) complexes with different organic ligands.

Global variations in H_2O/Ce: Relationships to arc magma geochemistry & slab surface temperatures

PAUL J. WALLACE[1*], DANIEL M. RUSCITTO[2], LAUREN B. COOPER[3], TERRY PLANK[4], ELLEN M. SYRACUSE[5], AND CRAIG E. MANNING[6]

[6]University of California, Los Angeles, USA, manning@ess.ucla.edu

We have compiled a dataset of 114 primitive arc magma compositions from melt inclusion and whole rock analyses to compare volatile contents, slab tracers, and calculated subduction component compositions between 18 subduction zone segments spanning the global range in slab thermal structure [1]. The average primitive magma H_2O content in our dataset is 3.3 ±1.2 wt.% (1 s.d.) for melts erupted within 50 km of the volcanic front. Although there is a wide range of volatile contents in magmas within individual arcs, the highest values occur in magmas erupted from vents along the volcanic front, where the subducting slab is located 104 ±29 km (avg. ±1 s.d.) beneath the surface. This observation, coupled with positive correlations between H_2O, Cl, S, and B contents and predictions from geodynamic models, provides strong evidence for the active supply of subduction-related components from the slab beneath volcanic arcs. Furthermore, calculated subduction component compositions become increasingly solute-rich in arcs with hotter slabs (lower thermal parameter), suggesting that fluids/melts of differing compositions are added beneath different arcs.

We have also calculated slab fluid temperatures for 51 volcanoes in 10 subduction zones [2] using the newly developed H_2O/Ce thermometer. The temperatures, adjusted to *h*, the vertical depth to the slab beneath the volcanic arc, range from ~730 to 900°C, and agree well (within 30°C on average for each arc) with sub-arc slab surface temperatures predicted by recent thermal models. The coherence between slab model and surface observation implies predominantly vertical transport of fluids within the mantle wedge. Slab surface temperatures are well reconciled with the thermal parameter (the product of slab age and vertical descent rate) and *h*. Arcs with shallow *h* (80 to 90 km) yield a larger range in slab surface temperature (up to ~200°C between volcanoes) and more variable magma compositions than arcs with greater *h* (120 to 180 km). This diversity is consistent with coupling of the subducting slab and mantle wedge, and subsequent rapid slab heating, at ~80 km. Slab surface temperatures warmer than the H_2O-saturated solidus implicate ubiquitous melting at the slab surface. Our results imply that melts or solute-rich fluids, and not H_2O-rich fluids, are thus the agents of mass transport to the mantle wedge.

Leak fluid chemistry control on ^{90}Sr sorption mechanism in sediments

S. H. WALLACE[1*], S. SHAW[1], K. MORRIS[2], J. S. SMALL[3] AND I. T. BURKE[1]

[1]School of Earth and Environment, University of Leeds, UK, *eeshw@leeds.ac.uk
[2]School of Earth, Atmospheric and Environmental Science, University of Mancherster, UK
[3]National Nuclear Laboratory, Risley, Warrington, UK

Strontium-90 is present in contaminated land at nuclear sites around the world and is also an important component of nuclear waste inventories. The mobility of ^{90}Sr in the subsurface is often controlled either by adsorption to sediment particle surfaces or incorporation reactions into secondary mineral precipitates. Here, we present an overview of a multidisciplinary study examining the behaviour of ^{90}Sr in West Cumbrian unconsolidated aquifer sediments under a range of groundwater compositions relevant to contaminated land scenarios.

Batch experiments have been used to test the influence of pH and ionic strength (IS) on the degree of adsorption to sediments. In other experiments hyperalkaline cement waters were used to investigate the effect of mineral alteration and secondary mineral precipitation on ^{90}Sr sorption. Experiments containing 20 ppm Sr^{2+} (spiked with ^{90}Sr tracer) were sampled from 2 days up to one year. Change in Sr speciation within sediments was determined using X-ray absorption spectroscopy and sequential extraction techniques. Mineral precipitates were characterised using SEM, microprobe and TEM techniques.

pH titration experiments showed the optimum pH for maximum ^{90}Sr sorption was between pH 6-8, and in experiments using low IS groundwaters ~99% of ^{90}Sr was removed from solution at circumneutral pH. In experiments with higher IS artificial waste tank leachate at pH 11 only ~80% of ^{90}Sr was removed, suggesting that higher concentration of ions in solution inhibited ^{90}Sr sorption. When both Na^+ and Ca^{2+} solutions were used as competing ions, sorption decreased markedly in experiments when IS was greater than 5 mmol L^{-1}, closely matching model fits to the data. Sr K-edge EXAFS analysis of sediment samples revealed Sr-O bond distances at 2.60 Å, indicating outer-sphere sorption. Sequential extractions found 70-85% of ^{90}Sr remained exchangeable after one year.

In contrast, experiments using high pH young cement water, found sorption to be >99% despite the extremely high IS, suggesting another mechanism of Sr removal predominated. Sequential extractions on a sediment sample aged at 70°C for a year, found that 25±6 % of ^{90}Sr was residual. Sr K-edge EXAFS analysis of a 70°C aged sample contained evidence for an additional Sr-O-Si(Al) bond distance at 3.45 Å consistent with Sr incorporation in a neoformed silicate mineral. XRD and electron microscopy analysis indicate that the neoformed mineral could be chabazite, a zeolite mineral.

These results indicate that at contaminated nuclear sites, ^{90}Sr in the environment will predominantly sorb at circumneutral pH, but can be remobilised if affected by higher IS solutions. In a high pH cementitious repository, alkali alteration of silicate minerals could provide a sink for ^{90}Sr, however even after alteration much of the ^{90}Sr may remain exchangeable with other ions in solution.

Geochronology and geochemistry of Precambrian basement from the Fort McMurray area, Alberta: A geothermal perspective

NATHANIEL WALSH,[1*], THOMAS CHACKO[1], LARRY M. HEAMAN[1], S. ANDREW DUFRANE[1], JOHN J.M. DUKE[2], JACEK MAJOROWICZ[3]

[1]Earth & Atmospheric Sciences, University of Alberta, Edmonton, Canada, nwalsh@ualberta.ca (*presenting author), Tom.Chacko@ualberta.ca, Larry.Heaman@ualberta.ca, dufrane@ualberta.ca

[3]Department of Physics, University of Alberta, Edmonton, Canada, majorowi@ualberta.ca

To reduce energy consumption and CO_2 emissions in oil sands processing, a study was recently initiated under the auspices of the Helmholtz-Alberta Initiative to examine the possibility of a cheaper source of hot water in northeastern Alberta by geothermal methods. The particular geothermal method being considered is Engineered Geothermal Systems (EGS), which aims to extract economic quantities of heat from low permeability and porosity rocks. The present study is the geochemical/petrological component of a larger investigation into the feasibility of using EGS as a hot water source for oil sands processing in the Fort McMurray area. Specifically, our aim is to document the rock types, mineralogy, crystallization ages and heat-producing element concentrations of 37 basement drill core samples recovered in 23 petroleum exploration wells drilled into Precambrian basement within a 125 km radius of Fort McMurray.

Most of the drill core samples are part of the Taltson Magmatic Zone (TMZ), a 500 km long, Paleoproterozoic orogenic belt, more than half of which is buried beneath Phanerozoic cover rocks. The investigated samples are mostly deformed granitoids but also include two amphibolites and one sample likely of metasedimentary origin. Preliminary U-Pb isotopic age determinations conducted on thin sections of these samples by laser-ablation MC-ICP-MS yielded zircon crystallization ages ranging from 1.84 to 2.4 Ga. On the basis of these data, the samples can be divided into five age suites. The oldest suite yields relatively poorly constrained ages between 2.2 and 2.4 Ga (n=5). A second group of samples indicate ages of ~2.0 Ga (n=2). The samples from suites 3 (n=6) and 4 (n=6) record two separate periods of granitoid intrusion at 1.95-1.97 Ga and 1.925-1.935 Ga, respectively. The ages noted above correspond well with ages that have been previously reported from the exposed part of the TMZ. The 5th suite (n=1), which is from the Rimbey domain immediately to the south of the TMZ, yielded an age of ~1.84 Ga

Heat-producing element concentrations (K, U, Th) are wide ranging but on average the younger granitoid suites have higher concentrations of these elements. The youngest suite (Suite 5) has by far the highest U content (13.6 ppm) of any of the rocks analyzed in the present study. The temperature recorded at the base of the 2.36 km deep Hunt Well, which is located near the Fort McMurray town site, is ~47°C [1]. Given that the Hunt Well is drilled in the older (ca. 2.2-2.4 Ga) and less radiogenic rock suite, it seems reasonable to conclude that geothermal gradients at other locations within the study area may be at least as high as those documented at the Hunt Well.

Origin of saline aqueous fluids in the lower crust

JOHN V. WALTHER

Department of Earth Sciences, Southern Methodist University, Dallas, TX 75275, USA, (walther@smu.edu)

Low viscosity H_2O plus NaCl fluids are an important component of metamorphism in the lower crust. They contain up to 50 wt% NaCl (X_{NaCl} = 0.24) that varies widely over short distances judging from fluid inclusion observations. The origin of these fluids is still being debated. Downward circulation of salt-rich surface fluids by thermal convection has been proposed [1]. These fluids are ruled out because they are too buoyant to penetrated downward into the middle or lower crust where fluid pressure = rock pressure and buoyancy controls fluid movement. Low-density H_2O-rich fluids at these depths like magmas tend to rise but not sink.

H_2O with NaCl is given off by upper mantle and lower crustal magma during the final stages of their crystallization. By interacting with deeply buried evaporites these fluids could become even more saline [2]. The fluids could then flux upward. However, considering the dynamics of fluid flow it is likely that these fluids will coalesce into major channelways as they are transported upward. This is similar to flow in the dendritic pattern of stream flow on the earth's surface. These mantle and lower crustal fluids are then likely to be contained in widely spaced fractures and not produce the extensive metamorphism or variable salt concentration observed.

This leaves fluids produced locally during metamorphism by the destruction of hydroxyl containing minerals as they are buried. These fluids are produced at every volatile mineral that is undergoing destruction with increased pressure and temperature and therefore can be pervasive. In pelites ~2 moles of fluid per 1 kg of rock is produced to medium grades of metamorphism [3]. This process is responsible for the low salinity fluids that are a component of mid-crustal metamorphism. How can some of these fluids become more saline at lower crustal levels while others are less so?

The H_2O-bearing minerals, hornblende in mafic rocks and mica in pelites that survive to lower crustal levels have lower thermodynamic activities. This occurs because Cl^- and F^- are present in the OH^- sites in these minerals. For the activity of muscovite in mica:

$$SiO_2 + KAl_3Si_3O_{10}(OH)_2 \rightarrow KAlSi_3O_8 + Al_2SiO_5 + H_2O$$

$$\mathbf{K} = a_{ksp}a_{kyn}a_{H2O}/a_{qtz}a_{mus}$$

$$a_{mus} = (X_K)(X_{Al\sim M1})(X_{Al\sim M2})^2(X_{Si})^3O_{10}(X_{OH})^2$$

When this low activity mica finally becomes unstable, high Cl^- fluids are produced with F^- partitioning into the remaining minerals. For the same activity of the hydrous phase if the F^- changes locally the fluid produced will change its Cl^- fluid concentration. Mica and hornblende compositions whose destruction produces $X_{Cl} > 0.24$ can be present [4],[5]. Destruction of compositionally different hydrous phases, stable in the lower crustal because of their high salt content, can account for the range of salinities observed in fluid inclusions.

Mössbauer evidence of rapid pyrite formation during the interaction between dissolved sulfide and lepidocrocite

M. WAN[1*], C. SCHRÖDER[1,2] AND S. PEIFFER[1],

[1]Department of Hydrology, University of Bayreuth, Bayreuth Germany, moli.wan@uni-bayreuth.de (* presenting author); s.peiffer@uni-bayreuth.de

[2]Center for Applied Geoscience, Eberhard Karls University, Tübingen, Germany, christian.schroeder@ifg.uni-tuebingen.de

Mössbauer spectroscopy has been applied to study mineral transformation during the interaction between lepidocrocite and dissolved sulphide with two different initial concentration ratios. Synthetic lepidocrocite enriched with the Mössbauer sensitive isotope Fe-57 was reacted with dissolved sulphide at neutral pH in an anoxic glove box, the initial molar ratios of iron and sulphide being 3.125 and 0.5, respectively. Solid samples for Mössbauer analysis were collected by filtration at different time steps after 15 min, 2hrs, 48hrs, 72hrs and 1 week for the 3.125 iron-sulphide ratio; and after 72h and 1 week for the 0.5 iron-sulphide ratio. Dissolved and solid phase ferrous iron, dissolved sulphide and elemental sulphur were measured with wet chemistry analysis techniques in parallel runs.

Mössbauer spectra provide evidence for rapid pyrite formation within 48hrs during the reaction at an initial molar ratio of 3.125. Pyrite formation was accompanied by a decrease of elemental sulphur and mackinawite, which is the main iron intermediate product with minor pyrrhotite and magnetite. At the ratio of 3.125, excess lepidocrocite existed and dissolved sulphide was completely consumed after 15min. Acid extractable Fe(II) concentration was in excess of that of Fe(II) bonded as FeS, which has been reported before[1,2] and the difference of the two iron species was defined as excess Fe(II)[2]. In the experiment with an initial ratio of 0.5, lepidocrocite was completely transferred to mackinawite. In this system dissolved sulphide was not completely consumed even after 1 week. No pyrite could be detected. Species including elemental sulphur and mackinawite were stable in 1 week without any further transformation. The long term preservation of unstable iron sulphide minerals at a low concentration of dissolved sulphide is consistent with the observation in marine sediment [3].

These experiments show an important linkage between rapid pyrite formation and surplus lepidocrocite and/or the excess Fe(II) formed during reaction. Together with wet chemistry analysis results we propose that some of the electrons donated by sulphide oxidation are preserved temporally in the lepidocrocite bulk and lead to formation of the excess Fe(II) fraction and ultimately rapid pyrite formation.

The characterization and evaluation of different biochars as reactive materials for Mercury (II) stabilization

ALANA O. WANG[1*], PENG LIU[1], CAROL J. PTACEK[1], DAVID W. BLOWES[1], RICHARD C. LANDIS[2], WILLIAM R. BERTI[2], JAMES A. DYER[2]

[2]E. I. du Pont de Nemours and Company, Wilmington, USA

Introduction and Objectives:

Biochars, produced through low-temperature pyrolysis of environmental biomass, have considerable potential for stabilizing heavy metal in aquatic and sediment systems through surface adsorption reactions. Recent advancements in the uses of biochars to remediate heavy metals, such as Pb, Cd, and Cu, have not been extended to Hg. The complex properties of biochars can also limit the understanding about the leaching potential for nutrients and trace elements. The objectives of this study are to characterize and evaluate different types of biochars for their potentials for Hg treatment and soluble elements releasing. In this study, three biochars produced from different raw materials were evaluated, including spent mushroom soil, pine bark, and fresh mushroom soil containing poultry manure. These biochars were first characterized by surface area, total sulphur and total carbon content, scanning electron microscope/energy dispersion X-ray spectroscopy (SEM/EDX), and Fourier transform infrared spectroscopy (FT-IR). These biochars were then evaluated through a series of laboratory batch studies using Hg-spiked river water or natural river water as the equilibrating solution witin 2 days and 14 days reaction time. Subsequent washing experiments were conducted to evaluate the sustained reactivity of biochars.

Results and Discussions:

The mushroom soil-based biochars (spent, and fresh mushroom soil) were observed to have higher surface area than the wood-based biochar, which are consistent with their irregular distorted porous structures as observed by SEM. The surfaces of all three biochars were also observed to have various functional groups as indicated through FT-IR analyses, which might stablize Hg and release nutrients and trace elements. In batch studies with all three biochars using Hg-spiked river water, greater than 80% and greater than 95% of Hg was removed from the Hg-spiked river water with an initial concentration of 8000 ηg L^{-1} within 2 days and 14 days reaction time, repectively. When compare these bacth tests, the mushroom soil-based biochars were found to reduce greater amount of Hg from the Hg-spiked river water than the wood-base biochar, indicating better surface adsorptions. In batch studies using natural river water, the alkalinity and concentrations of nutrients (NH_3-N, PO_4-P, DOC), anions (SO_4^{2-}, Cl^-), and trace elements (As, Pb, and Cu) were observed to increase especailly in the river water containing the mushroom soil-based biochars. The effective Hg removal and the soluble constituents releasing were all consistent with the presence of functional groups observed by FTIR. Step-wise washing of these biochars resulted in substantial decrease in the release of nutrients and anions with minor decrease in the Hg removal rates. In fact, greater than 85% Hg removal rates were observed in all batch equilibrating solutions after using these washed biochars. These results suggest that, of all biochars evaluated, both the unwashed biochars and the washed biochars have the potential to immobilize Hg without the addition of soluble constituents as mentioned above.

Ore texture and titanomagnetite composition of the Hongge Fe-Ti-V oxide deposit, SW China: implications for the origin of the deposit

CHRISTINA YAN WANG[1*], MEI-FU ZHOU[2]

[1] Key Laboratory of Mineralogy and Metallogeny, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China, wang_yan@gig.ac.cn (* presenting author)

9h. Trace elements in oxide minerals from ore deposits: Petrogenetic interpretation and implications for exploration

The Hongge magmatic Fe-Ti-V oxide deposit in the Panxi region, SW China, is hosted in a layered mafic-ultramafic intrusion. The 2.7-km-thick, lopolith-like intrusion consists of the Lower, Middle and Upper zones, which are mainly composed of olivine clinopyroxenite, clinopyroxenite and gabbro, respectively. Abundant oxide layers mainly occur in the Middle zone and the lower part of the Upper zone.

There are net-textured, massive and disseminated Fe-Ti oxide ores. Fe-Ti oxides include Cr-rich and Cr-poor titanomagnetites and granular ilmenite. Both Cr-rich and Cr-poor titanomagnetites contain ilmenite lamellae. Cr-rich titanomagnetite is usually enclosed in olivine and clinopyroxene of disseminated ores in the lower parts of both the Lower and Middle zones and contains 1.89 to 14.9 wt.% Cr_2O_3 and 3.20 to 16.2 wt.% TiO_2, whereas Cr-poor titanomagnetite typically occurs in net-textured and massive ores of the Middle and Upper zones and contains <0.4 wt.% Cr_2O_3 and 0.11 to 18.2 wt.% TiO_2.

Cr-rich titanomagnetite of the disseminated ores is clearly an early crystallized phase, whereas Cr-poor titanomangetite of the net-textured and massive ores crystallized later. Occurrence of Cr-poor titanomagnetite, granular ilmenite and apatite as clusters in the net-textured ores may have formed from Fe-Ti-(P) rich melts. We propose that these Fe-Ti-(P) rich melts were immiscible in silicate magmas similar to the formation of magmatic sulfide ores and that immiscibility occurred because of oversaturation of Fe, Ti and P during the crystallization of silicate minerals. The segregation of dense Fe-Ti-(P) rich melts behaved like a heavy mineral that settled downward in a silicate crystal mush to form net-textured and massive Fe-Ti oxide ores as part of the cumulate sequence.

The co-evolution of prokaryotes-eukaryotes and ocean chemistry on the North China Craton during Mesoproterozoic (1.6–1.3 Ga)

CHUNJIANG WANG*, MENG WANG, JIN XU, YONGLI LI, YAN YU, JIE BAI, TING DONG, JUN WANG, SHIPENG HUANG, XIAOYU ZHANG, LEI WANG, XIAOFENG XIONG, AND HAIFENG. GAI

State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum, Beijing 102249, China, wchj333@126.com (* presenting author)

The North China Craton is one of the representative research regions for revealing the co-evolution of life and ocean environment during the early-middle Mesoproterozoic (1.6–1.3Ga). Here, we report the results of a comprehensive study including biomarkers, C-S-isotopic and trace elemental compositions, based on high-resolution geochemical sampling from 6 sections and 4 core-drills.

The Mesoproterozoic sedimentary successions on North China Craton record a suit of negative $\delta^{13}C_{carb}$ values, averaging from -2.4‰ to -1.7‰ for the carbonate sequences, which are more negative than the uniform $\delta^{13}C_{carb}$ values (0.0–1.0‰) of the Mesoproterozoic sedimentary successions worldwide [1]. It may suggest that the primary production and organic carbon burial in the North China Carton were extremely low during the Mesoproterozoic, which are probably the main constraints for sustaining an intermediate redox state in the oceans during the Mesoproterozoic Era. The $\delta^{13}C_{org}$ values of the three organic-rich sequences (Gaoyuzhuang, Hongshuizhuang and Xiamaling Fm) are -34.1‰, -32.7‰ and -31.5‰ in avereage, respectively. Likewise, the $\delta^{13}C_{org}$ values are highly homogeneous in each Formation, and present a well coupling with $\delta^{13}C_{carb}$ in the secular variation.

The carbonate sediments usually present eukaryotic biomarker assembly including C_{26}–C_{29} regualr steranes, 4- and 3-m-steranes as well as very lower concentrations of dinosteranes, but the shales have no detectable steranes. Our biomarker data reveal well co-evolutions of eukaryotes/prokaryotes and ocean environments on the North China Craton during the Mesoproterozoic.

Mo concentrations are 4.7, 42.1 and 17 ppm, and Mo/TOC values are 5.0, 8.9 and 5.2 (ppm/wt%) in average for Gaoyuzhuang, Hongshuizhuang and Xiamaling Fm, respectively. The Mo-lean figures are consistent with the Mo enrichment pattern in Mesoproterozoic black shales [2, 3]. The $\delta^{34}S$ values of sulfides decrease from 7.1–20.6‰ in Gaoyuzhuang Fm to -6.3–7.7‰ in Xiamaling Fm, indicating an enhanced S geochemical cycling during Xiamaling period (1.4–1.3Ga).

The size dependent interaction between nanoparticles and collagen: Implications for biomineralization

DONGBO WANG[1(*)], JING YE[1], STEVEN HUDSON[1], VIVEK PRAHBU[1], KEANA SCOTT[2] AND SHENG LIN-GIBSON[1]

[1]Polymers Division, National Institute of Standards and Technology, dongbo.wang@nist.gov (* presenting author)

[2]Surface and Microanalysis Division, National Institute of Standards and Technology

Collagen is the primary structural protein found in connective tissues, making up more than 25 % of the whole-body protein content. It is also the primary biological molecule responsible for the organization of mineralized tissue. Bone and teeth are surprisingly complex organic/inorganic hybrid structures mainly composed of type I collagen and the calcium phosphate mineral – hydroxyapatite (HA). These tissues are hierarchically organized from the nanometer to the meter length scales. Traditionally, collagen mineralization was thought to occur by calcium phosphate nucleation and growth processes from dissolved ions. Recently, these ideas have been challenged and the new concept of "non-classical" mineralization has emerged[1]. In biological tissues it is now proposed that the mineralization process starts with the formation of small amorphous calcium phosphate (ACP) clusters, which infiltrate collagen, and then transform to form intrafibular HA.

We begin to test this new "non-classical" understanding of collagen mineralization by studying the interaction between collagen matrices and colloidally stable/non-reactive gold nanoparticles as models for ACP. We measure *in situ* changes in collagen matrix mechanical properties after introduction of gold nanoparticles using Quartz Crystal Microbalance with Dissipation monitoring (QCM-D). The QCM-D data show a particle size dependent interaction, where 2 nm particles strongly interact with the collagen matrix and cause stiffening in the bulk. Larger particles (3 nm – 40 nm) only interact to the surface of the collagen matrix and don't penetrate into the bulk. We observe the same interaction dynamics with both positively and negatively charged nanoparticles. These results have been confirmed through imaging by AFM and FIB/STEM. However, 2 nm particles, which are comparable in dimension to ACP clusters may not fully infiltrate into collagen fibrils. Therefore size alone likely does not fully explain the ability of ACP clusters penetrate into collagen and form mineralized structures. Continuing work focuses on using QCM-D to investigate stabilized calcium phosphate nanoparticles and their interactions with collagen matrices.

Geochronology and tectonic nature of "Precambrian" basement in eastern Heilongjiang province, NE China: constraints from zircon U-Pb dating

F. WANG[1], F.H.GAO[1*], W.L. XU[1], W.L. HAO[1], H.H. CAO[1]

[1]College of Earth Sciences, Jilin University, Changchun 130061, China (jlu-wangfeng@sohu.com, *gaofuhong213@sina.com)

NE China is located in the eastern section of the Central Asian Orogenic Belt (CAOB) [1]. The region includes the Erguna, Xing'an, Songnen-Zhanguangcai Range, and Jiamusi massifs from west to east. Recently, with application of modern dating techniques, previously beleived Precambrian strata in the Erguna, Xing'an, and Jiamusi massifs have been almost disintegrated into sedimentary and igneous rocks with different Paleozoic ages rather than Precambrian [2-4]. Then, when did the previously determined Precambrian strata including the Dongfengshan (DG), Zhangguangcailing (ZG), and Yimianpo groups (YG) in the Songnen-Zhangguangcai Range Massif form? These Precambrian strata are composed of a set of meta-sedimentary and volcanic rocks. The dating results, together with field geology, indicate that the oldest sedimentary unit from the DG deposited later than 821 Ma, whereas the youngest sedimentary unit deposited during Early Permian (275~271 Ma), that the sedimentary rocks from the YG formed later than Late Triassic (223 Ma), whereas the volcanic rocks from the YG formed in Early Jurassic (179~189 Ma) and Early Permian (271~292 Ma), respectively, and that the oldest sedimentary rocks from the ZG formed during 450~426 Ma, whereas youngest sedimentary rocks formed during 226~211 Ma. The above dating data indicate that the ZG and YG formed from Early Paleozoic to Early Mesozoic, whereas the majority of the DG formed from Early to Late Paleozoic, some of them formed in the Neoproterozoic. Combined with field profile and dating results, we conclude that the ZG could be a tectonic mélange and the melanging could take place during Early-Middle Jurassic.

Furthermore, sediment provenance analysis indicates that nearly all the sediments of these previously beleived Precambrian strata directly sourced from the Phanerozoic intrusions in the Songnen-Zhangguangcai Range and Jiamusi massifs while widespread occurrence of the detrital zircons with ages of 0.8~0.9 Ga and 1.8 Ga as well as 2.4-2.5 Ga implies the existences of the Neoproterozoic magmatisms and remnants of an ancient Precambrian basement within the Songnen-Zhangguangcai Range Massif in eastern Heilongjiang Province, NE China.

This research was financially supported by research grants from the Natural Science Foundation of China (Grant 41072038).

3D geochemical exploration in Luanchuan district, China

GONGWEN WANG [1*], EMMANUEL JOHN M. CARRANZA[2]

[1]China Universityof Geosciences, Beijing, China, gwwang@cugb.edu.cn (*presenting author)
[2]Faculty of Geo-Information Science and Earth Observation (ITC), University of Twente, Enschede, The Netherlands,carranza@itc.nl

The Luanchuan district in the Henan province of China is known for its large porphyry-skarn type Mo deposits and hydrothermal vein type Pb-Zn-Ag deposits. Jurassic intrusions are associated with Mo-W deposits, whereas the Luanchuan Group is associated with Pb-Zn-Ag deposits. The Pb-Zn-Ag deposits are distributed around the Jurassic porphyry-Mo intrusions and hosted in a metamorphic sedimentary formation consisting of terrigenous clastic rock and carbonatite of either Mesoproterozoic or Neoproterozoic age, which is intruded by Neoproterozoic gabbro and syenite and Jurassic acidic porphyries. The Mo and Pb-Zn-Ag deposits are controlled by Jurassic structural and magmatic activities. Anticline structure is associated with the Mo-W deposits, whereas syncline structure is associated with the Pb-Zn-Ag deposits. However, in fault and fold structrual zones, porphyry intrusions can generate complex and multiple types of mineral deposits. For example, the outcropping Yuku porphyry-type Mo-W deposit led to the discovery at depth of the hydrothermal vein-type Pb-Zn-Ag orebody in the Luanchuan Formation based on borehole data. Thus, analysis and integration of exploration data sets in three-dimension (3D) is desirable

Multiple scales and multiple types of geochemical exploration datasets were used to identify mineral potential targets in 3D. The vertical range of the datasets is less than 2.5 km. District scale (1:50,000) stream sediment multi-element geochemical were analyzed using multifractal modeling, resulting in delineation of Mo-W anomalies zones associated with intrusions and and Pb-Zn-Ag anomalies associated with the Luanchuan Formation, and NW- and NE-trending fault structures. The anomalous zones were further used to identify potential targets by integrating the information with a '2.5D' geological model (e.g., mineralized strata and Jurassic intrusions) based on 1:10,000 scale digital elevation model of the study area. Prospect scale (1:2,000) structural-lithological data and 14-element lithogeochemical data along nine exploration lines (105 km) were analyzed and integrated, resulting in delineation of Mo-W and Pb-Zn-Ag mineralized zones. The lithogeochemical data were analyzed using PCA and multifractal mapping. The delineated mineralized zones were further used in conjunction with a 3D geological model of the study area [1] to identify concealed Mo and Pb-Zn-Ag deposits. Deposit-scale borehole geological and geochemical data were used (a) to delineate probable mineralized zones by multifractal concentration-volume modeling of geochemical data and (b) and to estimate metal resources by fractal modeling based on available orebody thickness and metal grade data. The analyses resulted in identification of eight potential Mo targets and 15 potential Pb–Zn–Ag targets.

Types and metallogenic age of molybdenum deposits in Eastern Jilin Province, NE China

H. WANG*, Y. S. REN, AND H. N. HOU

College of Earth Science, Jilin University, Changchun, China, wang_hui2007@ qq.com (* presenting author)

The eastern Jilin Province is an important molybdenum metallogenic centralized region, besides the Daheishan deposit (super large-scale), over ten large or medium-scale molybdenum deposits have been discovered in recent ten years, such as Fuanpu, Jidetun, Dashihe, Liushengdian and Shuangshan molybdenum deposits. The rich molybdenum resources have drawn much attentions. According to the newly research data, molybdenum deposits in this area generally belong to the porphyry type, but the mineralization types can be listed as veinlet-disseminated type and stringer-network vein type.

The Daheishan molybdenum deposit is one of typical veinlet-disseminated porphyry deposits. The molybdenum ore bodies are hosted in a complex massif which is mainly consisted of the granodiorite porphyry and biotite granodiorite, and composed of veinlet-disseminated molybdenites. The zonation of mineralization and wall-rock alteration is obvious. The granodiorite porphyry in the complex massif playing an important role in molybdenum mineralization has a zircon U-Pb age of (170±3) Ma[1], and the Re-Os isochron age of molybdenites is (168±3.2) Ma[2], which suggest that Daheishan molybdenum deposit was formed in early Yanshanian period.

Comparatively, the stringer-network molybdenum mineralization is more common and important than the veinlet-disseminated mineralization in this area. Such newly discovered deposits as Liushengdian, Dashihe and Shuangshan molybdenum deposits belong to this type. The similar characteristics of these deposits are as follows. Firstly, most molybdenum ore bodies are consisted of quartz-molybdenite veins accompanying a spot of single molybdenite veins. Secondly, the wall-rock alteration zonation is ofen weak or even lacking. Thirdly, not all the ore-bearing rock-bodies are metallogenic rock-bodies, for example, the currently discovered ore bodies of Dashihe deposit are all hosted in Neo-proterozoic strata made up of epimetamorphic rocks. The Re-Os weighted mean ages of Liushengdian, Dashihe, and Shuangshan deposits are (169.36±0.97) Ma, (186.7±5) Ma and (173.3±1.1) Ma, indicating that molybdenum mineralization took place in early Yanshanian period.

The molybdenum deposits which occurred in eastern area of Jilin Province are the products of porphyry-fluid metallogenic system and mainly formed in early Yanshanian period (metallogenic ages vary from 190Ma to 165Ma). Metallogenic process was possibly influenced by the subductin of the Pacific plate. There are two mineralization types including veinlet-disseminated type and stringer-network vein type, and most belong to the latter. The stringer-network vein is a significant prospecting indicator in this area.

[5]Dept. of Earth Sciences, Natl. Taiwan Normal Univ., Taipei, Taiwan

Since the Cenozoic time, the SE Asian continental margin was subjected to extension, which is generally believed as a consequence of the India-Asia collision during late Cretaceous [1]. This extension led to submergence of the margin and formation of rift basins with widespread intraplate basaltic volcanism. The Paleogene volcanics occur sporadically in the rift basins, whereas only Neogene basalts are exposed on land in Penghu Islands and NW Taiwan [2, 3]. In this study, volcanic rocks recovered from the CPC deep boreholes in the SW Taiwan, in the Taiwan Strait and in Penghu Islands, and from the outcrop on Huahsu islet are studied for their ages and geochemical characteristics. $^{40}Ar/^{39}Ar$ dating results of these volcanic rocks show two episodes of volcanic activities: ~57-38 Ma (Eocene) and ~11-10 Ma (Miocene). The volcanic rocks are composed dominantly of basalts and basaltic andesites, with few dacites and rhyolites, but no andesite was found. The two episodes of basaltic rocks have distinct chemical characteristics. Some Eocene basalts belong to alkaline series, while all Miocene basalts are sub-alkaline. In comparison to the Miocene basalts, the Eocene basalts are more depleted in basaltic components such as Ca, Fe and Ti but have higher Al content. They are also more enriched in large ion lithophile elements (LILE) and light rare earth elements (LREE) and depleted in high field strength elements (HFSE). The Sr-Nd-Pb isotope compositions show the Miocene basalts are relatively homogeneous and unradiogenic ($\varepsilon Nd = 3.8 \sim 6$) similar to the depleted onland Miocene basalts [3] and the MORB-type South China Sea basalts [4], whereas the Eocene basalts have the wider range ($\varepsilon Nd = 5.6 \sim -3.2$) with more radiogenic feature towards an enriched mantle source. The overall geochemical characteristics suggest these two episodes of basalts originated from distinct mantle sources: a refractory mantle source metasomatized by subduction-related processes to generate the Eocene basalts and a fertile but isotopically depleted mantle source similar to that of MORB for the Miocene basalts. These two mantle sources most likely reside in the lithospheric mantle and asthenospheric mantle, respectively. The change of magma mantle sources with time reflects evolution of the tectonic regime from the initial rifting along the continental margin to upwelling of the asthenosphere due to thinning of lithosphere. Considering the extension regime is dominant in the Paleogene, together with lack of the intermediate andesite indicative of subduction, the subduction origin proposed for the Eocene basalts due to their HFSE depletion appears unfavorable.

Introduction

Calcium orthophosphate (Ca-P) is the most ubiquitous form of P among the geological phosphate-bearing minerals [1]. Unraveling the kinetics of Ca-P precipitation and dissolution is important for our understanding of the transformation and mobility of dissolved phosphate species in soils [2]. Here we use *in situ* atomic force microscopy (AFM) coupled with a fluid reaction cell to study the interaction of phosphate-bearing solutions with calcite surfaces.

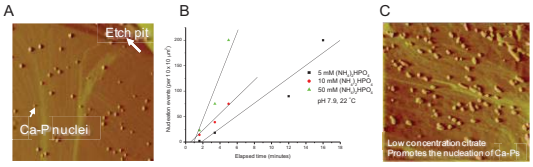

Figure 1: Kinetic analysis of surface nucleation of Ca-P phases on calcite substrates. (A) AFM image of Ca-P particles on a calcite surface during *in situ* nucleation events. Image 10 × 10 μm. (B) Plot against time of different concentrations of $(NH_4)_2HPO_4$. (C) AFM image of Ca-P phases on calcite in the presence of 1 μM citrate with 50 mM $(NH_4)_2HPO_4$ at pH 7.9. Image 10 × 10 μm.

Results and conclusion

We observe that the mineral surface-induced formation of Ca-P phases is initiated with the aggregation of clusters leading to the nucleation and subsequent growth of Ca-P phases on calcite, at various pH values and ionic strengths relevant to soil solution conditions. A significant decrease in the dissolved phosphate concentration occurs due to the promoted nucleation of Ca-P phases on calcite surfaces at elevated phosphate concentrations and more significantly at high salt concentrations. Also, kinetic data analyses show that low concentrations of citrate caused an increase in the nucleation rate of Ca-P phases. However, at higher concentrations of citrate, nucleation acceleration was reversed with much longer induction times to form Ca-P nuclei. These results demonstrate that the nucleation-modifying properties of small organic molecules may be scaled up to analyze Ca-P dissolution - precipitation processes that are mediated by a more complex soil environment. This *in situ* observation, albeit preliminary, may contribute to an improved understanding of the fate of dissolved phosphate species in diverse soil systems.

The Early Cretaceous tectonomagmatic events in the northern Lhasa Terrane have been associated with subduction, slab breakoff of the Bangong–Nujiang Ocean seafloor, and final Lhasa–Qiangtang amalgamation [1]. However, mantle dynamic processes involving crust-mantle interaction in the northern Lhasa Terrane during the Late Cretaceous are poorly known largely due to the limited understanding of the nature of related magmatic records. In this paper we report a dataset of bulk-rock major and trace element, Sr-Nd isotope, zircon U-Pb age, and zircon Hf isotopic data of the Zhuogapu volcanic rocks, ~50 km SE Nyima in the northern Lhasa Terrane. Zircon SHRIMP U-Pb dating reveals that the Zhuogapu volcanic rocks were emplaced at ca. 91 Ma. These rocks consist of andesites and dacites, having MgO of 2.78–5.86 wt.% and 2.30–2.61 wt.% with $Mg^{\#}$ of 54–64 and 55–58, respectively, comparable to high-Mg andesite and high-Mg dacite elsewhere [2]. Eight andesite samples have small negative $\varepsilon_{Nd}(t)$ (–3.2 to –1.7), with $(^{87}Sr/^{86}Sr)i$ of 0.7054–0.7065. Similar Sr-Nd isotopic compositions are also present in the three dacite samples [$\varepsilon_{Nd}(t)$ = –2.7 to –2.2, $(^{87}Sr/^{86}Sr)i$ = 0.7056–0.7060]. Thirteen analyses from a dacite sample give positive zircon $\varepsilon_{Hf}(t)$ (+5.6 to +8.7). Geochemical data indicate that the dacites could not have been produced by fractional crystallization (or plus assimilation) of the andesites. In combination with the other coeval magmatic rocks that show within-plate basalt [3] and adakitic affinities [4] recently reported in the northern Lhasa Terrane, the Zhuogapu Mg-rich volcanic rocks are interpreted as a result of varying extents of mixing between the juvenile lower crust-derived melts and ancient Lhasa basement-derived melts. Considering the development of the Upper Cretaceous molasse that unconformably overlies the underlying strata and the timing of lithospheric stacking or crustal thickening that occurs during the Late Cretaceous [5], we propose that the generation of the coeval 90 Ma magmatism in the northern Lhasa Terrane may be a result of lithospheric delamination. The abundant inherited zircons of ca. 90 Ma with positive zircon $\varepsilon_{Hf}(t)$ from Miocene ultrapotassic rocks in the central Lhasa Terrane (Zhidan Zhao, personal communication, 2011) suggest an extensive magma underplating at the base of the central–northern Lhasa lower crust, corroborating our lithospheric delamination model.

Breakdown of the Ostwald step rule: The precipitation of calcite and dolomite from seawater at 25° and 40°C

TINGTING WANG[1*], AND ALFONSO MUCCI[2]

[1]Department of Earth and Planetary Sciences, McGill University tingting.wang@mail.mcgill.ca (* presenting author)
[2]Department of Earth and Planetary Sciences, McGill University alfonso.mucci@mcgill.ca

The scarcity of modern dolomite contrasts strongly with its common abundance in Precambrian sedimentary rocks of marine origin, leading to the paradox commonly referred to as the "dolomite problem". Whereas dolomite can readily be precipitated from aqueous solutions above 100°C [1], many researchers have attempted unsuccessfully to synthesize dolomite at room temperature from natural seawater [2,3,4]. Nevertheless, by alternating between intervals of dissolution and precipitation in artificial brines, Deelman (1999) succeeded in synthesizing dolomite at low temperatures (between 313K and 333K) [5]. He concluded that multiple cycling of a solution between supersaturation and undersaturation with respect to calcite and/or aragonite would cause the metastable phases to dissolve, while preserving more stable nuclei (i.e. dolomite and/or low-magnesian calcite) in solution. In this study, natural seawater was equilibrated with $CaCO_3$ (mixture of calcite and aragonite) at a pCO_2 of 10%. After the solution reached equilibrium, the solid was removed by filtration and ambient air (pCO_2 ~390 ppm) was bubbled through the CO_2-charged seawater solution, leading to a highly supersaturated solution and the nucleation and precipitation of aragonite. Following the precipitation, the ambient air-equilibrated solution and the precipitate were purged with a 10% CO_2:N_2 gas mixture and most of the original precipitate was redissolved. Once equilibrium was reached with the gas phase, the solution should be undersaturated with respect to aragonite, in equilibrium with calcite, but remain supersaturated with respect to dolomite. The cycle was repeated 18 times and ultrapure N_2, instead of ambient air, was used in the last cycle, to maximize precipitate recovery. As the solution remains supersaturated with dolomite at all times, after each cycle, dolomite nuclei should be preserved and accumulate at the expense of aragonite and calcite. The experiments described above were carried out at 25° and 40°C. Preliminary results show that, whereas aragonite was obtained during the first few cycles, only calcite was detected in the last cycle of the experiments carried out at 25°C.

Natural gas accumulation characteristic of the reef-oolitic reservoir in LG area, Sichuan basin

WANG TONGSHAN[1*], LI XIA[1], AND LI QIUFEN[1]

[1] Research Institute of Petroleum Exploration & Development, PetroChina
wts2007@petrochina.com.cn (*presenting author)

Reef and oolitic gas reservoirs previously discovered in Changxing Fm.–Feixianguan Fm. of Sichuan Basin mainly are distributed in the platform margin zone near Kaijiang-Liangping Bay. This zone has high prospectivity for gas exploration at present [1]. Longgang area is located in the main body of platform margin zones on the southwestern sides of the bay. Longgang area is located in the gentle structural belt lying west of the Huayingshan fault zone.

Reef and oolitic reservoirs are controlled by the high energy facies belts on the south sides of Kaijiang-Liangping Bay, with only slight changes in width and spatial location corresponding to variations in paleoenvironment and paleotopography at different geological periods. The lithologies and spatial types of the reef and oolitic reservoirs are similar, as are their other properties such as porosity and permeability. The oolitic reservoirs of the Feixianguan Fm. in the Longgang area have a porosity of 2%–12% (5.8% on average) and a permeability of 0.06mD–223.7mD (27.7 mD on average). The gypsum rock units in the Lower Triassic Jialingjiang Fm. and Middle Triassic Leikoupo Fm. are thick (117m–557m), widely distributed, and act as the effective caprock for reef and oolitic gas accumulations. The type and salinity of formation water also support the strong preservation conditions of the reef and oolitic series of strata. The homogenization temperatures of fluid inclusions in the reef and oolitic reservoirs generally include three phases. The homogenization temperature for phase I was low (<120°C), indicating liquid hydrocarbon inclusions and early charging of liquid hydrocarbons. The homogenization temperature for phase II was 130°C–150°C, reflecting gas-liquid two-phase hydrocarbon inclusions as well as mixed charging of liquid hydrocarbons and their associated gas with gaseous hydrocarbons sourced from coal measures. The homogenization temperature for phase III was higher than 160°C, indicating brine-bearing gas hydrocarbon inclusions. In addition, the Laser Raman detection result shows H_2S-bearing high temperature gas hydrocarbon inclusions (dominated by methane) as well as liquid hydrocarbon pyrolysis and gas generation and accumulation events (Fig 1). Tectonic activities in the Himalayan period caused gas reservoirs to be destroyed or reformed. Gas reservoirs were subsequently shaped after the Himalayan period.

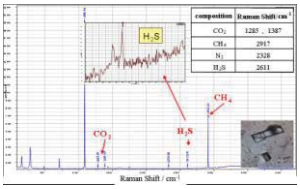

Figure1: Raman spectra of reef and oolitic reservoir fluid inclusions

This study has great significance in the promotion of research into gas accumulation and the development of gas fields in the region.

Mapping geo-anomalies of hydrothermal mineralization in southeastern Yunnan district, China

WENLEI WANG[1*], JIE ZHAO[1], QIUMING CHENG[1,2,3] AND JIANGTAO LIU[1,3]

[1]Department of Earth and Space Science and Engineering, York University, Toronto, Canada, bznb@yorku.ca (*presenting author)
[2]Department of Geography, York University, Toronto, Canada
[3]State Key Laboratory of Geological Processes and Mineral Resource, China University of Geosciences, Wuhan and Beijing, China

Based on existing literature [1], controlling factors of hydrothermal mineralization in southeastern Yunnan district are granite intrusions, sedimentary carbonate rocks and complex structural features. Geo-anomalies associated with the superposition of these factors benefit mining activities in this area. Current research conducts an anomaly analysis by local singularity theory to characterize the influence of faults on the spatial distribution of geochemical signatures for enhancing mineral prospectivity.

Singularity theory is efficient to identify things' changing behaviors produced by geological processes, and the things can be materials, physical or chemical properties, events, and others with multifractality [2]. Discontinuously distributed geochemical signatures by tectonics are commonly used to delineate potential areas for targets of interesting. Applying singularity theory, geochemical anomalies of selected ore forming and associated elements are investigated and sorted into positive and negative, representing element accumulation and depletion properties, respectively. The positive anomalies well indicate weak local anomalies which are hidden within strong variance of background and were not properly identified by means classic methods. Moreover, selected element assemblages are integrated by Principal Component Analysis (PCA) to illustrate that the distribution of ore forming materials has undergone various geological processes. In the context of complex geologic structures, like highly faulted area, ore forming materials will have more space and time for migration and interaction with surroundings. Fault intensity defined as total length of faults per unit area is one of representatives of geologic structure complexity. By singularity theory, areas with increased intensity are identified to highlight spatial distribution properties of multi-element signatures.

For modeling mineral prospectivity, PCA is used further to integrate anomalies of element assemblages and fault intensity, patterns of which indicate both distribution of elements and migration tracks. The cross referencing of anomalies from geochemical and fault intensity efficiently characterizes the migration and sedimentation processes of ore-bearing hydrothermal solutions, and further supports researches on ore control mechanism.

[8]Institute of Global Environmental Change, Xi'an Jiaotong University, Xi'an, China, cheng021@umn.edu

Recent paleoclimate data and modelling results revitalized the debate on the cause of the extreme cold events in the North Atlantic during the last glacial period, the so-called Heinrich Stadials (HS), and their durations. We established a new speleothem $\delta^{18}O$ record from Botuvera Cave, southern Brazil, with significantly improved data resolution and U/Th chronology. The $\delta^{18}O$ profiles from multiple stalagmites show that the HS0 (YD), HS2, HS3 and HS4 are about 1,000 years long, centred approximately 12.0, 24.6, 30.0 and 39.0 kyr BP, respectively, whereas HS1 is about 3,000 years long, lasting from 17.5 to 14.5 kyr BP. Following the earlier studies, we interpret the calcite $\delta^{18}O$ as a proxy of South American Summer Monsoon (SASM) intensity in the region. The abrupt drops on calcite $\delta^{18}O$ during the HS intervals, with an amplitude of ~ 2‰ VPDB, suggest that climate change in this region is manifested as a dramatic increasing of rainfall. The one-to-one correlation with the updated Hulu Cave record confirms our previous finding that on millennial timescales, precipitation change in southern Brazil is anti-phased with that in the north, which is probably controlled by the meridional migration of the intertropical convergence zone (ITCZ). Thanks to micromill sampling techniques and high sample growth rates, we are able to characterize detail precipitation changes in southern Brazil during HS. For example, we did not observe SASM reversals in any HS except HS1 within which a minor $\delta^{18}O$ jump of ~ 0.5‰ can be identified at 15.3 kyr BP. Typically, precipitation increases abruptly in the earlier stage of HS, whereas during the later stage, precipitation decreases more gradually. This asymmetric pattern of change is different from the temperature behavior in the North Atlantic, which warms much more dramatically in the final stage of a HS than it cools in the initial phase. Such decoupling may suggest that ITCZ meridional migration is preferably controlled by the temperature gradient between the high and low latitudes in the cold hemisphere.

Isotope exchange rates and equilibrium fractionation between Cr(III) and Cr(VI)

XIANGLI WANG*, THOMAS M. JOHNSON

University of Illinois at Urbana-Champaign, Geology
wang298@illinois.edu (* presenting author)
tmjohnsn@illinois.edu

Kinetic fractionation of Cr stable isotopes resulting from reduction of mobile and toxic Cr(VI) to immobile and relatively non-toxic Cr(III) has been applied to monitoring and quantifying the extent of reduction in Cr-contaminated groundwater [1]. However, equilibrium fractionation resulting from isotope exchange between Cr(III) and Cr(VI) [2], if fast enough, can potentially overprint kinetic isotope fractionations. In this study we measured the exchange rates between solid Cr(III) and dissolved Cr(VI) at 25°C using a ^{50}Cr-enriched tracer method. We also measured the equilibrium fractionations between 0.2 M dissolved Cr(III) and 0.2 M dissolved Cr(VI) under acidic conditions at 25°C, 40°C, and 60°C.

At 60°C, the dissolved 0.2M Cr(VI) and Cr(III) reach isotopic equilibrium after ca. 39 days with $\Delta^{53}Cr_{VI\text{-}III} = 4.9 \pm 0.1$ ‰. At 40°C, the system reaches equilibrium at ca. 319 days with $\Delta^{53}Cr_{VI\text{-}III} = 5.2 \pm 0.1$ ‰. At 25 °C, the system evolved only ca. 20% toward equilibrium after 684 days of exchange.

The isotope exchange rates between solid Cr(III) (10 ppm to 100 ppm) and dissolved Cr(VI) (200 μM to 1400 μM) were measured over a range of conditions (pH 6.5 to pH8) and fit to an isotopic exchange model[3] to obtain the rate law: $R = 5.91 \times 10^{-3} \cdot [Cr(VI)]^{0.48} \cdot [Cr(III)]^{0.64} \cdot [H^+]^{0.39}$, where R gives the isotope exchange rate in mol/L/day. Using this rate law, we estimate that in an aquifer containing 20 μM Cr(VI) and 10 ppm solid Cr(III) with a pH of 7.5, it would take ca. 20 years to evolve halfway toward equilibrium.

Goethite, which we hypothesized might increase the exchange rate as a semi-conductor, actually slowed exchange somewhat, probably due to adsorption of Cr(VI). Anthraquinone-2, 6-disulfonate (AQDS), as an analog of electron shuttle molecules in natural organic matter, accelerated the exchange rate by a factor of 10.

Based on our results, we conclude: 1) higher temperatures, higher concentrations, lower pH, absence of adsorbing agents, and presence of electron shuttles contributed to faster isotope exchange rates between solid Cr(III) and dissolved Cr(VI); 2) For Cr-contaminated aquifers without organic electron shuttles and/or little exposed Cr(III), equilibrium fractionation will not overprint the kinetic-fractionation-based isotope method to monitoring remediation of Cr contamination; 3) For Cr-contaminated aquifers with abundant exposed Cr(III) and dissolved organic electron shuttles present, $^{53}Cr/^{52}Cr$ ratios of dissolved Cr(VI) may be affected by isotopic exchange over several years time or longer. This would tend to shift the ratios toward equilibrium values and away from values generated by kinetic isotope fractionation occurring during Cr(VI) reduction.

Understanding the contrasting geochemical features of the crust in the Jiangnan orogen

XIAO-LEI WANG [1*], GUO-CHUN ZHAO [2], JIN-CHENG., ZHOU [1], JIN-HAI. YU [1]

[1] State Key Laboratory for Mineral Deposits Research, Department of Earth Sciences, Nanjing University, Nanjing 210093, PR China, wxl@nju.edu.cn (* presenting author)

[2] Department of Earth Sciences, The University of Hong Kong, Pokfulam Road, Hong Kong, gzhao@hkucc.hku.hk

The primary uniform South China Block (SCB) was formed due to the Neoproterozoic amalgamation between the Yangtze Block to the northwest and the Cathaysia Block to the southeast, as recorded by the Jiangnan orogen (JO) in the interior of the SCB [1]. A significant crustal heterogeneity is confirmed here by the zircon Hf and whole-rock Nd isotopes for the rocks from the western and eastern segments of the JO. The Neoproterozoic granitoids of the eastern segment have positive zircon $\varepsilon_{Hf}(t)$ and neutral whole-rock $\varepsilon_{Nd}(t)$, obviously contrasting to the rocks from the western segment that show moderate negative epsilon values. This is also consistent with the whole-rock $\varepsilon_{Nd}(t)$ results for the low-greenschist-facies metamorphosed basement sequences in the JO. U–Pb dating results for detrital zircons constrain the duration of these sequences at ca. 0.86–0.82 Ga, obviously later than the timing of arc-continent collision in the area. Hf isotopes of the detrital zircons imply consistent crustal growths at 1.00–0.85 Ga and 2.60–2.45 Ga for both segments. However, another crustal growth at 1.75–1.50 Ga is significant for detrital zircons from the western segment. This growth period is absent in the Yangtze Block, but appears in the southern part of the Cathaysia Block. These U-Pb dating and Hf isotopic results suggest that the arc-continent collisional belt may have been the dominant source for the sequences in both segments but there exists an additional source from the Cathaysia Block and its adjacent continents (India and Antarctic?) for the western segment of the JO. Moreover, the 1.9–1.7 Ga and 2.6–2.4 Ga age peaks of the JO are consistent with those of the Cathaysia Block, while the age peaks of 3.0–2.7 Ga and 2.1–1.9 Ga that are characterized for the Yangtze Block are unmatched in the JO. Therefore, the basement sequences in the JO have close affinities with the crust of (1) the arc-continent collisional belt and (2) the Cathaysia Block and its adjacent continents during early to middle Neoproterozoic. More incorporation of old recycled crusts from the Cathaysia Block led to the more unradiogenic isotopic features of the basement sequences in the western JO.

Changes in fire regimes on Chinese Loess Plateau since the last glacial maximum and implications for linkages to paleoclimate and past human activity

XU WANG[1*], ZHONGLI DING[1], AND PING'AN PENG[2]

[1]Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China, xuking@mail.iggcas.ac.cn (* presenting author)

[2]Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China

A high-resolution black carbon (BC) record from 27.5 kyr BP to present was reconstructed using a chemical oxidation method on loess and paleosol samples from the Lijiayuan section of the Chinese Loess Plateau. The black carbon mass sedimentation rates (BCMSR) and carbon isotopic record reveal a paleofire history and its relationship with climate and vegetation changes at the study site. The BCMSR record was decomposed into two components: background BCMSR and the BCMSR peaks. The background BCMSR represents regional fires and shows high fire activities occurred contemporaneous with the Younger Dryas, Older Dryas, Heinrich events and Greenland stadials as registered in the loess grain size record. This suggests a rapid response of regional fires on the Loess Plateau to abrupt climate changes. Spectral analysis of background BCMSR showed two meaningful periodicities of 1620 and 1040 years, close to the cyclicity of the East Asian monsoon as recorded in the stalagmite $\delta^{18}O$ record in Central China. This indicates a tight control of millennial scale wet–dry changes in the monsoonal climate on regional fires on the Loess Plateau. By contrast, the BCMSR peaks are considered to reflect local fire episodes. The occurrences of local fires were more frequent during the last glacial period, with a maximum frequency of ~6 episodes/1000 years during the Last Glacial Maximum (LGM) (22.3 to 14.6 kyr BP), when the climate was drier and more continuous grassy fuels existed on the landscape. During the last glacial–interglacial transition (LGIT) period (14.6 to 11.0 kyr BP), fire frequency was largely reduced due to an increase in precipitation and more woody vegetation. If the LGIT period is taken as an analog for the projected near future, then future global warming alone may not produce large wildfires in northwestern China. Wildfires remained infrequent during the early-to-middle Holocene. Biomass burning increased after 4.0 kyr BP, when the climate became drier and land-use was more intensive. BC carbon isotope ratios may well reflect changes in the vegetation being burnt (i.e., grasses versus trees), yielding results consistent with the associated pollen data in the region.

A peatbog located in central France and impacted by both historical uranium mining activities and continued uranium leaching from granite rocks harbors U-enriched zones reaching a concentration of 4,000 mg/kg [1]. The mechanism leading to this remarkable accumulation is unknown. In order to unravel it and to evaluate the impact of proposed remediation strategies, extensive depth-resolved sampling of soil and porewater was carried out at three different areas as well as at a U-free background location in July and November 2011. Extensive physicochemical and microbial characterization of the four locations was conducted.

The porewater results show decreasing dissolved oxygen (DO) and increasing Fe(II) concentrations at 15-35 cm, suggesting that a redox transition zone (RTZ) occurs at that depth. The Fe(II) and total Fe profiles overlap exactly, suggesting that there is no measurable Fe(III) in the porewater. Secondly, a strong correlation was found between the U and Fe and U and total organic carbon (TOC) profiles, suggesting that U mobility may be controlled by adsorption to Fe oxides above the RTZ and by organic matter complexation in the porewater below that zone. Chemical extraction of U from soil revealed that U is concentrated at shallow depths (above 45 cm). Moreover, soil U occurs as a mixture of U(IV) and U(VI) and the profile of the ratio of U(VI)/U_{total} displays no clear trend as a function of depth. The persistence of U(VI) in a reduced environment may be attributable to its stabilization by complexation with organic matter. Finally, a clay layer, composed mainly of muscovite and quartz and rich in U, occurs at a depth of 10-25 cm in the peat soil. This unusual occurrence may have resulted from an anthropogenic input into the peat bog. The results to date suggest the involvement of iron oxides in immobilizing U in the oxic zone and the role of organic matter in binding U below the RTZ. Further mineralogical and microbial characterizations are underway to probe that current intrepretation of the data.

Abundances of sulfur, selenium and tellurium in mantle peridotites: constraints on planetary fractionation and late accretion

ZAICONG WANG* AND HARRY BECKER

Institut für Geologische Wissenschaften, Freie Universität Berlin, Germany, zaicongwang@gmail.com (* presenting author)

The addition of a chondritic late veneer after core formation has been a popular explanation for the high abundances and mostly chondritic ratios of highly siderophile elements (HSE) in the silicate Earth. The HSE are mostly hosted by sulfides, which also control the mantle's budget of S, Se and Te [1]. S, Se and Te are moderately to highly siderophile at high P-T conditions [2], but they also are moderately volatile elements with very similar 50% condensation temperatures [3]. Thus, the detailed fractionation of these elements in the mantle, also in relation to HSE abundances, may provide insight into both the volatile element composition of a late veneer and the influence of metal-silicate partitioning on their mantle abundances. Until recently, the mantle abundances of Se and Te have not been well constrained and the influence of secondary alteration, partial melting and refertilization on S, Se and Te abundances are incompletely understood [1,4]. To address this problem, we have obtained new precise S, Se and Te data on post-Achean peridotites. Fresh samples of variable fertility were digested in a high pressure asher and S, Se and Te concentration data were obtained on the same digestion aliquot by isotope dilution ICPMS. Sulfur, Se and Te concentrations display excellent linear correlations, and decrease with decreasing Al_2O_3 contents. In spite of large concentration variations, Se/Te remains relatively constant (6.8 ± 3.1, 2sd, n=39, total range from 3.8 to 10.0) with variable fertility. S/Se in lherzolites also displays no systematic variation (2710±1580, n=27, most within 2000-4000), whereas harburgites tend to have higher values. Similar results (S/Se=3120 ± 500, Se/Te=8.6±2) have been obtained on lherzolites from Lherz (Pyrenees), which are believed to reflect melt refertilization [4]. The absence of substantial systematic variations of S/Se and Se/Te with fertility suggests that during moderate degrees of partial melting or refertilization no systematic fractionations occur between S, Se and Te. This appears to be at odds with Se and Te data on MORB [5], but the latter may have been influenced by crustal fractionation processes. We conclude that Se/Te in mantle peridotites is constant, but 20-30% lower than CI chondrite (Se/Te ≈ 9), whereas S/Se might be about 10-20% higher than in CI chondrites. If the experimental partition coefficients are valid [2], the Se and Te budget of the mantle should reflect the contribution from a late veneer, whereas the suprachondritic S/Se, possibly hints at significant residual S in the mantle after core formation. CI chondrite normalized Te/Ir_N, Se/Ir_N and S/Ir_N of the mantle are 0.5 to 0.6 and constrain the predominant composition of the late veneer. These values are consistent with slightly volatile depleted CM2 or transitional C1/C2 chondrites.

Study on the influence factors of oil cracking

ZHAOYUN WANG[1]*, YONGXIN LI[1], SHIZHEN TAO[1], TIANSHU ZHANG[1] AND WENZHI ZHAO[2]

[1] Research Institute of Petroleum Exploration and Development, Petrochina, Beijing, China, wzy@petrochina.com.cn (*presenting author), lyxin@petrochina.com.cn, tsz@petrochina.com.cn, zhangtianshu@ petrochina.com.cn

[2] PetroChina Exploration & Production Company, Beijing, China, zwz@petrochina.com.cn

Oil cracking gas is an important source of deep gas. The oils generated from kerogen have three kinds of existing states: dispersive liquid hydrocarbon inside of source rocks, dispersive liquid hydrocarbon outside of source rocks and concentrated liquid hydrocarbon outside of source rocks, which is paleo-oil pool.

A comparetive study on the gas generating from oil cracking and from kerogen shows that large quantities of gas are generated from oil when temperature reaches 160℃, that is the major period of gas generation from oil cracking occurs later than that from kerogen degradation, giving rise to the relay contribution of natural gas generation at different evolution stages. The above knowledge enlarges exploring field of deep gas.

The average activity energy of oil cracking methane is relevant to oil physical properties through kinetic experiments. That of light oil and heavy oil is 62.34 Kcal/mol and 68.86 Kcal/mol, respectively. Both the oil samples were selected from Lunnan area, Tarim basin in China.

In view of the overall situation, high pressure constrains the decomposition of oil to gas, but this repression is not noticeable in fast buried condition and it also has different effect at different evolution stages.

Through kinetic experiments on mixtures of oil with various minerals, using mixture with mudstone represents dispersive liquid hydrocarbon inside of source rocks while with calcareous rock and sandstone represent dispersive liquid hydrocarbon outside of source rocks, we infer that the carbonatite has the greatest influence on oil cracking and can largely reduce the activation energy of oil cracking gas, which leads to the decrease of pyrolysis temperature. The mudstone ranks the second and the sandstone the smallest. The corresponding Ro value of main gas generating period in different medium are as follows: 1.5%～3.8% with pure crude oil, 1.2%～3.2% with dispersive oil in carbonatite, 1.3%～3.4% with dispersive oil in mudstone and 1.4%～3.6% with dispersive oil in sandstone.

Mg isotope fractionation between aragonite and fluid

ZHENGRONG WANG[1*] SHUANG ZHANG[1] CASEY SAENGER[1] AND PING HU[1]

[1]Department of Geology and Geophysics, Yale University, New Haven, USA, zhengrong.wang@yale.edu

The detectable Mg-isotope variations in biogenic aragonite (including corals, aragonitic forams and sponges) can potentially be applied as a paleoproxy. In this study, we report the result of a set of inorganic precipitation experiments to evaluate factors that could control Mg isotope fractionation between aragonites and fluid.

These 'free drift' experiments were conducted at 23.5-55 ^{o}C in freshwater by passive degassing for 1-4 weeks, with initial Ca concentration ([Ca]) spanning 400-2000 ppm and Mg/Ca molar ratio of 5.0. The solution chemistry (including pH and alkalinity) was closely-monitored over the course of the experiments. Observations using SEM after experiments demonstrate the occurrence of aragonite as major mineral phases. Magnesium from final solution and aragonite precipitates was purified by two chromatographic columns to remove Na, Ca, Sr and Ba, and pure Mg solution (in 5% HNO_3) was analysed for $^{26}Mg/^{24}Mg$ ratio by MC-ICP-MS (Neptune) at Yale University.

Our results show the initiation of aragonite precipitation occurred at different time for experiments having various [Ca], i.e., in an experiment initially having higher [Ca] aragonite started to precipitate earlier (e.g., a couple of hours for [Ca] = 2000ppm vs. a couple of days for [Ca] = 400 ppm), with a drop in pH and alkalinity at lower pH (e.g., pH = ~ 6.5 for [Ca]=2000ppm vs. pH = ~ 8.2 for [Ca] = 400 ppm). The Mg isotope fractionation between aragonite and final solution decreases noticeably with increasing temperatures, having a temperature sensitivity of ~0.01-0.0133‰/^{o}C. This fractionation also depends on [Ca], i.e., Mg isotope fractionations in aragonites precipitated from solutions with higher [Ca] are smaller, and have smaller temperature sensitivity. These results can be understood by a kinetic model that can explain both Mg and O isotope fractionation in aragonites, and are consistent with our previous observations and models on the kinetic process of aragonite precipitation from seawater during CO_2 degassing. This temperature-dependent Mg isotope fractionation has the potential to be used as a paleo-thermometer to extract SSTs from coral skeletons, and provide constraints on biomineralization process.

Petrogenesis of the Guposhan granitic complex, south China

ZHIQIANG WANG[1*], BIN CHEN[1,2], AND XINGHUA MA[1]

[1]Key Laboratory of Orogenic Belts and Crustal Evolution, Peking University, Beijing 100871, China, wangzq@pku.edu.cn (*presenting author)

[2]Institute of Geology and Exploration Engineering, Xinjiang University, Urumqi 830046, China, binchen@pku.edu.cn

Most Mesozoic granitic complex from south China consists of predominant intrusions and late-stage, supplementary intrusions (volumetrically much smaller than the former). Traditionally, supplementary intrusions were considered to be residual melts through fractionation of the predominant intrusions. We choose to study a typical granite complex, the Guposhan pluton, and propose a different model for its origin. The predominant intrusions of the Guposhan complex are the Wanggao biotite monzogranite/ syenogranite, the Lisong hornblende biotite monzogranite and the Xinlu biotite monzogranite. They are intruded by the late-stage, supplementary Baishuidai syenogranite. One sample from the supplementary granite is chosen for zircon La-ICP-MS U-Pb dating, and yields a concordant age of 155.3±1.5Ma, which is significantly younger than the predominant granites (162 Ma) of the Guposhan complex. In the plots of SiO_2 versus other major oxides and trace elements, the data points of the predominant and supplementary granites show different evolutionary trends, and compositional gaps are visible between the two phases, especially in the plots of Fe_2O_3 、P_2O_5、TiO_2、Sr、Ba versus SiO_2. Trace element modeling using Rb-Ba and Sr-Ba co-variations suggests that the supplementary phase is unlikely to be the derivative from the predominant granites via fractionation. So we conclude that the supplementary granite formed through a new partial melting event related to an extensional regime. The supplementary granite is a typical A-type granite, having high SiO_2, alkaline, HFSE contents as well as high Ga/Al and Fe/Mg ratios, and is extremely depleted in Ba, Sr, P, and Ti. The predominant phases of the Guposhan complex probably have formed through a process of magma mixing between dominantly crustal melts and minor mantle-derived magmas, as is suggested by the presence of micro mafic enclaves, and by the significantly varied Nd isotopic compositions, with εNd(t)=-6.0 to -3.7 (predominant intrusions) and -5.6 to -3.4 (supplementary intrusions). The trace elements and Nd isotopic data suggest that the basement rocks (major source rocks for the Guposhan complex) should be dominated by paleoproterozoic orthometamorphic rocks. We suggest that the flat subduction of the Pacific slab and subsequent break-off and rollback have triggered the extension of the lithosphere in the mid- to late Jurassic. Asthenospheric upwelling and basaltic underplating played an important role in causing the partial melting of the basement rocks in South China.

Oxidative Dissolution of Uraninite in the Presence of Manganese Oxide

ZIMENG WANG[1*], SUNG-WOO LEE[2], BRADLEY M. TEBO[2], AND DANIEL E. GIAMMAR[1]

[1]Department of Energy, Environmental and Chemical Engineering, Washington University, St. Louis, MO, USA zimengwang@wustl.edu (*presenting author), giammar@wustl.edu

Manganese is present at appreciable concentrations at several U-contaminated sites, and coupling of the biogeochemical cycles of U and Mn may affect the fate and transport of uranium. The long-term stability of U(IV) species produced in the subsurface during *in situ* bioremediation can potenitally be limited by reoxidation to more mobile U(VI) species. Manganese oxide (MnO_2), which can be produced biologically even at low dissolved oxygen concentration, can act as a powerful oxidant that accelerates the oxidative dissolution of UO_2. Laboratory studies have been performed to investigate the physical and chemical factors controlling the interaction between UO_2 and MnO_2.

Because both MnO_2 and UO_2 are insoluble at environmentally relevant conditions, the degree to which physical contact was necessary for UO_2 oxidation was unknown. A well-mixed multi-chamber reactor with a permeable membrane was used to eliminate direct contact of the two minerals while still allowing transport of aqueous species. The oxidation of UO_2 was not significantly enhanced if MnO_2 was physically separated. Complete mixing of MnO_2 with UO_2 lead to a much greater extent and rate of U oxidation. It suggests that effective redox reactions between UO_2 and MnO_2 may require physical contact or close proximity. We hypothesize that dispersion and colloid migration of U(IV) species, and the spatial dynamics of biological Mn oxidation are critical factors in assessing the impact of coupled U-Mn biogeochemical processes on U stability in the subsurface.

Continuous stirred-tank reactors (CSTR) were used to quantitatively examine the rates of MnO_2-mediated UO_2 dissolution and the effects of chemical factors (mixing ratio and carbonate concentration). MnO_2 dramatically promoted the UO_2 dissolution at steady states, but the degree of promotion leveled off when the MnO_2:UO_2 ratio exceeded a certain value. UO_2 oxidation by MnO_2 was faster at higher carbonate concentrations. Substantial amounts of U(VI) were retained on MnO_2 surfaces through adsorption. The amounts of U(VI) adsorbed on MnO_2 were inversely related to UO_2 dissolution rates, suggesting that the U(VI) product could passivate MnO_2 surfaces. The release of Mn into the effluent was less than that of U, indicating that the fate of Mn and the changes of its oxidation states were more complex than previously anticipated. Based on the fundamental understandings of grain-to-grain contact, electron transfer, and surface speciation, a conceptual model was proposed to predict the oxidation rate of UO_2 by MnO_2. The model is applicable to broader water chemistry conditions and may be relevant to other redox processes involving two poorly soluble minerals.

Compositional evolution of melts during ascent through the ocean crust based on olivine-hosted melt inclusions

WANLESS, V.D.[1*], SHAW, A.M.[1], AND BEHN, M.D.[1]

[1]Woods Hole Oceanographic Institution, Woods Hole, USA, dwanless@whoi.edu (* presenting author)

Here we present volatile (CO_2, H_2O, F, S, Cl), major, and trace element data from >150 olivine-hosted, glassy, melt inclusions and glasses erupted on the fast-spreading East Pacific Rise (EPR) and intermediate-spreading Juan de Fuca Ridge (JdFR). We provide geochemical constraints on both compositional variations and depths of crystallization beneath the respective ridge axes using vapor-saturation pressures derived from volatile concentrations. Vapor-saturation pressures calculated from equilibrium CO_2-H_2O concentrations suggest crystallization occurs over a range of depths from below the crust-mantle transition to the seafloor for both the fast-spreading EPR and the intermediate-spreading JdFR. Combining these depths of crystallization with major and trace element concentrations of the melt inclusions, results in a detailed picture of how melt compositions evolve as they ascend through the ocean crust.

Major and trace element concentrations of the melt inclusions show no consistent fractional crystallization or melt-rock reaction trends with depth. For example, the most primitive melt inclusion compositions (MgO >9.5 wt%) are found at all depths within the crust, while the more evolved compositions are restricted to the shallow crust. This suggests that some melts ascend through the ocean crust with little to no differentiation, while other melts crystallize during ascent. Melt-rock reaction processes should result in a decrease in Al_2O_3 and CaO/Al_2O_3 concentrations with decreasing depth due to olivine and plagioclase assimilation and precipitation of clinopyroxene, however, this is not observed in our melt inclusions. Finally, major element and volatile concentrations from the EPR are more variable in the upper crust compared to the lower crust. For instance, Cl concentrations in EPR melt inclusions formed in the upper crust range from 10 to 66 ppm, compared to only 42 to 51 ppm in melt inclusions formed deeper in the crust. This may result from higher degrees of fractional crystallization and/or increased fluid-rock interaction in the shallow crust.

Evaluating the control on the kinetic Cr isotope fractionation factor: a reactive transport modeling approach

CHRISTOPH WANNER* AND ERIC L. SONNENTHAL

Lawrence Berkeley National Laboratory, Berkeley, CA, USA, cwanner@lbl.gov (* presenting author)

Fractionation of the four stable Cr isotopes (^{50}Cr, ^{52}Cr, ^{53}Cr and ^{54}Cr) is a well-accepted proxy for demonstrating Cr(VI) reduction occurring in geological systems [1]. Regarding Cr(VI) contaminated sites, tracking of Cr(VI) reduction is especially powerful when assessing the natural Cr(VI) reduction capacity or when performing an efficiency control of in-situ remediation measures. For typical near neutral pH-values, field scale Cr(VI) reduction efficiency has been quantified using a Rayleigh-type model assuming that the effective kinetic Cr isotope fractionation factor α_{kin} is known [2]. This requirement, however, is often very difficult to achieve. Even at the laboratory scale, published values for α_{kin} vary over a large range (0.9950-0.9985) [1, 3-4]. Most of these studies propose different Cr(VI) reduction mechanisms as being responsible for the wide range of α_{kin}. Alternatively, varying reaction rates and/or transport limitations have been suggested as the cause for the large range of α_{kin}.

To quantitatively assess the different possible contributions on α_{kin} two series of reactive transport model simulations were performed using the code Toughreact [5]. The proposed reaction network is based on a novel multi-continuum approach and the specification of a $^{53}Cr(OH)_{3(s)}$ – $^{52}Cr(OH)_{3(s)}$ solid solution forming the product of Cr(VI) reduction. In doing so, Cr(VI) reduction was considered to occur at solid surfaces and Cr isotope fractionation was modeled by defining an equilibrium fractionation factor only.

Simulating Cr(VI) reduction occurring along a 1D flow path suggested that for a given reaction mechanism α_{kin} can vary over a large range. According to our simulations, the lower range of α_{kin} (=larger fractionation) is defined by a reaction mechanism's theoretical equilibrium fractionation factor. In contrast, high reduction rates and/or transport limitations induced by Cr(VI) transport to reactive surfaces can shift α_{kin} to values close to 1 (=no fractionation). In the second series of model simulations our modeling approach was used to propose an alternative kinetic interpretation for the low α_{kin} observed in the Cr(VI) reduction experiment performed by Dossing et al. [4].

Our generic model simulations suggest that the individual contributions of reaction rates, transport limitations and reaction mechanisms should be addressed more carefully when interpreting experimentally determined kinetic Cr isotope fractionation factors and Cr isotope data derived from field sites. Reactive transport models that can treat isotopic fractionation caused by homogeneous and heterogeneous reactions coupled to transport form a unique tool for quantitative assessment of these individual contributions and for providing constraints on the field scale Cr(VI) reduction efficiency.

Regional evaluation of catchment-scale weathering: surface-water chemical indicators of lithology, and mechanical and biological effects

WANTY, R.B.[1*], BERN, C.[1], VERPLANCK, P.L.[2], SCHMIDT, T.S.[3], TODOROV, T.[1], SANJUAN, C.[2], AND FEY, D.L.[2]

[1]U.S. Geological Survey, MS 964d Denver Fed. Ctr., Denver, CO 80225, USA rwanty@usgs.gov, cbern@usgs.gov, ttodorov@usgs.gov (* presenting author)

[2] U.S. Geological Survey, MS 973 Denver Federal Center, Denver, CO 80225, USA, plv@usgs.gov, csanjuan@usgs.gov

[3] U.S. Geological Survey, Fort Collins Science Center, 2150 Center Ave., Bldg. C. Fort Collins, CO 80526. tschmidt@usgs.gov

In central Colorado, USA, samples were collected from 227 alpine streams between 2004 and 2007 [1] to evaluate the effects of catchment lithology on stream-water chemistry, aquatic communities, and weathering mechanisms. The study area, about 55,000 km^2, includes catchments with a variety of lithologies. The area also includes zones of hydrothermal alteration which have added metals such as Zn, Pb, Cu, Cd, Au, and Ag to the rocks. Abandoned mines in some of the catchments have introduced these metals to the weathering environment.

In altered and mined catchments, rapid weathering of sulfide minerals such as pyrite dominates the aqueous geochemical signature (low pH and high metal and SO_4 concentrations). In unaltered and unmined catchments, catchment lithology determines certain aspects of stream-water quality, including pH, salinity, and relative and absolute concentrations of major and trace elements. Dissolved Ge concentrations are greater in streams draining certain lithologic groups, including the Pikes Peak Granite, although secondary chemical effects, such as the relation between Ge and F, are possible. Prior studies of Ge/Si systematics in lithologically homogeneous areas like Hawai'i [2] have traced weathering processes, but in this study lithologic effects appear to play a stronger role in Ge variations.

Average catchment slope was calculated using GIS software. Steeper slopes likely promote exposure of fresh mineral surfaces because of mechanical processes and decreased soil and vegetation. Across a wide range of lithologies, our data show a small ($r^2 = 0.08$) but significant ($p<0.01$) increase in average weathering rate with increased slope. The effect is greater in catchments with hydrothermal alteration and historical mining.

Benthic macroinvertebrates (n=153) were collected in 125 streams to evaluate effects of trace-metal concentrations on insect abundance and diversity. As metal concentrations increase, sharp drops in diversity and abundance are observed, beginning at lower metal concentrations than were previously reported [3], and likely the result of synergistic effects of several metals on stream biota.

Isotopic and geochemical evidence for the natural migration of Marcellus-like brine to shallow drinking water in northeastern Pennsylvania

NATHANIEL R WARNER[1]*, S. OSBORN[2], A. DOWN[1], K. ZHAO[1], R. JACKSON[1], A. VENGOSH[1]

[1] Division of Earth and Ocean Sciences, Nicholas School of the Environment, Duke University, Durham, NC USA, nrw@duke.edu (*presenting author), adrian.down@duke.edu, zhao.kaiguang@duke.edu, jackson@duke.edu, vengosh@duke.edu

[2] Geological Sciences Department, California State Polytechnic University Pomona, Pomona, CA USA, sgosborn@csupomona.edu

The recent increase in production of natural gas from the unconventional shales of the Appalachian Basin represents an important new energy resource. But the drilling and hydraulic fracturing processes required to obtain the gas have generated an increased concern over possible contamination of shallow drinking water resources [1]. Reports of shallow groundwater contamination caused by natural gas drilling are often dismissed based on the large vertical separation between the shallow drinking water wells and the shale-gas formations. Assessing the possible risk to shallow drinking water hinges on the hydraulic connectivity between the shale gas formations and the overlying aquifers.

In this study, we analyze the geochemistry of water samples from three principle aquifers, Catskill, Lockhaven, and Alluvium located across six counties of northeastern Pennsylvania (NE PA). We hypothesize that a detailed analysis of major (Br, Cl, Na, Ba, and Sr) and trace (Li) element geochemistry, coupled with utilization of a specific spectrum of isotopic tracers ($^{87}Sr/^{86}Sr$, $^{228}Ra/^{226}Ra$), could provide evidence of potential hydraulic connections between shallow drinking water aquifers and deep formation waters from the Marcellus or other deep formations. Findings suggest that mixing relationships between a fresh, shallow groundwater and a Marcellus-like brine could cause the groundwater salinization observed in some locations of NE PA. The occurrence of the saline water does not appear to be correlated with the location of shale-gas wells and the same water type was reported prior to the recent and rapid shale-gas development in the region [2]. However, the presence of these pathways could suggest specific areas in NE PA where shallow drinking water resources are at greater risk of contamination with deeper formation brines and gases during drilling and hydraulic fracturing of shale gas.

Towards determining noble gas partitioning between supercirtcial CO_2 and water

O. WARR[1*], A. MASTERS[2], C. ROCHELLE[3] C.J. BALLENTINE[1]

[1]SEAES, University of Manchester, M13 9PL, UK

oliver.warr@postgrad.manchester.ac.uk (*presenting author)

[2]CEAS, University of Manchester, M13 9PL, UK

[3]British Geological Survey, Nottingham, NG12 5GG, UK

Geological storage of carbon dioxide within deep saline aquifers remains a solution to reduce global CO_2 emmisions [1]. However significant uncertainties remain in quantifying the rates of CO_2 dissolution into the water phase, rates of reaction with the aquifer minerals, and also in identifying techniques to trace reservoir leakage. Noble gas isotopes can play a key role in quantifying all of these areas [e.g. 2,3]. Nevertheless, the partitioning of noble gases between supercritcial CO_2 and water has never been determined, with studies to date assuming that noble gas partitioning between these phases can be approximated by data existing for gas/water systems. Indeed, the effect of significant volumes of CO_2 dissolved in the water phase on noble gas solubility in water has also not been determined and is presently neglected in modeling noble gases in natural systems.

We have taken an experimental and modeling approach to resolve this lack of information. We have constructed a Gibbs-Ensemble Monte Carlo (GEMC) model for calculating noble gas partitioning by simulating the molecular configurations of both the water-rich and carbon dioxide-rich phases. This model is currently at a stage where it reproduces carbon dioxide-water binary phase equilibria for the conditions of interest (40-140 Bars, 310-340 K) [4]. The model is now ready for input of noble gas atoms to determine their theoretical distribution between phases. Experimental work equilibrates noble gases between CO_2 and water in the British Geological Survey high-PT laboratory. We extract an aliquot of each phase at equilibrium and determine the noble gas concentration of each using a quadrupole mass spectrometer system developed at the Univeristy of Manchester.

Preliminary results from the experimental program suggest that noble gas solubilities are increased in the water phase when the water contains a high dissolved CO_2 content. In a sub-critical gas/water system at 50°C supporting a 37 bar CO_2 phase, an enhancement in noble gas solubility in water can be observed for Helium and Argon respectively. Confirmation of this increase in solubility is underway with an analytical program that expands the pressure and temperature range to includes the supercritical phase.

Abstract

Rare mafic rocks exposed in NW Bhutan, eastern Himalaya, preserve evidence for a granulite-facies event overprinting patchy evidence for precursor eclogite-facies conditions. These rocks yield U-Pb zircon ages of 15.3 ± 0.3 to 14.4 ± 0.3 Ma, interpreted as dating the timing of eclogite-facies metamorphism due to the trace element geochemistry of the zircons [1]. Monazite U-Th-Pb ages of 13.9 ± 0.3 Ma in leucosomes within associated pelitic opx-bearing granulites suggest that granulite-facies conditions were reached rapidly after eclogite-facies conditions [2]. Furthermore, U-Pb ages of rutile in both mafic and pelitic rocks of 10.1 ± 0.4 and 10.8 ± 0.1 Ma respectively, suggest that exhumation proceeded at rates of >40°C Ma^{-1} following the initiation of cooling [3]. These high grade rocks are exposed in the hanging wall of the Kakthang thrust system which emplaced them over older (21-17 Ma, U-Pb monazite) amphibolite-facies rocks which never reached eclogite or granulite facies conditions. Finally, 14.6 ± 1.2 Ma U-Pb ages of titanite in mafic rocks in the nearby Jhomolari Massif [3], which show textural evidence for eclogite-facies overprinted by an amphibolite event, suggest a third unit of high grade metamorphic rocks in Bhutan which experienced a distinct metamorphic history.

Taken together, these data show that rocks were exhumed from distinct middle and lower orogenic crustal levels at different times during the later stages of the India-Asia collision. Their exhumation raises questions about the mechanisms by which crustal material is transported in collision belts. Lower crustal eclogites have no inherent buoyancy, and therefore require a tectonic driver coupled with a lowering of viscosity to promote their exhumation. A strong, cold Indian plate indentor may have driven this hot weak material towards the surface. Multiple pulses of exhumation from different orogenic levels at different times are predicted by this "plunger" mechanism in numerical channel-flow models e.g. [4] which also predict the different PTt paths recorded in nature.

Metamorphic rocks seek meaningful cooling rates: New views from muscovite $^{40}Ar/^{39}Ar$ dating

C.J. WARREN[1*], S.P. KELLEY[2], S.C. SHERLOCK[1]

[1]Department of Environment, Earth and Ecosystems, CEPSAR, The Open University, Walton Hall, Milton Keynes, MK7 6AA, UK. (*c.warren@open.ac.uk)

[2]Department of Physical Sciences, CEPSAR, The Open University, Walton Hall, Milton Keynes, MK7 6AA, UK.

Abstract

The cooling and exhumation rates of metamorphic terranes determined using muscovite $^{40}Ar/^{39}Ar$ chronology underpin many tectonic models. Infra-red laser single grain fusion and UV-laser spot-profiling $^{40}Ar/^{39}Ar$ muscovite data from variably overprinted high pressure terranes in Oman [1], the Alps [2] and Norway show that individual samples and even individual grains can yield age ranges which span >50 Ma. Samples analysed in this spatially detailed way commonly yield bulk average ages that are similar to ages determined by single- or multi-grain step heating techniques. This result suggests that the latter technique may commonly mask the absolute variation in $^{40}Ar/^{39}Ar$ age between and within grains. Core to rim $^{40}Ar/^{39}Ar$ age profiles within individual grains determined by UV laser ablation vary from no determinable difference across the grain to grains with older cores or even apparently older rims [1]. These data suggest heterogeneous grain boundary Ar reservoirs during metamorphic evolution. Many of the single grain fusion ages are older than the timing of peak metamorphism determined from e.g. U-Pb on zircon and are therefore attributable to "excess argon" (^{40}Ar decoupled from its parent ^{40}K). For ages which are younger than the timing of peak metamorphism, it is more difficult to assess whether any resulting ages constrain the "true" timing of cooling and exhumation due to a varying amount of excess argon contamination, inefficient Ar removal from the grain boundary or system resetting by deformation or recrystallisation. Careful evaluation of the metamorphic pressure-temperature-time history experienced since the time of mica crystalisation coupled with detailed UV-laser intra-grain age profiling and predictions from numerical diffusion modelling places constraints on data interpretation [3]. In many cases the age variability is best explained by spatial and temporal variations in grain boundary Ar concentration which act to hinder open system Ar removal. Muscovites affected in this way do not yield "true" cooling ages as suggested by the Dodson equation [4] and cooling rates based on these ages may not be tectonically reliable.

[4]Brown University, Geological Sciences, Meredith_Hasings@brown.edu

Introduction

Alpine ecosystems, which are generally nutrient poor and exist under extreme climatic conditions, are particularly sensitive to environmental and climatic stressors, including enhanced N and S deposition. The magnitude of regional N and S emissions in Western Canada oppose the Canadian norm and are increasing, a trend that is forecast to continue. However, evaluation of the magnitude of atmospheric deposition, and processes controlling deposition at potentially vulnerable alpine sites is lacking.

Methods

This study evaluates the controls on summer 2010 nitrogen (N) and sulphate (S) deposition to alpine valleys in the Southern Canadian Rocky Mountains. Deposition is evaluated using bulk precipitation collected from sites at three elevations, in adjacent valleys, on opposing sides of the Continental Divide. Major ion concentrations and stable isotope signals ($\delta^{18}O_{H2O}$ and $\delta^{2}H_{H2O}$, $\delta^{34}S_{SO4}$ and $\delta^{18}O_{SO4}$, $\delta^{15}N_{NO3}$ and $\delta^{18}O_{NO3}$) of the precipitation in combination with synoptic metrological conditions are evaluated.

Results

A dominant source of well mixed atmospheric sulphate is suggested by the relatively uniform precipitation $\delta^{34}S$ values (7.2 ± 3.8‰). These values are higher than commonly reported for well mixed continental sources in North America, and suggest the influence of an emission source with higher positive $\delta^{34}S$ values such as coal, oil, or sour gas. Strongly correlated $[NO_3^-]$ and $[SO_4^{2-}]_{nss}$ ($r=.88$ $p<0.1$) implies they have a common pollutant origin.

Generally, the north-west facing Robertson Valley (RB) receives lower precipitation volumes, but higher NO_3^- loads, and similar SO_4^{2-} and NH_4^+ loads, than the south-east facing Haig Valley (HG).

Precipitation accumulated over discrete intervals also shows variable trends in stable isotope signals as well as ion loads with elevation. Increasing elevation is usually associated with higher $\delta^{34}S_{SO4}$ and $\delta^{18}O_{NO3}$ and lower $\delta^{18}O_{H2O}$ and $\delta^{15}N_{NO3}$ although inverse relationships also occur. We anticipate evaluation of the synoptic metrological conditions, along with back trajectory analysis associated with each sampling interval will help elucidate the dominant controls on atmospheric N and S deposition at the field sites.

Trace metal isotope fractionation during adsorption to Mn oxyhydroxide: mechanisms, patterns, and further questions

LAURA E. WASYLENKI[1]*

[1]Dept. of Geological Sciences, Indiana University, Bloomington, Indiana, USA, lauraw@indiana.edu*

Adsorption to mineral surfaces is the often the first step when dissolved trace metals are removed from the water column and associated with sediment. Many factors govern the concentrations and isotopic compositions of adsorbed trace metals, and recent research has yielded some mechanistic insight into those factors. Whether the set of atoms adsorbed is the same set eventually incorporated within a mature sediment is unclear (and unlikely), and this complication demonstrates the need to better understand how adsorbed metals become more permanently incorporated in sediments.

My colleagues and I have conducted simple experiments in the past five years to quantify metal stable isotope fractionation during adsorption of several paleoceanographically important trace metals (Mo, U, Zn, Cd, Ni) to the mineral birnessite, a predominant phase in hydrogenetic ferromanganese crusts. In all of these experiments, the lighter isotopes of the metal in question have preferentially adsorbed. Our results indicate that we are measuring equilibrium, rather than kinetic, isotope effects.

In some cases (Mo and U), the fractionations we see in our experiments exactly match the fractionations observed in nature between dissolved metal in seawater and metal in young ferromanganese crusts. This strongly suggests a direct relationship between adsorption and final incorporation of these trace metals. EXAFS spectra from experimental and natural samples demonstrate that the observed isotope effects are driven by differences in coordination chemistry between dissolved and adsorbed metals.[1,2]

For Zn, Cd, and Ni, the fractionations observed in experiments do not match what is observed in nature. Chemical and mineralogical (and perhaps biological) differences between our simple experimental systems and nature may be the cause for the discrepancies. Other hypotheses involve additional reactions occurring during incorporation of metal into mineral structures or following burial that can modify the set of trace metal atoms and the metal isotope ratios initially associated with sediment. These hypotheses and their implications for isotope paleoproxies will be discussed.

Anomalous Fractionations of Sulfur Isotopes during High Temperature Reactions between Solid Organic C- and Oxidized S Compounds

YUMIKO WATANABE[1*], HIROSHI HAMASAKI[1], ANDREW P. CHORNEY[1] AND HIROSHI OHMOTO[1]

[1]NASA Astrobiology Institute and Department of Geosciences, Penn State University, University Park, USA, yxw129@psu.edu; hzh114@psu.edu; apc5060@psu.edu; hqo@psu.edu

Until recently, many researchers have thought that UV-photolysis of volcanic SO_2 gas in an O_2-poor (i.e., $pO_2 < 10^{-6}$ atm) atmosphere created the anomalous isotope fractionations of sulfur isotopes (AIF-S) found in many (but not all) sedimentary rocks >2.4 Ga in age. However, we suggest that redox reactions between solid organic compounds (e.g., kerogen in sedimentary rocks) and oxidized S-bearing compounds (e.g., SO_4^{2-}, SO_2) at elevated temperatures (T > ~150°C) may have created most (if not all) AIF-S signatures in nature, based on the following discoveries: (1) SO_2 photolysis using a broad-band UV lamp, which simulates the UV spectra of the sunlight, produced the AIF-S signatures that differed significantly from those in natural rocks [1, 2]; (2) AIF-S signatures occur in some post-2.4 Ga samples, including the ~1.8 Ga black shales in Finland [3], and most interestingly in SO_4 in pollutants in the Beijin air, which were produced by the burning of pyrite-rich coals [4]; (3) Shales with large AIF-S signatures are characteristically kerogen- and pyrite-rich black shales that deposited under the influence of large-scale submarine hydrothermal activity [5]; and (4) The reduced S-bearing compounds, generated from reactions among simple amino acid crystals, sulfate crystals and H_2O at 150-200°C, possess variable AIF-S signatures ($\Delta^{33}S$ = 0.2 to +13‰; $\Delta^{36}S$ = -1.3 to +1.1‰), and most of the data ~~are~~ match with those in sedimentary rocks [6, 7]. Reactions using some complex organic compounds did not produce AIF-S. The results of these laboratory experiments, and also those of our recent study on reactions between activated carbon and SO_2(g) at 150-200°C, suggest that variable fractionations of S isotopes occur during: (i) adsorption of oxidized S-species on the surfaces of solid C-bearing compounds; (ii) series of reduction of the adsorbed S-species on/in the solid; and (iii) desorption of the reduced S-compounds. The isotope effects during (i) and (iii) are probably due to the chemisorption isotope effects proposed by Lasaga et al. (2008) [8], which may affect on one or more S isotopes, whereas those during (ii) may be caused by the magnetic isotope effects that affect only on ^{33}S.

Therefore, the AIF-S record in sedimentary rocks may indicate the evolutions of the biosphere (species and abundances) and environments (e.g., influence of submarine hydrothermal activity) rather than of the atmosphere.

Raman spectroscopic study on the Cr^{6+} speciation in aqueous fluids at elevated P and T

ANKE WATENPHUL[1*] AND CHRISTIAN SCHMIDT[2]

[1]Hamburger Synchrotronstrahlungslabor HASYLAB at Deutsches Elektronen-Synchrotron DESY, Hamburg, Germany, anke.watenphul@desy.de (* presenting author)
[2]GFZ German Research Centre for Geosciences, Potsdam, Germany, hokie@gfz-potsdam.de

In oxidizing environments, chromium is hexavalent. There is a considerable number of Cr^{6+} minerals, which are almost exclusively chromates. Chromium(VI) is much more mobile than Cr^{3+} due to the higher solubility of Cr^{6+} in aqueous fluids. Chromium(VI) equilibria in aqueous solutions have been studied at ambient P and T, e.g. as function of pH and total Cr^{6+} concentration [1]. Here, we report first results on changes in the aqueous Cr^{6+} speciation with pressure and temperature.

We recorded Raman spectra of an H_2O + 11.7 wt% $K_2Cr_2O_7$ fluid and a D_2O + 19 wt% $K_2Cr_2O_7$ fluid up to 1.6 GPa and 400 °C using a hydrothermal diamond-anvil cell [2] and quartz as pressure sensor [3]. The Raman spectra reflect mostly the chromate $[CrO_4]^{2-}$ – dichromate $[Cr_2O_7]^{2-}$ equilibrium. The normalized integrated intensities of the stretching bands of $[Cr_2O_7]^{2-}$ tend to decrease and that of $[CrO_4]^{2-}$ to increase slightly with pressure. The ratio of the integrated intensity of these bands does not change significantly with temperature. The formation of $[CrO_4]^{2-}$ is strongly suppressed in the D_2O fluid, but this has no effect on the observed behavior of the $[Cr_2O_7]^{2-}$ and $[CrO_4]^{2-}$ species with pressure and temperature.

In both experiments, a new band at 260–290 cm^{-1} appears in the spectra at temperatures above 200 °C. The intensity of this broad band shows no distinct dependence on pressure, but increases strongly at 300 and 400 °C, which is coupled with a decrease in the intensity of bands assigned to chromate and dichromate bending modes. This suggests the formation of another Cr-species in the fluid. In analogy to Raman bands of phosphate [4] and sulfate [5] in aqueous solutions, the new band is tentatively assigned to a restricted translation mode from Cr–O···HOH or Cr–O···DOD and may thus result from hydrated chromate or dichromate ions in the solution at elevated temperatures. This interpretation is supported by the observed band shift by about 20 cm^{-1} to lower wavenumbers in the experiment using D_2O, which indicates an involvement of hydrogen or deuterium in the species.

Geochemistry across the Frasnian / Famennian Boundary, Hongguleleng Formation, Xinjiang Province, China

WATERS, JOHNNY A.[1], CARMICHAEL, SARAH K. [1], DEREUIL, AUBRY A. [1], SUTTNER, THOMAS J.[2], KIDO, ERIKA[2], AND CHEN, XIUQIN[3] , TALENT, JOHN A[4], MAWSON, RUTH[4]

[1] Department of Geology, Appalachian State University, Boone, NC 28608, USA. watersja@appstate.edu*
[2] Commission for the Palaeontological and Stratigraphical Research of Austria, Austrian Academy of Sciences, Graz, 8010, Austria
[3] State Key Laboratory of Palaeobiology & Stratigraphy, Nanjing Institute of Geology & Palaeontology, Nanjing, China
[4]Department of Earth and Planetary Sciences, Macquarie University, Sydney, NSW, Australia

The Hongguleleng Formation has yielded a very diverse Famennian shallow marine community and records the rebound from the Frasnian–Famennian (F/F) extinction event in a highly fossiliferous shallow marine setting associated with a Devonian oceanic island arc complex. Faunas from the Hongguleleng demonstrate that the rebound from the F/F extinction event happened much more rapidly than previously thought and suggest that central Asia may have acted as a refugium. This study uses a multiproxy geochemical approach to put constraints on environmental changes, which occurred at the F/F boundary (Late Devonian) within the Hongguleleng Formation. Recent conodont studies place the F/F boundary approximately three meters above the base of the Hongguleleng Formation, giving us an opportunity to conduct detailed geochemical and sedimentological studies across the boundary in a unique setting (oceanic island arc complex) in a part of the world which has a paucity of data at this interval. Changes in the detrital flux were evaluated by examining variations in mineral composition and diagnostic elemental ratios. The hydrothermal and volcanic influence on sedimentation was estimated using Al/(Al+Fe+Mn) and Zr/Al_2O_3 proxies. The input of nutrients was determined by excess P_2O_5 and Ba. The degree of anoxia during deposition was constrained by the V/Cr ratio and the concentration of redox sensitive metals in the sediment.

Samples were collected from the basal six meters of shale and limestone in the Hongguleleng Formation and the upper one meter of shale and volcaniclastic sandstone in the underlying Zhulumute Formation. This interval also spans the *linguiformis* / *triangularis* conodont zone boundary which forms the F/F boundary. Although the Kellwasser event is not recognizable in outcrop by evidence of black shale, it can be recognized geochemically as series of dysoxic and anoxic events that span three meters of section below the boundary. The same interval also shows high levels of biological productivity based on excess Ba and P_2O_5 proxies. The upper limestone surfaces in this interval often have large concentrations of brachiopods. In contrast, limestones and shales in the lower Famennian show oxic to slightly dysoxic conditions. Pulses of volcaniclastic and hydrothermal components to detrital sedimentation are common throughout the interval and are recognized by mineralogy and Al/(Al+Fe+Mn) and Zr/Al_2O_3 .

The analysis of multiple geochemical proxies allows us to confirm the presence of the Kellwasser event in the open oceanic part of Paleotethys. The tectonic setting of the Hongguleleng Formation is in contrast to the sections previously studied, which were located near Laurussia, Gondwana, Siberia, and the South China plate. We plan additional studies of C, O and Sr isotopes in the near future to further refine our model of changing climatic and oceanographic conditions in the Hongguleleng Formation.

Resolving the effects of degassing vs. magma mingling in andesites and dacites from Medicine Lake Volcano.

LAURA E. WATERS[1*] AND REBECCA A. LANGE[1]
[1]University of Michigan, Ann Arbor, MI, USA, lewaters@umich.edu

Abstract

A detailed petrologic study is presented for seven phenocryst-poor andesites and dacites erupted from Medicine Lake Volcano, CA. This volcanic edifice has erupted phenocryst-poor liquids ranging over the complete compositional spectrum from basalt to rhyolite, often coevally (Donnelly-Nolan *et al.,* 2008), which makes it the ideal place to evaluate and resolve the effects of degassing vs. magma mingling in producing complex textures and zonation patterns in the phenocrysts of intermediate magmas. Despite having only 2 to 10% phenocrysts (+ microphenocrysts), the andesites and dacites featured in this study are each multiply saturated with six to seven mineral phases (plagioclase + orthopyroxene + clinopyroxene + ilmenite + titanomagnetite + apatite ± hornblende). Plagioclase, orthopyroxene and clinopyroxene phenocrysts often display diffusion-limited growth textures (e.g., swallow tail and hopper textures, large melt hollows, etc.). Temperatures (±1σ) were calculated with the two Fe-Ti oxide geothermometer of Ghiorso & Evans (2008) and range from 960 (±25) to 1021 (±16)°C for the andesites and from 876 (±18) to 966 (±19)°C for the dacites. Oxygen fugacities, relative to the Ni-NiO buffer (ΔNNO ± 1σ), range from -0.2 (±0.02) to 1.1 (±0.1). With temperature known, the plagioclase-liquid hygrometer of Lange *et al.* (2009) was employed to determine pre-eruptive melt water concentrations. Maximum melt water concentrations, based on the most calcic plagioclase phenocryst in each sample, range from 3.4 to 4.2 wt% H_2O for the andesites and from 4.2 to 5.8 wt% H_2O for the dacites. These results require that the magmas were fluid saturated at pressures >0.9-1.7 kbars (~3-6 km), and underwent degassing upon ascent to the surface. Plagioclase phenocrysts span a wide range in composition (20-40 mol% An). Some of this variability can be attributed to degassing, owing to the fact that dissolved water strongly affects plagioclase composition. The basis of the plagioclase-liquid hygrometer is that dissolved hydroxyl groups preferentially speciate with Na vs. Ca, thus reducing the albite component in the melt, leading to more calcic plagioclase at higher melt water concentrations. Orthopyroxene, like plagioclase, also spans a wide range in composition (≤ 27 mol% En) in the andesites and dacites, and again some of this compositional variability can be attributed to changing melt water concentration during degassing. Because hydroxyl groups preferentially speciate with Mg vs. Fe^{2+}, higher melt water contents lead to more Fe-rich orthopyroxenes. Thus, the effect of degassing is to produce more sodic plagioclases and more Mg-rich orthopyroxenes. According to calculations based on the JANAF tables, plagioclase is expected to be more sensitive than orthopyroxene to changing melt water concentrations during degassing, and the Fe-Ti oxides are expected to change little. Therefore, another diagnostic tool to resolve the effects of degassing vs. magma mingling in andesites and dacites, in addition to phase equilibrium experiments to verify phenocrystic compositions, is the observed variability of calculated temperatures from all possible pairs of ilmenite and titanomagnetite crystals.

Fire as a Gaian mechanism to regulate atmospheric oxygen: an experimental investigation

ANDREW J WATSON[1*] AND JAMES E. LOVELOCK[2]

[1] School of Environmental Sciences, University of East Anglia, Norwich, U.K., a.watson@uea.ac.uk [2]Coombe Mill Experimental Station, Devon, U.K. and Oxford University, U.K.
(* presenting author)

In his first book on Gaia, Lovelock suggested the idea that fire might be an important regulator of atmospheric oxygen. Here we describe experimental investigations undertaken in the 1970s, but not widely published then, designed to test this idea. Rate of spread and the energy required for ignition were measured in paper, as an analogue for natural fuels, and the results were mapped as functions both of the moisture content of the fuel and the atmospheric oxygen tension. These can be translated approximately into probabilities of ignition and rates of spread of wildfires under different oxygen mixing ratios, by comparison with fire danger rating indices. The results suggest that wildfire destructiveness has a rapidly increasing dependence on atmospheric oxygen at the present concentration of about 21%. Consideration of the importance of fire in limiting productivity on land today, then suggests that fire is an important factor setting the current and past atmospheric oxygen concentrations, and that this sensitivity can provide an explanation for why atmospheric oxygen is stable on geological time scales, at present levels.

Zircon as a Witness to Earth's First 500 Myr: an Experimentalist's View

E.B. WATSON[1]*, D.J. CHERNIAK[2], D. TRAIL[3], N.D. TAILBY[4]

[1]New York Center for Astrobiology, Rensselaer Polytechnic Institute, Troy, NY, USA, watsoe@rpi.edu (*presenting author)
[2]Department of Earth and Environmental Sciences, RPI, Troy, NY, USA, chernd@rpi.edu
[3]New York Center for Astrobiology, RPI, Troy, NY, USA, traild@rpi.edu
[4]New York Center for Astrobiology, RPI, Troy, NY, USA, tailbn@rpi.edu

The past decade has seen major advances in our understanding of the first 500 million years of Earth history. Cataclysmic events such as the formation of the core, atmosphere and Moon are understood mainly through models and isotopic systematics of large reservoirs (e.g., meteorites, Earth's mantle and/or atmosphere, Moon rocks), but when it comes to details of early-Earth conditions, we must turn to the geologic record. Ancient zircons are the most tenacious record of the early-Earth story. Even though their original host rocks are long gone, Western Australia's Hadean zircons still provide insight into not only the protolith of the magmas in which they grew but also the conditions that prevailed during early crustal magmatism.

The interpretation of chemical and isotopic signatures in natural zircons has been significantly expedited by laboratory experiments that define the high P-T equilibria and kinetic properties of this remarkable mineral. Most basic among these properties is the saturation behavior of zircon in magmas. Knowledge of zircon saturation as a function of melt composition, temperature and pressure provides broad constraints on zircon crystallization scenarios, Hadean or otherwise. In combination with analyses of ancient zircons, other experimentally determined properties shed light on petrogenetic processes and protoliths. The Ti content of zircons provides estimates of magmatic temperatures, and Ce anomalies inform us about oxygen pressures (fugacities) that prevailed during zircon crystallization (and, by inference, in Earth's early crust and mantle). Knowledge of magmatic oxygen fugacities gives us indirect insight into the nature of C-O-H-N-S molecular species in gaseous volcanic emanations. The general picture of early Earth portrayed by the oldest zircons is that the sedimentary cycle was in full swing within 150 Myr of Earth's origin, the oxygen fugacity of the mantle was similar to that of today, and volcanic inputs into the atmosphere were similarly "modern" in molecular character, and neutral—that is, mainly CO_2 and H_2O.

Information is preserved in zircons not only because the crystals themselves have survived, but also because diffusive transport of most ions in zircon is very slow. Oxygen (in H_2O-free environments), U, Th, Pb, Hf, rare earths, Ti, and have been shown to diffuse so slowly that post-crystallization re-setting is unlikely in a zircon that has not been damaged by radioactive decay. On the other hand, O (under H_2O-present conditions), Li, and H may be mobilized in ancient zircons that experience post-crystallization re-heating. Even in the case of Li and O, however, there is evidence that original abundances and/or isotope ratios have been preserved in some cases.

A summary will be provided of experiment-based knowledge of zircon properties (and limitations), followed by a general perspective on early Earth that emerges from "decoding" Hadean zircons.

Diffusion/Deposition/Remobilization of Uranium in Bioreduced Zones

DAVID WATSON[1]*, GUOPING TANG[1], JENNIFER EARLES[2], AND SCOTT BROOKS[1]

[1]Oak Ridge National Laboratory, Environmental Sciences Division, watsondb@ornl.gov (* presenting author), tangg@ornl.gov, earlesje@ornl.gov, and brookssc@ornl.gov

It is common practice to inject substrates and other reactants to reduce the mobility and/or toxicity of subsurface contaminants through bioreduction and other remediation techniques. These injections result in manipulated zones that are in a state of chemical disequilibrium. For example, bioreduction can significantly reduce the concentration of contaminants (like U) and other inorganics in groundwater but increase the concentration on the solid phase. Due to preferential transport through subsurface heterogeneities, there will be abrupt aqueous concentration gradients between well connected high permeability zones that receive a high concentration of treatment media (low U zone) and adjacent lower permeability zones that do not receive treatment media (high U zone). The objective of this study is to assess the diffusion of U into bioreduced zones from adjacent unreduced zones, deposition of the U in the bioreduced zone and remobilization of U after the bioreduction has stopped.

Laboratory bottle tests, field observations at the U.S. DOE Oak Ridge Integrated Field Research Challenge site during U bioreduction experiments and numerical modelling were employed to meet these objectives. U contaminated soils encapsulated in polyacrylamide hydrogels (Spalding and Brooks, 2005) were used in the lab and the field to determine U release and diffusion rates (Figure 1). A two site kinetic model was used to predict release and diffusion of U from unreduced zones to adjacent reduced zones.

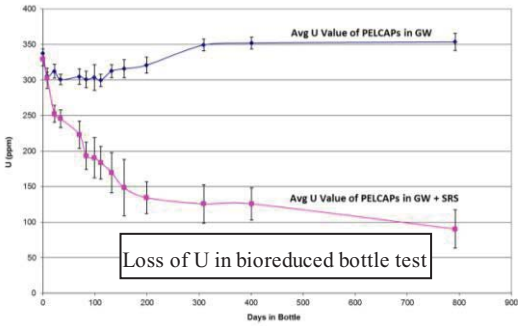

Figure 1: Loss of U from soils encapsolated in hydrogel observed for over 800 days during bioreduction of groundwater.

The results of our study suggest that U will migrate from unreduced zones into reduced zones when bioreduction is active resulting in "extra" U being deposited in high permeability transport pathways. However, if bioreduction conditions are not maintained, an unintended consequence may be an increase in the U flux (relative to pre-bioreduced conditions) as the "extra" U is released as a result of oxygenated groundwater entering the previously reduced zone.

Rapid core segregation in planetesimals: Results from in-situ X-ray microtomography

HEATHER. C. WATSON[1*], KASEY TODD[1], YANBIN WANG[2], TONY YU[2]

[1] Northern Illinois University, Dekalb, IL, USA. hwatson@niu.edu (* presenting author)
[2] Center for Advanced Radiation Sources, The University of Chicago, Chicago, IL, USA

Differentiation of the terrestrial planets into silicate mantles and metallic cores is one of the most significant events in their history. Although a magma ocean scenario is often used to explain this event for large planets such as Earth, smaller planets and planetesimals likely never achieved the high temperatures necessary for such wide scale melting. In these smaller bodies, ^{26}Al decay is thought to contribute enough heat to melt only the core forming metallic phase, and leave the silicate as a solid phase. W-Hf isotopic signatures in meteorites suggest that some planetesimals differentiated within just a few million years [1]. Achieving core segregation on this time scale by a percolative flow mechanism whereby core material drains though a solid silicate mantle via an interconnected network of melt faces two major problems: (1) in a hydrostatic situation, the *percolation threshold* is above 5 vol% melt, so the process would lead to inefficient core formation, and several vol% of core material would remain stranded in the mantle, which is not supported by observations (2) the *permeability* of fully connected melts at microstructural equilibrium is low enough that some planetesimals may still not be able to differentiate on the short time scale that is required [2]. It has been suggested that shear deformation can cause isolated melt pockets to become connected even at low melt fractions [3,4].

Here, we have measured the change in permeability of core forming melts in a silicate matrix due to deformation. Mixtures of San Carlos olivine and FeS close to the equilibrium percolation threshold (~5 vol% FeS) were pre-synthesized to achieve an equilibrium microstructure, and then loaded into the rotational Drickamer apparatus at GSE-CARS, sector 13-BMD, at the Advanced Photon Source (Argonne National Laboratory). The samples were then pressed to ~2GPa, and heated to ~1100°C. Alternating cycles of rotation to collect X-ray tomography images, and twisting to deform the sample were conducted. Qualitative and quantitative analyses were performed on the resulting 3-dimensional x-ray tomographic images to evaluate the effect of shear deformation on permeability and migration velocity. Preliminary results from Lattice-Boltzmann simulations show a marked increase in the permeability with increasing deformation, which would allow more rapid and efficient core formation in planetesimals.

Large-volume silicic magma genesis at Yellowstone, Heise, and Caetano: Isotope and geochronology insights from three supervolcanoes in the western U.S.A.

KATHRYN E. WATTS[1]*, JOSEPH P. COLGAN[1], DAVID A. JOHN[1], ILYA N. BINDEMAN[2], AXEL K. SCHMITT[3], CHRISTOPHER C. HENRY[4]

[1]U.S. Geological Survey, Menlo Park, CA, U.S.A., kwatts@usgs.gov (*presenting author)
[2]University of Oregon, Eugene, OR, U.S.A.
[3]University of California, Los Angeles, CA, U.S.A.
[4]Nevada Bureau of Mines and Geology, Reno, NV, U.S.A.

Large caldera "supervolcanoes" are fed by silicic magma chambers that may reach thousands of km^3 in size. We investigate the processes and time scales by which voluminous silicic magmas are generated by combining laser ablation/fluorination O isotope analyses of major phenocrysts with ion microprobe U-Pb dates and O isotope analyses of accessory zircon. We compare these for three supervolcanoes in the western U.S.A.–Yellowstone (Wyoming, 2.1-0.64 Ma), Heise (Idaho, 6.6-4.5 Ma), and Caetano (Nevada, 34 Ma). Yellowstone and Heise are multi-cyclic caldera complexes that produced large volumes of crystal-poor, anhydrous, high-silica rhyolites, many with low-δ^{18}O signatures diagnostic of remelting large volumes of hydrothermally altered rock in the shallow crust (δ^{18}Omelt=0-4‰). U-Pb ages and δ^{18}O compositions for doubly fingerprinted zircon spots reveal that caldera-wide batch assembly of heterogeneous melts with unique δ^{18}O compositions occurs over short time scales (~0.1-0.3 Ma) prior to voluminous tuff and lava eruptions at Yellowstone and Heise. Caetano is a single caldera that produced large volumes of crystal-rich, hydrous (biotite- and hornblende-bearing), low- and high-silica rhyolites with exclusively normal-high δ^{18}O signatures (δ^{18}Omelt=10-11‰). U-Pb ages of Caetano Tuff zircons range from within error of sanidine ^{40}Ar/^{39}Ar eruption ages to ~3 Ma older, indicating a prolonged period of magma assembly and growth. In addition to having different crustal sources, magma assembly time scales, and petrological characteristics, Caetano is also disparate from Yellowstone and Heise in that it has not produced any large-volume pre- or post-caldera rhyolite lavas. However, two resurgent granitic plutons intrude the intracaldera Caetano Tuff, providing clear evidence for magmatism postdating caldera collapse. U-Pb zircon ages, sanidine ^{40}Ar/^{39}Ar eruption ages, whole-rock major and trace element geochemistry, and O isotope signatures indicate a genetic connection between the Carico Lake resurgent pluton (δ^{18}Ozircon= 8.2±0.1‰) and the Caetano Tuff (δ^{18}Ozircon= 8.3±0.1‰), supporting the model of linked volcanic-plutonic components in caldera settings.

A bio-nanotechnological approach to the remediation of alkaline Cr(VI) containing leachate from chromite processing ore residue

MATHEW WATTS[1*], RUSSELL THOMAS[2], JONATHAN R LLOYD[1]

[1]University of Manchester, Manchester, UK, (*correspondence mathew.watts@postgrad.manchester.ac.uk)
[2]Parsons Brinckerhoff, Bristol, UK

Interactions at the microbe-mineral interface are known to produce reactive nano-scale mineral phases. These nanoparticles (NPs) can be harnessed in an innovative "bio-nanoremediation" approach to various contaminated land problems. The purpose of this study was to develop a novel treatment strategy for the redox active metal, chromium via reduction of mobile toxic Cr(VI) to the relatively insoluble and non-toxic Cr(III). Hyperalkaline (pH≈12) Cr(VI) leachates ascociated with chromite processing ore residue (COPR) have led to significant environmental Cr(VI) contamination. Over the last century up to 1.5 million m^3 of COPR were produced and landfilled in the urbanised area of Glasgow, UK, alone [1]. This has led to sustained leaching of residual Cr(VI) contaminating groundwaters and tributary streams flowing in to the River Clyde.

Cr(VI) removal from COPR related waters was assessed for a nano-engineered magnetite (BnM) biomineral. This nanoparticle, exhibiting reducing properties due to its high surface Fe(II) content, was synthesised via reduction of amorphous ferrihydrite by the Fe(III)-reducing bacterium *Geobacter sulferreducens* [2]. The biogenic magnetite was then subjected to a one-step functionalization process, to generate nanoscale Pd(0) on its surface giving a novel magnetically recoverable bio-nanocatalyst (Pd-BnM) [3]. These biogenic NPs were then compared to a synthetic alternative, nano Zero Valent Iron (nZVI), for remediation applications.

Using pure Cr(VI) solutions at environmentally relevant alkaline pH values, an approximate 50% loss in efficiency (compared to performance in acidic conditions) was observed in both the BnM and nZVI NP treatments, with the nZVI demonstrating a greater capacity for removal. The Pd-BnM performed best, with sustained Cr(VI) removal when supplied with hydrogen gas, removing 240 mg Cr(VI) per g of NP within 50 hours reaction time (reaching over 450 mg after 290 hours) in comparison to a maximum of 29 mg removal when supplied with formate as an electron donor for metal reduction. The fate of the Cr was investigated using TEM and XPS analysis.

Following application of the NP treatments to the COPR leachate slurry, complete removal of the 1.6 mM Cr(VI) in solution was achievable with comparable removals to those observed from pure Cr(VI) solutions. This study therefore demonstrates the ability of both biogenic and synthetic NPs for removal of Cr(VI) from alkaline leachates from COPR.

Ethanol binding, orientation and bilayer structure on R-plane corundum surfaces

Glenn Waychunas[1*], Jaeho Sung[2] and Y. Ron Shen[2]

[1]Lawrence Berkeley National Laboratory, Earth Sciences Division, Berkeley, CA, USA , gawaychunas@lbl.gov (* presenting author)

Introduction

The interaction and binding of organic species with mineral surfaces is a large frontier in geochemistry. Mineral surfaces may sequester, sort, or contribute to breakdown reactions of organic molecules, but much of the details of these processes are poorly informed. Compared to inorganic sorbates, which interact with a surface by forming covalent and hydrogen bonds, and couple strongly to surface water molecules; organic structures may have partial or dominant hydrophobic interactions and reduced interaction with waters, multiple charges on a single molecule (e.g. zwitterion), and complex multi-site interactions with surface functional groups. In addition, a range of conformations may be possible, allowing adaptation to a surface, but differing from the solvated water-borne entity. These considerations have limited both the scope and utility of many past studies, with the vast majority involving measurement of uptake without information on the actual binding geometry or reaction mechanisms. The topic is one of profound interest given enormous numbers of industrial organic pollutants, natural biological agents, and pharmaceutical breakdown products entering the environment.

Results

We are developing a program to couple sum-frequency vibrational spectroscopy (SFVS), surface x-ray scattering methods, and computer simulations to characterize organic species interactions with well-known mineral surfaces. The first work involves ethanol as a single monolayer, and as a bulk liquid, on the corundum R-plane (1-102) surface [1]. SFVS spectra in the C-H range show that the monolayer has a well-defined anisotropic arrangement consistent with the R-plane termination. Specific molecular orientations and anisotropy can be explained by the formation of two hydrogen bonds between the ethanol molecules and the hydroxyls on the surface [2]. When bulk ethanol is present, the first layer is similarly anisotropic, but the second is apically opposite with a nearly isotropic distribution.

Calibrating the silica-phytolith paleothermometer

ELIZABETH A. WEBB[1*], FREDERICK J. LONGSTAFFE[2], AND ZHENZHEN HUANG[3]

[1]Western University, London, Ontario, Canada, ewebb5@uwo.ca (* presenting author)

Paleoclimate potential of phytolith $\delta^{18}O$ values

Plants absorb aqueous silicic acid from soils and precipitate silica phytoliths in cells along the transpiration stream. Phytoliths are composed of opal-A and can accumulate in soils when plants decay. Ancient phytoliths can provide paleoclimate information because their $\delta^{18}O$ values vary with temperature and the $\delta^{18}O$ values of plant water. However, a detailed understanding is required of how the $\delta^{18}O$ values of phytoliths vary in response to flucutations in temperature and plant water $\delta^{18}O$ values over the growing season.

Horsetail (*Equisetum hyemale*) plants were grown under constant temperatures for 6 months. The $\delta^{18}O$ values of watering-water, plant-water and atmospheric-water vapour were monitored monthly and the $\delta^{18}O$ values of phytoliths were determined after the plants reached maturity. Fluctuations in plant-water $\delta^{18}O$ values resulted from changes in the $\delta^{18}O$ values of atmospheric vapour, the maturity of the plant and related changes in transpiration. Higher plant-water $\delta^{18}O$ values occurred in the warmer growth chambers but also toward the apex each plant and these values increased over time. Phytolith $\delta^{18}O$ values increased from 35.9, 37.1, 37.5 to 43.4 ‰ in the 15, 20, 25 and 30 °C growth chambers, respectively.

Comparison to opal-A paleothermometers

Plant-water and phytolith $\delta^{18}O$ values were used to evaluate the fit of the observed phytolith oxygen-isotope fractionation to existing opal-A paleothermometer equations developed for diatoms and phytoliths grown under field conditions where temperatures were variable [1,2]. A linear relationship between $1000\ln\alpha$ and $10^6/T^2$ was not observed for the phytoliths when the plant-water $\delta^{18}O$ values were averaged over the growing season. Instead, the phytolith paleothermometer equation most closely resembles recent diatom paleothermometers [1] when plant-water $\delta^{18}O$ values from the latter half of the growing season are used for plants grown at 20-30°C and when plant-water from the mid-growing season is used to calculate $1000\ln\alpha$ for the plants grown at 15°C. These results support earlier finding [2] that the $\delta^{18}O$ values of phytoliths are dominated by phtyoliths produced later in the growing season. Horsetails grown at 15°C were unhealthy at the end of the experiment and phtyolith deposition was likely restricted after the fifth month.

This study demonstrates that the oxygen-isotope fractionation between phytoliths and water is similar to that observed for diatom opal-A. However, interpretation of a phytolith oxygen-isotope paleothermometer must consider the timing of silica deposition. Non-ideal growth conditions can limit phytolith formation, creating disequilibrium between silica and average seasonal plant water.

Plankton diversity and ocean circulation regulate the ocean nitrogen reservoir

THOMAS S. WEBER[1*], CURTIS DEUTSCH[2]

[1]University of California Los Angeles, Los Angeles, USA, tweber@atmos.ucla.edu (* presenting author)
[2]University of California Los Angeles, Los Angeles, USA, cdeutsch@atmos.ucla.edu

Regulation of the ocean N reservoir

The average elemental composition of marine plankton is closely matched to the availability of the major nitrogen (N) and phosphorus (P) nutrients. This is understood to arise from biological control over the ocean's N budget, in which removal of N by denitrification selects for diazotrophic phytoplankton that add new N to the ocean when it limits the growth of other species. Current understanding of this feedback mechanism derives from box models of the ocean, which lack a realistic representation of physical mixing and the spatial heterogeneity of biological processes.

Role of plankton diversity and ocean circulation

We show that in the context of a realistic ocean circulation and a uniform 'Redfieldian' N:P ratio of plankton biomass, this feedback mechanism consistently yields too little N relative to observations. The solution lies in the large-scale variability of phytoplankton N:P ratios, which range from ~10:1 in diatom-dominated regions to >20:1 in low-diatom regions [1]. Because diazotrophs compete with high N:P subtropical plankton, the N reservoir is restored towards a higher value than in the Redfieldian case. However, low N:P communities outside the subtropics do exert some leverage over the ocean's nutrient balance, because their stoichiometric signature is transported to diazotrophic habitats through shallow pathways of ocean circulation.

Conclusions

Our study demonstrates that a combination of local ecosystem dynamics, plankton biogeography, and large-scale circulation patterns control the availability of fixed N in the ocean, and thus ocean fertility and carbon storage over millennial timescales.

Solubilities of H-O-C-S-Cl volatiles in fluids and silicate melts and their control on magmatic processes

JAMES WEBSTER[1]*, BETH GOLDOFF[2], M. FRANCESCA SINTONI[3], BENEDETTO DE VIVO[4]

[1]American Museum of Natural History, New York, USA, jdw@amnh.org (* presenting author)
[2]American Museum of Natural History, New York, USA, bgoldoff@amnh.org
[3]University of Naples Federico II, Naples, Italy, francescasintoni@gmail.com
[4]University of Naples Federico II, Naples, Italy, bdevivo@unina.it

The fluid-driven ascent of buoyant magma, explosive volcanic eruptions, and mineralizing hydrothermal processes are controlled by the abundances and solubilities of the dominant magmatic volatile components H_2O, CO_2, $H_2S/SO_2/SO_3$, and Cl in melts and in coexisting fluids and/or sulfide liquids. The efficacy of these processes depends on the presence, quantity, and composition of fluids that are dominantly aqueous; their presence in magma is the cause of excess magmatic and volcanic degassing. The solubilities of these volatiles in melts and fluids are constrained by experimental observations and thermodynamic and empirical modelling, but until recently the experimental constraints have been largely limited to simple binary volatile systems: H_2O-CO_2, H_2O-Cl, H_2O-S.

Recent and emerging experimentally derived solubility data on H-O-C-S-Cl volatile components in basaltic to rhyolitic melts provide fundamentally important constraints and new insights on volatile behavior in complex natural systems. It is well established that trace quantities of CO_2 and/or Cl dramatically reduce the concentrations of H_2O in melt required to force exsolution of one or more fluid phases from volatile-bearing melts. Recent research further demonstrates that the addition of S reduces Cl solubility by 25-30 percent relative in rhyodacitic, trachytic, phonolitic, and a variety of basaltic melts for oxygen fugacities at and above NNO ([1]; see summary in [2]). Hence, the overall influence of adding relatively oxidizing S is to reduce Cl and H_2O solubilities in melts and to enhance the stability of fluid(s) which fosters excess magmatic degassing. Other experimental work shows reduced CO_2 solubilities in various melts and increased solubilities in coexisting fluid at shallow crustal pressures. The (fluid/melt) partition coefficient for CO_2 in haplogranitic melts increases by nearly a factor of ten with the addition of geologically relevant abundances of reduced S^{2-} to silicate melt at oxygen fugacities of NNO-0.4 to NNO+0.3 [3]. Other research [4] at more reducing conditions (NNO-1.6 to NNO-3.2) observed decreased CO_2 solubility in basaltic melt due to dilution of CO_2 in the coexisting fluid by the presence of comparatively reduced C species. Moreover, ongoing research shows that the addition of Cl to a CO_2-H_2O vapor reduces the solubility of CO_2 in a coexisting phonolitic melt by 80 relative percent; this apparently results from the condensation of saline brine from the vapor phase and the formation of two fluid phases [5]. These new experimental observations will be interpreted in light of and applied to processes of fluid exsolution and excess magmatic degassing for subduction-related and other magmas.

Glacially derived iron as the key driver for biogeochemical processes in Arctic fjord sediments (West Svalbard)

L. M. WEHRMANN[1*], J. D. OWENS[1], M. J. FORMOLO[2], T. G. FERDELMAN[3] AND T. W. LYONS[1]

[1]University of California, Riverside, Riverside, CA, USA, laura.wehrmann@ucr.edu, jowens@student.ucr.edu, timothyl@ucr.edu (* presenting author)
[2]University of Tulsa, Tulsa, OK, USA, michael-formolo@utulsa.edu
[3]Max Planck Institute for Marine Microbiology, Bremen, Germany, tferdelm@mpi-bremen.de

Glaciers deliver an important fraction of bioavailable iron to the high latitude oceans. This iron is produced by mechanical and microbially enhanced chemical weathering, e.g., oxidation of iron-sulfide minerals in proglacial and supraglacial environments, and may enter the marine system in aqueous form, as (nannoparticulate) Fe-(hydr)oxides, or more stable Fe mineral phases [1]. A fraction of glacial iron is delivered directly to the open ocean by icebergs [1]. However, little is known about the fate of the large iron pool that enters high latitude coastal marine waters, particularly fjord systems, by glacial meltwater runoff.

In two comprehensive sampling campaigns along the Western Svalbard coast in 2010 and 2011, sediment cores were collected at Smeerenburgfjorden, Kongsfjorden, and Van Keulenfjorden along transects from the mouth of the fjords to the tidewater glaciers at the terminal end of the fjords. Results of pore water and solid phase analyses show that the input of glacially derived iron plays an important role in biogochemical processes in the fjord sediments by controlling the cycling of sulfur and manganese and by providing a large Fe-oxide pool for dissimilatory iron reducers. High solid phase reactive iron concentrations and high dissolved Fe concentrations in the pore water prevail in Kongsfjorden and Van Keulenfjorden, and suggest a benthic flux of dissolved iron from the sediment to the water column. Correspondingly, the concentration and sulfur isotope composition of chromium reducible sulfur (CRS) in the iron-dominated fjord sediments largely reflect the delivery rate and isotope composition of detrital pyrite originating from the adjacent glaciers. These values deviate strongly from the sulfur isotope composition of sedimentary acid volatile sulfur (AVS), which presumably formed from hydrogen sulfide production during organoclastic sulfate reduction, although nearly constant pore water sulfate concentrations with depth in Kongsfjorden and Van Keulenfjorden sediments argue for low production.

Overall, our data point to extensive benthic iron cycling in Svalbard fjord sediments, probably coupled to considerable oxidative sulfur cycling promoted by sediment bioirrigation by the benthic macrofauna. Our findings contribute to the hypothesis that benthic recycling of glacially derived iron in high latitude fjord sediments facilitates the transport of this micronutrient across the fjords while maintaining its bioavailability for fertilization of primary productivity on the adjacent continental shelf.

What do post-shield and rejuvenated lavas tell us about the source of the Hawaiian mantle plume?

DOMINIQUE WEIS[1*], DIANE HANANO[1], MICHAEL O. GARCIA[2] AND DENNIS GEIST[3]

[1]Pacific Centre for Isotopic and Geochemical Research, Earth & Ocean Sciences, Univ. of British Columbia, Vancouver, BC V6T1Z4, Canada, dweis@eos.ubc.ca, dhanano@eos.ubc.ca

[2]Department. of Geology and Geophysics, Univ. Hawai'i, Honolulu, HI 96822, USA, mogarcia@hawaii.edu

[3]Department of Geological Sciences, Univ. of Idaho, Moscow, ID, 83844-3022, USA, dgeist@uidaho.edu

On Hawai'i, volcanoes lie on two geographical trends (Loa and Kea). Their shield lavas define two clear geochemical trends over ~5 Myr, distinct in Pb, Nd, Sr and Hf isotopes [1,2] and in elemental concentrations [3], that reflect the sampling of different components in the deep source of the mantle plume, at the core-mantle boundary.

Hawaiian volcanoes also include post-shield and rejuvenated lavas, alkalic in composition, that occur just after the shield phase or after an eruptive hiatus of variable duration (~0.5-2 Myr), respectively. These magmas correspond to smaller degrees of partial melting and provide finer resolution of compositional variation in the plume source. We compiled all recent high-precision literature data on late-stage lavas (130 samples for Pb and 103 for Sr, Nd and Hf isotopes), and added new data for Kaula and Middle Bank volcanoes (32 samples). Except Hualalai, which is characterized by a very distinct Loa signature [4] of very low $^{206}Pb/^{204}Pb$ ratios (<18.02) and light $\delta^{7}Li$ (down to 0.75 ‰), most post-shield lavas plot on the Kea side of the Pb-Pb boundary of [2]. Two groups appear: 1) post-shield lavas from the Big Island and Maui Nui (<1.7 Ma) with isotopic compositions partly overlapping those of the shield lavas from their respective volcanoes, and 2) post-shield lavas from Oahu and Kauai (>3.6 Ma) with more distinct isotopic signatures than their respective shield, and more depleted isotopic compositions (lower $^{206}Pb/^{204}Pb$, $^{87}Sr/^{86}Sr$ and higher ε_{Nd}, ε_{Hf}). These latter compositions overlap with the homogeneous field defined by rejuvenated lavas, mostly from the same volcanoes, but significantly younger (<2.5 Ma). Rejuvenated lavas and >3.6 Ma post-shield lavas define mixing trends subparallel to those of the shield lavas in all binary isotope diagrams. Middle Bank post-shield lavas (6.4 Ma) are the only known exception, with Pb ratios overlapping those of Mauna Kea post-shield lavas.

Most post-shield and rejuvenated lavas on Hawai'i are devoid of the enriched signatures present on Loa trend volcanoes that have been related to sampling of the Pacific ultra-low-velocity-zone [1]. This implies either that this enriched material is not sampled by lower degrees of partial melting, or that the late-stage lavas only derive from the northeast part of the plume, which is more homogeneous and controlled by the Kea component. In contrast to shield lavas, there is also no systematic isotopic variation with time for the post-shield and rejuvenated lavas, therefore providing further insight into the source heterogeneity of the Hawaiian mantle plume.

The biological control mechanisms for forming functional mineralized hard materials have developed over long periods of time during evolution. In some way, evolution went hand in hand with the transition from unicellular to multicellular organisms. Our research team takes advantage of a non-mineralizing model organism with uni- and multicellular stages as part of its life cycle: The slime mold *Dictyostelium discoideum*. We recently achieved transgenic expression of a mollusc myosin chitin synthase in *Dictyostelium* and observed that this complex enzyme involved in shell biomineralization is enzymatically active in our cellular model system [1,2]. Clearly, this is only one side of the coin. There are a number of other biomineralization proteins on the other side, which interact with either chitin or mineral phases, or both. The fact that the native extracellular matrix of *Dictyostelium*, in principle, inhibits mineral precipitation can be exploited to match certain environmental conditions with heterologously expressed biomineralization genes, which then favor mineralization with increasing levels of control. Our transgenic approach might be suitable to identify key molecules in the evolutionary pathway of biomineralization inspired from contemporary organisms with some impact for today's environmental challenges such as climate change.

We determined B/Ca on four planktonic foraminiferal species (*Globigerinoides ruber, Globigerinoides sacculifer, Orbulina universa,* and *Globorotalia menardii*) on a Thermo Element 2 high resolution ICP-MS. The material is from biweekly sediment trap samples collected in Cariaco Basin, Venezuela (10°30' N, 65°31' W) over a three year period between May 2003 and May 2006. The data are compared to local hydrography and water column chemistry to evaluate environmental controls on B incorporation into foraminiferal calcite. In addition, seasonal variability of B speciation in the foraminiferal calcite is assessed using ^{11}B magic angle spinning (MAS) nuclear magnetic resonance (NMR) on samples of *O. universa* from January, February, and April 2007 and of *G. menardii* from December 2006. The B/Ca (μmol/mol) data displays clear depth stratification with the surface dwelling *G. ruber* having the highest B/Ca, followed by *G. sacculifer* and the deeper dwelling *G. menardii* and *O. universa* having the lowest, consistent with a decrease in pH with depth. The data also show a repeatable seasonal pattern with the highest values occurring when the water column is stratified in June and July and the lowest occurring during upwelling in December and January. However, none of the environmental variables have a strong correlation with B/Ca. The ^{11}B MAS NMR *O. universa* data show a seasonal change in the speciation of B within the foraminiferal calcite. During January the boron is almost entirely incorporated (~ 90%) in a previously unrecognized trigonal form. However, in April only ~75% of the boron is in this trigonal form, whereas the rest of the boron is divided evenly between borate and boric acid. The observed trigonal form has a C_q of 3.0, which is similar to the theoretical value of 3.15 [1] for the corner-sharing borate carbonate complex, $B(OH_2)CO_3^-$. It is hypothesized that during calcification boron is converted to a borate carbonate complex, which is ultimately converted to either borate or boric acid with each equally likely [1, 2]. Our results support this hypothesis except that most of the boron does not complete this reaction, but remains in the intermediate borate carbonate complex form.

Elevated dissolved uranium (U) concentrations up to 170 μg L^{-1} were measured in shallow (<25 m depth) domestic water wells near Bonnyville, Alberta. This area of Alberta is covered in glacial till deposits up to 200 m thick with several regional interglacial sand and gravel aquifers. Sediment coring for mineralogical analyses and installation and monitoring of nested piezometers were conducted at two sites to determine the source of U in shallow aquifers in the area. Field observations indicated that the till at both sites showed signs of oxidation at depths down to 6 m, suggesting that the primary source of U in the shallowest underlying aquifer may be from weathering and leaching of overlying U-bearing minerals. Speciation modelling showed that porewater was undersaturated with respect to secondary U minerals in the vadose zone, but that groundwater became saturated with respect to secondary U-hydroxide minerals with depth as conditions became more reducing. The dominant U complexes in groundwater were found to be U-hydroxides for U(IV) species and uranyl carbonates for U(VI) species.

The quantitative mineralogical study included analyses of the oxidized and unoxidized till, aquifer sediments and secondary precipitate samples. No major mineralogical differences were observed between the till and sand sediments other than a higher proportions of dolomite and clay minerals present in the till samples. The major U carrier for both sediments was zircon. Two types of U-bearing zircons were observed, with the highest U concentrations up to 4500 ppm coming from the samples showing characteristics of metamict zircon, possibly altered at near-surface conditions in the oxidized till. The other type was a near-end-member zircon, which was observed more frequently in the unoxidized clay-till. A secondary precipitate collected from a plumbing fixture at one site exhibited elevated concentrations of U consisting of Ca-rich carbonates such as monohydrocalcite, which was likely acting as a sink for U. XANES characterization indicated that U is present as U(VI) coprecipitated with carbonate minerals. $^{234}U/^{238}U$ isotope ratios measured in groundwaters showed minimal variability between the two sites despite variations in U concentration and with depth suggesting a regional source rather than a point source. The combined results did not show any evidence of an anthropogenic source of U, but suggest that alteration of metamict zircon naturally present in near-surface environments (at near neutral pH and low temperatures) could result in the release of dissolved U, leading to elevated U concentrations observed in local groundwater.

The evolution of magmas at a large stratocone volcano, Mount Shasta, N. California

ALLISON M.WENDE[1*],TIMOTHY A. ZEICHERT[1], CLARK M. JOHNSON[1], BRIAN L. BEARD[1], ROBERT L. CHRISTIANSEN[2], ANDREW T. CALVERT[2]

[1]University of Wisconsin-Madison, Madison, USA, wende@wisc.edu (* presenting author) clarkj@geology.wisc.edu, beardb@geology.wisc.edu

[2]U.S. Geological Survey, Menlo Park, USA, rchris@usgs.gov, acalvert@usgs.gov

Mount Shasta, the largest stratovolcano in the Cascade volcanic arc, has been rebuilt since a major sector collapse in at least four major cone-building stages since ~300 ka [1,2]. In conjunction with earlier elemental and isotopic studies [3,4,5,6,7], new Sr, Nd, and Pb isotope data reported here, as well as in-progress U-Th isotope studies, document mantle and crustal contributions to magmas at Mt. Shasta.

The dominantly andesitic Mt. Shasta lavas are characterized by Sr, Ba, Th, Rb and Pb enrichment, depletions in Nb, Ta and HREE, and MORB-like Sr isotopic ratios. Major element modelling is consistent with fractional crystallization of an arc basalt type parent. However, incompatible element enrichments in the lavas 2–3 times higher than predicted by this model preclude magmatic evolution by fractional crystallization alone. Elevated Rb and Ba in other southern Cascade volcanoes are attributed to crustal contamination [6], which may also account for similar enrichments in the Shasta lavas. U-Th isotope data indicate Th enrichment [8] that may be explained by production of garnet in the lower crust via dehydration melting of amphibole.

Sr, Nd, and Pb isotopes indicate a blend of crust and mantle components. $^{87}Sr/^{86}Sr$ ratios vary from 0.7027 to 0.7035 and ε_{Nd} values range from +4 to +6. These compositions are more mantle-like than at Lassen Peak, although they extend to more crust-like compositions than primitive central Cascade lavas. $^{206}Pb/^{204}Pb$-$^{207}Pb/^{204}Pb$ variations form a tight linear array between Juan de Fuca/Gorda Ridge MORB and Cascade region upper crust, a trend that could reflect a subduction component or interaction with the crust. Upper crustal assimilation, however, fails to account adequately for all trace element and isotopic data, providing support for an important lower-crustal role. Evidence for a significant slab contribution comes from trace-element and isotopic variations: high $(Sr/P)_n$ lavas have Sr and Pb enrichments, large Nb and Ta depletions, and Juan de Fuca MORB or slab-like Sr and Pb isotopic ratios; low $(Sr/P)_n$ lavas have more radiogenic Sr and Pb isotopic ratios and lower $^{143}Nd/^{144}Nd$ ratios, similar to OIB, or a mantle like component [6]. Thus, magmatic evolution at Mt. Shasta involves fractional crystallization of an arc basalt type parent, variable slab-fluid influence, and potential assimilation of lower crust, but relatively little upper crustal assimilation. Many of the older lavas have more radiogenic Sr and Pb but non-radiogenic Nd, suggesting greater crustal assimilation in the early history Mount Shasta, reflecting evolution of the conduit system.

Tire-wear particles and their impact on human lung cells

MELANIE WENZEL[1*], SANDRA EBELING[2], IRMGARD MERFORT[2], VOLKER DIETZE[3], AND RETO GIERÉ[1*]

[1] Universität Freiburg, Geowissenschaften, 79104 Freiburg, Germany, melanie.wenzel@venus.uni-freiburg.de

[2] Universität Freiburg, Chair for Biology and Biotechnology, Dept of Pharmaceutical Sciences, 79104 Freiburg, Germany

[3] Deutscher Wetterdienst, Research Center Human Biometeorology, Air Quality Department, 79104 Freiburg, Germany

In the recent literature, there has been a debate about the real properties of tire-wear particles, especially concerning their size and chemical composition but also with respect to their effects on human health. The aims of this study, therefore, were to characterize tire-wear particles using geochemical and mineralogical techniques and to evaluate the toxicological properties of these particles. Another important goal was to develop standard experimental procedures, which lead to representative results.

Samples of tire-wear particles were produced in a standardized tire-test rig, which allowed for collection of particles from three different types of car tires. In addition, one pure-tire sample was obtained by grinding shredded scrap car tires. These four samples were characterized by using scanning electron microscopy (SEM) and optical microscopy with an associated image analysis system (IAS) in order to determine size distribution, chemical composition, particle structure, and optical properties. The investigations of the different samples indicated that a large fraction of particles have equivalent diameters <10 µm with distinct size distributions for the different samples. All samples contained particles smaller 5 µm. IAS showed that all samples contained both opaque and transparent particles. Usually only the opaque particles are regarded as tire material, whereas the transparent particles are assumed to originate from the pavement material. The amount of transparent particles can be used to trace impurities in the tire samples but a certain fraction also seems to originate from the tires themselves.

Subsequently, the tire-wear and tire particles were investigated in terms of their toxicity and their inflammatory effects on human lung cells (from the commonly used lung cell line A549). The experiments have shown that the lung cells, which were exposed for up to 8 h to various concentrations of particles in suspension between 5 and 50 µg/cm², did not show any increase in NF-κB-DNA binding activity. An exception is one sample, for which an 8 h exposure to 50 µg/cm² sample material, led to a stronger increase in NF-κB-DNA binding activity as measured by electrophoretic mobility shift assays (EMSA). The activation of the transcription factor NF-κB in cells is closely linked to inflammatory processes. The cytotoxicity tests revealed an increased cytotoxic potential for all samples from the tire-test rig but not for the pure-tire material. The extent of cytotoxicity, as measured by MTT-tests, varies with concentration. Whereas cytotoxicity was only slight for various particle concentrations, one sample induces cytotoxicity up to about 50%.
The question of the critical role played by size rather than chemical composition of the tire particles will be studied further.

Temperature, charge and radius dependence of multivalent cation adsorption on rutile (α-TiO_2) in aqueous 1:1 electrolytes

DAVID J. WESOLOWSKI[1], MICHAEL L. MACHESKY[2], MOIRA K. RIDLEY[3] AND MILAN PŘEDOTA[4]

[1]Oak Ridge National Laboratory, Oak Ridge, TN, USA wesolowskid@ornl.gov (*presenting author)
[2]Illinois State Water Survey, Champaign, IL, USA machesky@sws.uiuc.edu
[3]Texas Tech University, Lubbock,TX, USA Moira.Ridley@ttu.edu
[4]University of South Bohemia, Ceske Budejovice, Czech Republic predota@prf.jcu.cz

Sorption isotherms – percent adsorption of trace amounts (typically 10^{-3} molal) of multivalent cations (Ca^{2+}, Sr^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, Nd^{3+}, Y^{3+}) in 0.03 to 0.3 molal aqueous, non-complexing 1:1 electrolytes (NaCl, RbCl, NaTrifluormethanesulfonate) – on (Tioxide Corp.) rutile submicron powder suspensions were collected at approximately constant solution/solid ratio (~50 g solution/1 g of 15 m^2/g rutile). The pH at temperature was measured using a hydrogen-electrode concentration cell, and samples were taken through an *in situ*, submicron filter for analysis of unadsorbed cation concentration by ICP-AES. Under these conditions, the pH of 50% adsorption, readily extracted from the sigmoidal sorption isotherms, represents a model-independent measure of the relative sorption affinity of the multivalent cations, which are shown in the figure below to be remarkably systematic and increase strongly (lower $pH_{50\%}$) with increasing cation charge and temperature (linear with inverse temperature) and decreasing ionic radius. Alkaline earth cations sorb weakly and show ionic strength dependence, while smaller divalent transition metals and especially trivalent rare earths sorb much more strongly and do not exhibit significant ionic strength dependence. Multiplication of the $pH_{50\%}$ sorption value by $(Z^2/R)^{1/2}$, (Z=cation charge; R=bare cation radius in pm), greatly reduces the total variance at a given temperature. This behavior is also found for uraninite (UO_2) and may be typical of multivalent ion sorption on high-bulk-dielectric solids that exhibit inner-sphere cation sorption, as we have demonstrated for rutile by combined X-ray reflectivity and molecular modeling studies. The results have important implications for contaminant migration in subsurface environments and suggest a simple approach for recovery of rare earth elements from phosphate production waste streams, and separation from actinides.

VARIATION IN THICKNESS OF THE CHEMICAL WEATHERING ZONE AND IMPLICATIONS FOR EROSIONAL AND CLIMATIC CONTROLS ON EARTH'S GLOBAL WEATHERING THERMOSTAT

A. JOSHUA WEST[1*]

[1]University of Southern California, Department of Earth Sciences, Los Angeles, CA, USA, joshwest@usc.edu (* presenting author)

The variability of weathering fluxes on the modern Earth surface provides key information about how associated CO_2 consumption may have varied in Earth's geologic past. Understanding the functioning of the planet's thermostat rests on unravelling the range of parameters that are empirically observed to influence weathering. This has not proved to be an easy task, partly because little is known about where the most important weathering reactions take place. Indeed, the locus of weathering, and the depth at which weathering reactions take place, is difficult to measure directly. In this work, a new approach is used to try to infer how the thickness of the weathering zone varies, and how this influences variability in weathering and CO_2 drawdown.

The approach taken in this work centers on inverse analysis of a parametric model describing weathering, with respect to previously compiled data on weathering fluxes derived from the solute load of headwater catchments draining felsic bedrock [1]. Though there are significant uncertainties inherent in this approach, the results provide first-order constraints on the variability in the depth over which weathering takes place. Results suggest that the effective weathering thickness varies relatively little across several orders of magnitude of denudation rate. At low to moderate erosion rates, reactions in the soil zone dominate weathering fluxes at the catchment scale, but the contribution from soil weathering decreases significantly at higher erosion rates. Continually increasing silicate weathering fluxes at higher denudation rates are sustained by progressively greater contributions from weathering in bedrock.

These results have important implications for understanding the climatic and erosional forcing of weathering fluxes, with broad repercussions for models of carbon cycle evolution. Broadly speaking, increases in erosion lead to increases in weathering, but this effect becomes progressively less significant at the highest denudation rates. The weathering model used here implies that the effect of climate (temperature and runoff) on weathering fluxes is appreciably weaker at relatively low denudation rates on the modern Earth (the supply limited case), such that erosion is critical to maintaining climate-stabilizing feedbacks in the global carbon cycle. Whether these feedbacks continue to strengthen as denudation rates increase is not completely clear, because of the changing locus of reaction. In rapidly eroding settings, bedrock weathering at depth appears to become dominant, and the effect on climate-weathering feedbacks may be more complicated in this case, since it is not known how weathering at depth may respond to changes in climate at the Earth's surface. This question demands further attention.

Observational constraints on the Titan haze from Cassini/Huygens

ROBERT A. WEST[1]

[1]Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, USA, Robert.A.West@JPL.NASA.gov

Overview

Prior to the Cassini/Huygens mission, observations from the ground, from the Hubble Space Telescope, and from the Pioneer and Voyager missions established the general properties of Titan's haze. The haze is optically thick at visible wavelengths, it shows subtle hemispheric contrast with seasonal reversals, it shows unique structure in the winter polar region, it contains solids with organic composition, it has a 'detached' layer, and the particles in the main haze layer are aggregates of much smaller 'monomers'[1-3]. The Huygens mission put a probe into Titan's atmosphere in January, 2005 and the Cassini mission has made many remote sensing measurements from orbit beginning in 2004.

Findings of the DISR instrument on the Huygens Probe

The Descent Imager and Spectral Radiometer (DISR) instrument on the Huygens Probe is a composite instrument containing seven sub-assemblies. The solar aureole camera, in particular, sampled within a few degrees of the sun and measured polarization at two wavelengths. These measurements, combined with DISR spectrometer data from the blue to near-IR wavelengths provided the following picture of the haze at the probe landing site [4]. The main haze below 145 km altitude is composed of, on the average, aggregates of 4000 monomers whose radius is 40 nm. The haze density follows an exponential fall-off with a scale height of about 65 km above 80 km altitude. Between 80 km and 30 km the density is constant, and below 30 km it is again constant but with a different value. Particles are less absorbing below 80 km indicating condensation by one or more of several possible condensates.

Findings from the Cassini Orbiter

The Cassini orbiter carried, among other instruments, four optical sensing cameras and spectrometers covering the range from EUV to far-infrared. These instruments provided new detail at wavelengths, locations and times not available to the DISR and these together form a more complete picture of the haze. Highlights from these investigations [5] include (1) an axial tilt of the haze, temperature and wind fields, (2) a near-equatorial band, (3) compositional signatures in the spectra, (4) haze extincition profiles to nearly 1000 km altitude and observations of heavy ion precursors near 1000 km, and (5) large-amplitude seasonal variations in the altitude of the detached haze. The orbiter is expected to provide additional critical observations of the seasonal behavior of the haze until end of mission at solstice in 2017.

Fluctuations in ocean anoxia: Evidence from Cretaceous OAEs

S. WESTERMANN[1*], D. VANCE[1], C. ARCHER[1] AND S. A. ROBINSON[2]

[1]Bristol Isotope Group, School of Earth Sciences, University of Bristol, UK

[2]Department of Earth Sciences, University College London, Gower Street, London, UK

(* correspondence: stephane.westermann@bristol.ac.uk)

In sedimentary rocks, especially organic-rich deposits, redox-sensitive trace metal (RSTM) distrubutions have the potential to track change in the oxygenation state of the ocean over geological time. Oceanic anoxic events (OAEs) correspond to periods of profound and rapid environmental change, which have lead to both the widespread deposition of black shales and development of widespread anoxia in the ocean. Understanding the variations of redox conditions during these events is of primary importance, since recent observations and modelling have shown that processes invoked to explain the origin of OAEs are being observed today as a consequence of anthropogenic change.

Here, we compare RSTM distrubtion and molybdenum (Mo) isotope variations during two major Cretaceous OAEs (OAE 1a, Selli event & OAE 2, Bonarelli event). Whereas RSTM have the potential to provide insights regading the depositional conditions and processes in paleoceanographic systems, Mo-isotope data can, under certain circumstances, provide quantitative estimates of how the extent of seawater anoxia may have fluctuated in the past.

For OAE 1a, the RSTM contents in the samples of Gorgo a Cebara (Italy) indicate more reducing conditions, with evidence of watermass restriction within the Selli interval. The Mo isotopes show surprisingly negative values through the section. Before the Selli interval, an increasing trend in $\delta^{98/95}$Mo is observed with values ranging from -0.89 up to 0.08 ‰. Within the Selli level, $\delta^{98/95}$Mo values show a progressive shift towards more negative values. This trend is interrupted by a positive peak to 0.13 ‰, corresponding to samples with the highest Mo content (up to 94 ppm).

For OAE 2, the preliminary results on the samples from the sections of Bottacione and Monte Petrano (Italy) suggest fluctuations in the degree of anoxia during the Bonarelli event, reaching from suboxic to euxinic conditions in an unrestricted watermass system.

During both time intervals, the studied samples show variations in the oxygenation state of the western Tethys, reaching anoxic/euxinic conditions. However, the light $\delta^{98/95}$Mo values suggest that the redox conditions may not have been fully euxinic during OAE 1a. Our preliminary results on OAE 2 samples suggest a different paleoceanographic regime and more reducing conditions. Futher Mo-isotope measurement will be preformed on these samples in order to test ideas on the timing, extent and duration of one of the most pronounced OAEs.

What controls silicon isotope fractionation during dissolution of biogenic silica?

FLORIAN WETZEL[1*], BEN C. REYNOLDS[1], GERALD HAUG[2],

[1]Institute of Geochemistry and Petrology, Department of Earth Sciences, ETH Zurich, Switzerland, wetzel@erdw.ethz.ch (* presenting author)

[2]Geological Institute, Department of Earth Sciences, ETH Zurich, Switzerland

How nutrients are distributed and cycled in the oceanic water column determines what the net effect of biological activity on ocean-atmosphere ΔpCO_2 is. Paleoceanographers and paleoclimatologists are therefore interested in the past nutrient state of the sunlit surface ocean. Biological matter production and recycling involves isotope fractionation which enables the characterization and quantification of nutrient dynamics. Isotope studies of nutrients (carbon and nitrogen) have been used to characterize the nutrient state of the surface Southern Ocean over glacial-interglacial time scales, and recent advances in analytical techniques enabled the inclusion of silicon isotopes. The marine silicon dynamics, distribution and isotopic composition has been established. In the Southern Ocean diatoms are the dominating phytoplankton species essentially controlling silicon cycling by utilizing silicon to build their opaline frustules and remineralizing after death. While the isotope fractionation associated with silicon uptake by diatoms has been found to be essentially constant, the reverse effect, remineralization, could cause diatoms to not preserve their silicon isotope fingerprint from the surface ocean.

In our study we try to assess if isotope fractionation is involved in diatom dissolution and if so, what causes the effect and what are potential implications for silicon isotopes as a tracer for the biological pump. In all experiments we used 5 mM NaOH to start diatom dissolution. To terminate dissolution diatoms were either separated from NaOH by filtering or the unfiltered solution was directly loaded onto the cation exchange resin. Temperature, amount of opal, opal grain size fraction and community structure were varied.

We find that no analytically resolvable isotope effect during dissolution is observed for all filtered samples for the grain size fraction <20 µm, independent of temperature, amount of opal and community structure. Unreproducable isotope fractionation relative to the bulk sample was associated with dissolution of the 20-63 µm grain size fractions that have a heterogeneous community structure (e.g. radiolaria included). All non-filtered samples were found to react with the cation exchange resin and produced significant isotope fractionation. In our presentation we discuss the potential causes for the variability of isotope fractionation and are able to conclude that carefully cleaned and purified diatom material with a grain size of <20 µm reliably preserves the silicon isotope composition attained in the surface ocean.

Contrasting plateau- and intra-oceanic arc (IOA)-related plagiogranites, Nicoya and Santa Elena complexes, Costa Rica

SCOTT A. WHATTAM[1*] AND ESTEBAN GAZEL[2]

[1]Department of Earth and Environmental Sciences, Korea University, Seoul 136-701, Republic of Korea (*correspondence: whattam@korea.ac.kr)

[2]Department of Geosciences, Virginia Tech, Blacksburg, Virginia 24061, USA

Oceanic tonalite-trondhjemite-granodiorite (TTG) suites (i.e., oceanic plagiogranites) [1] are common in oceanic basins, subvolcanic regions of island arc systems and ophiolites. However, to our knowledge, plagiogranites are exceedingly rare in oceanic plateaus. Here, we present geochemical evidence from Costa Rica oceanic complexes for the existence of both plateau- and arc-related plagiogranites. The plateau-derived Nicoya Complex [e.g., 2] preserves low-Al (mean 12.22 wt.% Al_2O_3) plagiogranites whereby the arc-related Santa Elena Complex [3] encompasses high-Al (mean 17.96 wt.% Al_2O_3) plagiogranites.

In contrast to granites and continental trondhjemites, oceanic plagiogranites are characterized by very low K_2O (<0.5 wt.%). On a plot of SiO_2 vs. K_2O [4], all six Nicoya samples of granodioritic or granitic composition (i.e. with >63 wt.% SiO_2) and the single Santa Elena sample of granodioritic composition plot completely within the field of oceanic plagiogranite; four of five samples with 57-63 wt.% SiO_2 also fall within the field of oceanic plagiogranite. On various granite discrimination plots [5], Nicoya plagiogranites generally fall within the field of ocean ridge granite whereby Santa Elena plagiogranites consistently plot within the field of volcanic arc granites. This is consistent with the interpretation of Nicoya and Santa Elena mafic rocks as plateau/MOR and volcanic arc-related products, respectively. On the basis of chondrite-normalized REE plots, both the Nicoya and Santa Elena plagiogranites are consistent as localized, late-stage felsic differentiates of tholeiitic magma.

U-Pb SHRIMP (zircon) dating at the SHRIMP facility, Korea Basic Science Institute (KBSI) is currently underway on these Nicoya and Santa Elena plagiogranites. The geochemical data suggests that plagiogranites from each complex represent magmas which fractionated from a hydrous gabbroic source and are not the result of other mechanisms sometimes invoked for plagiogranite petrogenesis, e.g., anatexis of mafic crust. If this is accurate, Nicoya plagiogranites should be ~95-85 Ma, an interval of which corresponds to the most voluminous pulse of magmatism related to Galapagos plume activity. On the other hand, Santa Elena plagiogranites should be of the order of ~ 120 Ma, an age of which was obtained on associated gabbros via $^{40}Ar/^{39}Ar$ dating [3]. We integrate the new U-Pb ages with the aforementioned chemical evidence to constrain the petrogeneses of Nicoya and Santa Elena plagiogranites.

Can Experimental Dissolution Studies Reproduce Natural Weathering Rates?

A . F. WHITE[1*], D. V. VIVIT[2] AND M. S. SCHULZ[3]

[1*]U. S. Geo. Survey, Menlo Park, CA, USA, afwhite@usgs.gov.
[2] U. S. Geo. Survey, Menlo Park, CA, USA (deceased).
[3] U. S. Geo. Survey, Menlo Park, CA, USA msschultz@usgs.gov.

Introduction

Chemical weathering rates are controlled both by intrinistic mineralogic properities (e.g., defects and surface areas) and extrinistic effects (e.g., solution compositions and saturation states)[1]. During natural weathering, these properities are expected to evolve over geologic time scales which are not reproducable under laboratory conditions. A long term (12 years) experimental column study characterizes the changes of both the relative importance of individual mineral phases and their kinetic reaction rates for 4 pairs of crushed fresh and weathered granite rocks obtained from well-characterized watersheds.

Results

Effluents from the fresh granites indicated a progression in mineral reactivity, dominated initially by defect-dominated plagioclase surfaces (< 1 week), followed by the successive contributions from trace amounts of disseminated calcite (< 1 year) and the oxidation of biotite (<2 years) and finally, by the end of 12 years, by the stoichiometric dissolution of plagioclase. For weathered granites, accessory phases are absent or already oxidized, and effluents are dominated by bulk plagioclase dissolution throughout the experiments.

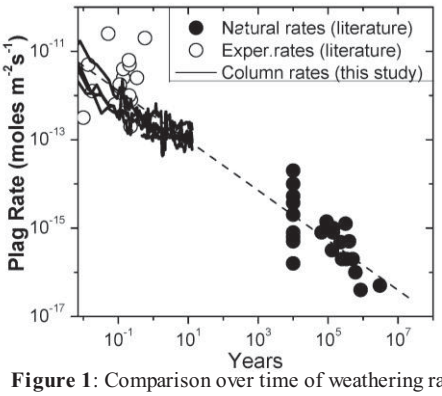

Figure 1: Comparison over time of weathering rates of plagioclase from this study and literature experimental and natural rates.

While initial plagioclase rates for the fresh granites, normalized against BET surfaces, were significantly faster than for weathered granites, the rates converged by the end of 12 years, indicating that extrinsic effects were removed during the course of the experiments. However both sets of rates, while less than those reported for previous experimental studies, remained 1 to 3 orders of magnitude faster than natural rates (Fig, 1). Calculations indicate that while effluents were saturated with respect to gibbsite and kaolinite, they remained significantly undersaturated with plagioclase due to fluid flow rates faster than for most natural conditions.

Updated and extended activity–composition models for thermodynamic calculations in metapelitic systems

WHITE RW[1*], POWELL R[2], JOHNSON TE[1] AND HOLLAND TJB[3]

[1]Institute for Geosciences, University of Mainz, Mainz, Germany, rwhite@uni-mainz.de (* presenting author) [8pt font size]

[3]Department of Earth Sciences, University of Cambridge, Cambridge, United Kingdom, tjbh@cam.ac.uk

The direct application of calculated phase diagrams to metamorphic rocks is dependent on the availability of sophisticated activity–compositional (a–x) models in large chemical systems. While the development of such models has advanced considerably in the last decade, existing models span a range of approaches and degrees of sophistication. The development of a new internally-consistent thermodynamic dataset [1] necessitates the modification of these models to be consistent with the dataset. However, this also provides the opportunity to undertake a thorough expansion, and modernisation of the models.

Updated models for chlorite, cordierite, biotite, staurolite, chloritoid, ilmenite-hematite and melt are presented. Key changes include consideration of ferric iron in chlorite & staurolite, with the additional inclusion of titanium in staurolite, a non-ideal model for cordierite and Fe-Mg order-disorder in chlorite. Calibration of the models has been undertaken in the NCKFMASHTO system utilising a large dataset of coexisting mineral pairs from experimental studies and rocks and via comparison with observed phase relationships in experimental studies and rocks. By developing all the models at the same time, each of the models utilises a consistent approach to formulation, order-disorder and the size of the mixing parameters (W). Thus, many of the inconsistencies between earlier models, which were developed at different times, are eliminated. Diagrams calculated with the new models compare favourably with previous diagrams, with some notable improvements. Extension of the models to include Mn is currently underway.

Implications of unsupported radiogenic Pb in ancient zircon

M.J. WHITEHOUSE[1*], M.A.KUSIAK[1,2] AND A.A.NEMCHIN[2]

[1]Swedish Museum of Natural History, Stockholm, Sweden, martin.whitehouse@nrm.se

[2]Dept. of Applied Geology, Curtin University, Perth, Australia, mkusiak@twarda.pan.pl, a.nemchin@curtin.edu.au

The complexity of zircon U-Th-Pb systematics from strongly layered early-Archean ortho- and paragneisses at Mount Sones and Gage Ridge (Napier Complex, Antarctica) was reported in some of the earliest SIMS zircon studies [1,2]. We report here new SIMS analyses untaken to further investigate this complexity. Notably brown/black coloured, non-cathodo-luminescent, relatively low-U (few 100's ppm) zircons from orthogneisses show a wide range in isotopic composition and exhibit a characteristic reverse discordance pattern. Analyses are distributed broadly along a discordia line (lower intercept ca. 2.5 Ga) that crosses concordia at ca. 3.3 Ga and extends to strongly reverse discordant compositions. As also noted in previous studies [1,2], inspection of the internal peak-hopping signal traces reveal spikes in Pb without corresponding spikes in U. The relatively low U content of the analysed grains as well as the distribution along a well-defined discordia line argues against operation of the well-documented matrix effect seen in SIMS analysis of high U zircon. Instead this effect appears to be related to redistribution of radiogenic Pb within the zircon, with both Pb-loss and Pb-gain (U migration is a less likely mechanism).

To further investigate and constrain the processes responsible for this phenomenon, we have undertaken two types of multicollector Pb isotope analysis in the same grains. Spot analyses exhibit a strong within-run correlation between the Pb count rate and the $^{207}Pb/^{206}Pb$ ratio/age, demonstrating Pb components (sometimes more than one in the same analysis) up to ca. 3.9 Ga. Scanning ion image analysis with a 2 μm spot size rastered over 70 x 70 μm reveal patchy variations of Pb within the zircon (Fig. 1) and in many cases "hot-spots" with $^{207}Pb/^{206}Pb$ ratio/ages up to ~4.2 Ga. These data are consistent with previous suggestions of radiogenic Pb redistribution and suggest that geochronology of ancient zircons such as the ≤ 4.4 Ga Jack Hills detrital zircon suite, which primarily utilises $^{207}Pb/^{206}Pb$ ages, may need to be treated with caution.

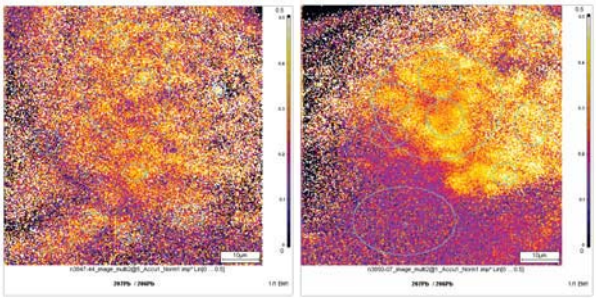

Figure 1: Scanning ion image of the $^{207}Pb/^{206}Pb$ ratio in zircons from Mt Sones and Gage Ridge.

What can zircon really tell us about Earth's earliest crustal evolution?

MARTIN J. WHITEHOUSE [1*] AND ALEXANDER A. NEMCHIN

[1] Swedish Museum of Natural History, Stockholm, Sweden, martin.whitehouse@nrm.se (* presenting author)

[2] Department of Applied Geology, Curtin University of Technology, Perth , Australia, a.nemchin@curtin.edu.au

High-spatial resolution studies of ancient (<4.4 Ga) detrital zircon from the Jack Hills, Western Australia, have yielded invaluable geochemical and isotopic data that are relevant to the evolution of the Earth's earliest crust. While zircon does indeed provide a unique "time capsule" from this period, its use in isolation can however lead to models for early crustal evolution that are at odds with other constraints.

Several lines of evidence from the Jack Hills detrital zircon suite appear to support the existence of modern-style plate tectonics, subduction and well-developed continental (-type) crust on the Earth as early as 4.4 - 4.5 Ga. These include: (1) stable isotope evidence for transfer of surface material to zircon crystallisation depths [1, 2]; (2) inclusion assemblages suggesting relatively high P-T conditions [3]; (3) Ti-in-zircon temperature and REE signatures suggesting crystallisation from evolved melts [4].

In contrast, observations both from zircon and post-Hadean isotopic reservoirs require several 100 Ma isolation of Hadean "proto-crust" and are therefore inconsistent with modern-style plate tectonics. These include: (1) Lu-Hf systematics of the Jack Hills zircons which show no significant input of juvenile material into their source region [5]; (2) unusually radiogenic initial Pb-isotope compositions of some early Archaean rocks requiring long-term high-μ source isolation [6]; (3) solar-like isotopic compositions of rare gases in modern plumes requiring ancient, long-term surface regolith accumulation and subsequent transfer to deep mantle [7]; (4) Th/Nb systematics of post-Hadean mantle-derived rocks recording progressive development of the crust-mantle system [8]; (5) graphite and diamond inclusions in some Jack Hills zircons which are inconsistent with a granite source [9]. These observations have been used to propose an alternative view of the Hadean Earth characterised by a less differentiated basaltic crust (or "stable lid") and the absence of modern style plate tectonics [10].

This apparent dichotomy of evidence needs to be addressed in formulating fully consistent models of the Hadean Earth. Specifically, proponents of plate-tectonic models need to explain the long term isolation of Hadean crust while proponents of models that exclude plate tectonics need to propose mechanisms that can deliver surface-derived materials to middle- lower-low crustal levels.

Ocean deoxygenation and nutrient redistribution: subarctic Pacific perspective

FRANK A WHITNEY[1]*, STEVEN BOGRAD[2] AND TSUNEO ONO[3]

[1] Institute of Ocean Sciences, Fisheries and Oceans Canada, Sidney, B.C., Canada, whitneyf@shaw.ca (* presenting author)
[2]Environmental Research Division, Southwest Fisheries Science Center, NOAA, Pacific Grove, CA, USA, steven.bograd@noaa.gov
[3]Subarctic Oceanography Division, Hokkaido National Fisheries Research Institute, Fisheries Research Agency, Kushiro 085-0802, Japan, tono@fra.affrc.go.jp

Abstract

Large regions of the global ocean are losing oxygen at rates dependent on processes governing their ventilation (gas exchange with the atmosphere). The most rapid losses are being observed in the Subarctic Pacific, a basin in which oxygen transport into its pycnocline (~100-500 m depth) occurs in localized regions undergoing changes in ice cover (Okhotsk Sea) or upper ocean stratification (Russian coast). Circulation of these waters brings them into contact with the atmosphere every few decades, then isolates them below a fresh surface layer where remineralization processes remove oxygen and regenerate nutrients.

Within the pycnocline, time-series measurements record nutrient increases matching oxygen losses. The enrichment of these waters immediately below the winter mixed layer appears to be counteracting an increasing buoyancy of surface waters, keeping nutrient supply stable over the past several decades. This trend has yet to be realized in models attempting to estimate impacts of global warming on ocean productivity.

Denitrification is a common sink for nitrate along continental margins throughout the North Pacific. As oxygen levels decline, an expansion of oxygen minimum zones (OMZ) is predicted to increase rates of nitrate loss and nitrous oxide production. In addition, warming oceans could release methane stored in frozen hydrates, placing new demands on oxygen.

Some biological consequences

Primary productivity in the SAP has not been impacted by increased upper ocean stratification. Our initial understanding of processes allowing the pelagic community to adapt to change suggests a successful future adaptation to climate changes. However, increased storage of nutrients in the upper ocean comes at a cost. Presently, we can only suggest a reduced export either to the subtropics or deep ocean is occurring. Satellite chlorophyll indicates an expansion of the low chlorophyll biome northward, an expected outcome of changing wind patterns.

Also, expanding OMZs are predicted to compress habitat, making some species more vulnerable to predation. In coastal waters of the SAP, oxygen levels sharply define habitat for complex assemblages, placing pressure on fish communities including those presently harvested. Habitat loss will compound stresses on these fish and their habitat. Realistic projections of oxygen losses in coastal waters are needed to provide sensible management options.

Mass dependent stable isotopic fractionation ($\delta^{88/86}$Sr) during the precipitation of barite, Zodletone Spring, Oklahoma

WIDANAGAMAGE, I.H.[1*], SCHER, H.D.,[2], SENKO, J.M.[3] AND GRIFFITIH, E.M.[1]

[1] Kent State University, Kent, U.S.A., iwidanag@kent.edu, egriffi9@kent.edu
[2] Universtiy of South Carolina, Columbia, U.S.A. hscher@geol.sc.edu
[3] The University of Akron, Akron, U.S.A. senko@uakron.edu

Barite precipitation in a continental setting occurs at Zodletone Spring, Slick Hills, southwestern Oklahoma and shows mass dependent stable $\delta^{88/86}$ Sr isotopic fractionation, exhibiting lower values in the mineral barite relative to the solution from which it precipitated as expected. [1] The possibility of using stable Sr isotopic fractionation in barite as a bio-signature could be useful in understanding ancient and extraterrestrial samples. Zodletone Spring flows into a stream which merges into the southern bank of Saddle Mountain Creek. The precipitation of barite on the crust encircling the spring and along the stream is suggested to be microbially mediated. [2] Anaerobic, anoxygenic bacteria oxidize sulfide to sulfate in the system inducing barite precipitation in the barium-enriched water (Ba, 0.4-0.01 mM, Sr, 0.2-0.3 mM). $^{87}Sr/^{86}Sr$ for the spring (0.7103) and the creek (0.7102) were identical in both barite and the waters. Thus barite records the value of the water in which it precipitated. These values are more radiogenic than the underlying carbonates suggesting a deep source of Sr to the spring (~1500 m) from an intrusive rhyolite. Barite is saturated in both the spring and creek. The saturation index of barite for the spring is 1.5 at 20.5^{o}C and 1.9 in the creek at 33.6^{o}C. Different morphologies of barite from the sites were seen. Barite crystals from the crust on the spring are 10-50 μm in diameter and form rosettes which are likely biogenic barite. Rosettes and diamond shape barite at the end of the stream are 10-20 μm, and probably have both biotic and abiotic origins. Barite crystals from the creek show rosettes, diamond and tabular shapes with diameters varying 5-30 μm. This is also probably a mixture of biogenic and abiotic barite. Barite crystals precipitated at the left bank of the creek are 6-10 μm and rosettes (~10%) and ellipsoidal crystals (~80%) indicating that the dominant type is likely abiotically precipitated barite (i.e. ellipsoidal). Preliminary data show the stable isotope fractionation during precipitation ($\Delta^{88/86}Sr_{\text{barite-water}}$) ranges from -0.25‰ to -0.33‰ in the spring and the creek. Given the uncertainty of the isotopic measurements (approximately 0.05‰) the stable isotopic fractionation does not appear to be significantly affected by processes resulting in the varied morphologies (abiotic or biotic) at this site.

Can Li isotopes help detect leakage in future CCS sites? The example of a natural analogue in France

WIDORY DAVID[1*], MILLOT ROMAIN[1]

[1]BRGM, Orléans, France, d.widory@brgm.fr

Introduction

Natural analogue sites where geologic CO_2 is leaking to the surface provide excellent opportunities to test approaches suitable for monitoring potential CO_2 leakage at carbon capture and storage sites. We tested here the possibility of completing the classical CO_2 chemical/isotope monitoring approach with the study of the Li isotope systematic, at a CO_2 analogue site near Sainte-Marguerite in the Massif Central (France).

Study site

The Sainte-Marguerite area is located in the southern part of the Limagne graben (French Massif Central). The basement, composed of highly fractured granite, outcrops toward the west of the study area, notably around the Saladis spring. An intercalated arkosic permeable interval between fractured granite and Oligocene marls and limestones acts as a stratiform drain for fluid migration while the overlying thick Oligocene interval is impermeable and acts as a seal. The Allier river bed is located near the contact between the basement and the sedimentary rocks. Deep CO_2-ladden fluids migrate through the arkose interval toward the Sainte-Marguerite area and sustain a number of local springs (Figure 1). The Sainte-Marguerite area is known for the travertine deposits associated with the CO_2-rich natural springs

Results

The previous characterisation of $\delta^{13}C$ and $\delta^{18}O$ from dissolved CO_2[1] indicated some water samples are in isotope equilibrium with degassing mantle CO_2 while other are not. The study of the corresponding δ^7Li isotope compositions (Figure 1) confirm that Li is explained by a binary mixing relationship between a ^7Li-depleted endmember originating from a deep thermal source, and Li originating from the Allier river.

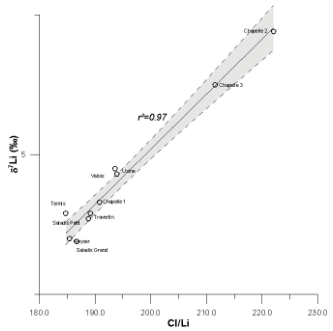

Figure 1: Li concentrations and isotope compositions covariations.

ZIRCON AS A PROBE OF PLANETARY IMPACT HISTORY

MATTHEW M. WIELICKI[1], T. MARK HARRISON[1], PATRICK BOEHNKE[1] AND OLEG ABRAMOV[2]

[1]Department of Earth and Space Sciences, University of California, Los Angeles, 595 Charles E. Young Drive East, Los Angeles, CA 90095

[2]U.S. Geological Survey, Astrogeology Science Center, 2255 N. Gemini Drive, Flagstaff, AZ 86001

The impact history of the early solar system remains controversial. The longstanding paradigm of a Late Heavy Bombardment (LHB) at 3.8-4.0 Ga that largely resurfaced the Moon (and by implication, ~30% of Earth) is to a significant degree supported by highly problematic interpretations of $^{40}Ar/^{39}Ar$ ages. Recent studies indicate that zircon has the potential to preserve evidence of impact events on Earth and possibly other solar system bodies. For example, LHB-era Jack Hills zircon grains and epitaxial rims grown between 3.85-3.95 Ga both show evidence of temperature excursions possibly due to impacts. Lunar zircons have also been interpreted to result from large-scale impacts on the Moon. However the geochemical signatures of zircons produced within impact events are poorly understood and caution must be used when assigning an impact as opposed to igneous origin. Ion microprobe U-Pb ages, Ti-in-zircon thermometry and trace element geochemistry of impact-produced zircon obtained from four preserved terrestrial craters reveal broadly similar thermal conditions of formation and provide a basis of comparison with which to distinguish zircon crystallized within an impact event from grains that formed by endogenic igneous processes. A zircon saturation model of hypothetical target rock compositions undergoing thermal excursions associated with the LHB was developed to predict the Ti-in-zircon temperature spectra expected from impacts. Modeled impact zircon production is a function of ambient temperature, Zr content, target composition, and impact energy. Impacts need to be sufficiently large to permit decompression melting of uplifted middle to upper crust (i.e., low energy bolides will not produce melt sheets and thus impact zircon). Target compositions were estimated from large geochemical databases (including meteorites for other solar system bodies such as the Moon and Mars) and selected through a Monte Carlo process allowing a spectrum of compositions to be randomly accessed. Model results for impact produced zircon yield a zircon crystallization temperature distribution significantly higher than that, for example, from Hadean Jack Hills zircons, but considerably lower than the temperature spectrum of lunar zircons. For modern terrestrial crustal target compositions, modeled results yield zircon formation temperatures remarkably similar to Ti-in-zircon crystallization temperatures for recent, large terrestrial impacts. Importantly, the model predicts that zircon growth in response to impacts form in dominantly felsic melts, with little to no zircon formed in mafic melts. This result appears to rule out most lunar zircons documented for both U-Pb age and [Ti] as having formed in response to impact melting and provides an explanation for the apparent absence of impact zircon from Mars samples.

Evidence of Bacterial Molybdenum Isotope Fractionation

MICHAEL WIESER[1*], BERNADETTE PROEMSE[2], RAYMOND TURNER[3], HALI MORRISON[1] AND ADAM MAYER[1]

[1]Department of Physics and Astronomy, University of Calgary, 2500 University Drive NW, Calgary, AB, T2N 1N4, Canada, mwieser@ucalgary.ca (*presenting author)
[2]Department of Geoscience, University of Calgary
[3]Department of Biological Sciences, University of Calgary

Although the trace metal molybdenum (Mo) is not very abundant, its occurrence is manifold. Molybdenum cofactors play key roles for many enzymes [1, 2, 3] during nitrogen fixation [4], nitrogen reduction, and other processes [5]. Enzymes use trace metals to catalyze chemical reactions by taking advantage of different oxidation states. Molybdenum is available to organisms as molybdate (MoO^{2-}) and varies in oxidation states between +IV, +V and +VI, hence mobilizing two electrons [1]. We have investigated Mo concentrations and the Mo isotopic composition ($\delta^{98/95}$Mo) of cell fractions of the bacterial strain Escherichia coli MC4100. Differential centrifugation was used to separate cytosol, cell membrane and LSP ("low speed pellet"). The cytosol, the intracellular fluid, had the lowest Mo concentrations, and the cell membrane itself the highest Mo concentration. First Mo isotope abundance results suggest that the incorporation of Mo into the cell is associated with isotopic fractionation during production of membrane-anchored Mo-containing proteins and the water-soluble Mo-containing proteins found in the periplasm.

High pressure experimental constraints on majorite transformation of chromium-rich garnets

C.H. WIJBRANS[1*], S. KLEMME[1], A. ROHRBACH[1]

[1]Institut für Mineralogie, Westfälische Wilhelms-Universität Münster, Germany, ineke.wijbrans@uni-muenster.de*

Garnet-Majorite transformation

Garnet is an important constituent of the upper mantle, as is evidenced by its frequent occurrence in mantle xenoliths and as inclusions in diamonds. With increasing pressure silica is incorporated into the octahedral site of garnet resulting in a majorite component [1]. The transformation of garnet to majorite is reported to depend on a number of factors besides pressure, such as bulk compositions and presence of other Al bearing phases (such as cpx) or melt [2]. Furthermore, the presence of the minor element chromium has been suggested to decrease the majorite stability with increasing pressure [3].

If true, the effect of chromium on majorite transformation has implications for the interpretation of the formation depth of diamond inclusions as the Cr/(Cr+Al) ratio is much higher in depleted lithospheric mantle compared to fertile mantle [4].

Experimental methods

To investigate this further, we performed sub-solidus high-pressure high-temperature experiments in a Walker-type multi anvil press (Bristol design) at pressures of 6, 9 and 12 GPa, and a range of temperatures. The starting materials consist of silicate glasses in the system Cr_2O_3-CaO-MgO-Al_2O_3-SiO_2, with varying $Cr_2O_3/(Al_2O_3+Cr_2O_3)$. Electron microprobe is used to determine the concentration of major and minor elements in the different phases.

Results

All experiments yielded garnet, opx, olivine and (minor) cpx as stable phases. Preliminary results indicate that for constant pressures and temperatures, the majorite component in garnet decreases with increasing Cr/(Cr+Al) of the bulk composition. There also appears to be a small temperature effect on the stability of the majorite component in garnet but more experiments are needed to confirm this.

Mineral and chemical composition of the biomass ash

WANDA WILCZYŃSKA-MICHALIK[1*], RENATA GASEK[1], MAREK MICHALIK[2]

[1]Institute of Geography, Pedagogical University, Kraków, Poland, wmichali@up.krakow.pl (* presenting author), rgasek@ap.krakow.pl

[2]Institute of Geological Sciences, Jagiellonian University, Kraków, Poland, marek.michalik@uj.edu.pl

Biomass is considered as important non-fossil renewable energy source. Its share in co-combustion with hard coal in power plants in Poland increases. Addition of biomass significantly modifies the composition and properties of fly ash and influences possiblilities of its application. The study is based on mineralogical and chemical analysis of ash obtained at temperature ca 470°C from various types of biomass.

Content of elements in ashes varies within broad range, e.g. Ca from below 2 (corn bran) to >16 wt% (sawdust); P from below 0.5 (beech bark) to >5 wt% (corn bran and palm kernels); Mg from 0.6 (beech bark) to 6.3 wt% (corn bran); K from 2.3 (beech bark) to >10 wt% (corn bran, sunflower, sawdust, olive residue, straw, palm kernels); S from 0.5 (beech bark, corn bran) to >3 wt% (sunflower).

Mineral composition of ash is variable. Beech bark ash is composed of quartz, calcite, fairchildite, lime, mica and barite and aluminosilicate spheres as minor components; olive residue ash contains quartz, arcanite, talc, kutnahorite and Fe oxides, and Zn sulphide as minor components; sunflower ash – fairchildite, arcanite, quartz ; straw ash – quartz, calcite, bustamite; palm kernel ash – quartz, calcite, bayerite, cristobalite, and Mg, K, Ca phosphates; sawdust ash – calcite, fairchildite, quartz, gatehauseite (?), and barite, zincite, lime, K and Mg phosphates as minor componets; corn bran ash – tephroite, quartz, corundum, and K and Mg phosphate aggregates composed of very small spheres (ca 1 μm in size).

Very small grains are abundant in the studied ash samples. For example, sunflower ash is composed of very fine carbonate and sulphate particles, straw ash is rich in small rods and prisms of quartz and carbonates.

Mineral and chemical composition of ash is related partly to the composition of plants but content and composition of detrital components (derived from soil, atmospheric dust particles deposited during cultivation or storage) is also important. Relatively big angular or rounded quartz grains of detrital origin are present in several samples (abundant in sawdust and beech bark ash). K-feldspar grains (up to 0.2 mm in size) are present in beech bark ash. Aggregates composed of kaolinite in iron oxides matrix (probably derived from soil) are present in palm kernels ash. Small detrital grains are probably also present but their identification is dubious.

Significant variation in mineral and chemical composition of biomass ash suggests that usage of various types of biomass in co-combustion with coal can result in strong variation of fly ash composition.

Study was supported by NCN grant No. 0579/B/P01/2011/40.

Pre-Late Heavy Bombardment terrestrial crust: review of the zircon evidence for its nature and origin

SIMON A. WILDE[1]*

[1] The Institute for Geoscience Research, Curtin University, GPO Box U1987, Perth, Western Australia 6845, s.wilde@curtin.edu.au (* presenting author)

Distribution

Evidence of pre-Late Heavy Bombardment (LHB) [1] crust on Earth is hampered by the myriad of subsequent geologic processes that could potentially destroy it. However, zircons pre-dating the LHB at 3.85-3.95 Ga are widely distributed on Earth. Locations include the Slave Craton of Canada [2], the Yilgarn Craton of Western Australia [3], Enderby Land in Antarctica [4], and the North [5] and South [6] China cratons, as well as in Tibet [7].

This distribution in four continents and in a variety of hosts that include igneous, metamorphic and sedimentary rocks – and with an age range for the hosts from 4.03 Ga to 0.05 Ga – establishes both the wide distribution and the long-term survival of the ancient grains, and potentially portions of ancient crust.

Origin

The question remains as to the origin and source of these ancient zircon crystals. Models for the site of generation include a solidified magma ocean, oceanic islands or extensive continental crust with oceans; driven by either modern-style plate tectonics or processes possibly unique to the early Earth. Intriguingly, zircon hafnium model ages indicate a dichotomy in the 3.95-4.4 Ga population: some extend back to 4.4-4.5 Ga, whereas others are younger and within error of the U-Pb crystallization age. Similarly, in the oldest rocks that just post-date the LHB, zircon hafnium model ages rarely extend back much beyond 4.0 Ga: what is the significance of this? In terms of preservation, evidence from the Yilgarn Craton indicates that ancient zircon was present in the mid/lower crust in the late Archean, becoming incorporated in granitoid magma at that time. However, in the North and South China cratons, the depository was tapped in the Phanerozoic. In the North China Craton, this occurred in the Ordovician, whereas in the South China Craton, ancient zircon was incorporated in Cenozoic volcanic rocks. So what are the controls on this distribution and how do they relate to continental formation, destruction and amalgamation? A variety of scenarios will be examined in an attempt to explain these features.

Objectives

The aim of this study is the investigation of the long term behavior of mineral phases and fluids in systems convenient for CO_2 injection and storage like saline aquifers or hydrate bearing sediments.

Introduction and Settings

Batch experiments were conducted to investigate the interactions of supercritical CO_2 (>7.4 MPa/ >31°C), brine and rock-forming mineral concentrates (albite, microcline, kaolinite, bentonite, biotite, muscovite, calcite, dolomite, and anhydrite) using a newly developed experimental set-up. The solid to fluid ratio was about 1:50. Experiments with mixtures of supercritical CO_2 (99.5 vol.%) and SO_2 or NO_2 impurities (0.5 vol.%) take into account the incomplete purification of industrial captured CO_2 using the oxyfuel technology. In addition, the vessels were not evacuated before the experiments and therefore contained oxygen (ca. 10 cm^3 per experiment), which is also expected in industrially captured CO_2. Before, during and after the experiments approximately 3 ml of fluids were sampled every time and analyzed for pH instantaneously and for dissolved constituents using ICP-MS and IC. After up to 1000h lasting experiments the dissolution and solution characteristics of the solids were examined by XRD, XRF, SEM and EDS, respectively.

Results

Our results suggest the formation of sulfuric acid and nitric acid, reflected in pH values between 1 to 4 for experiments with silicates and anhydrite and between 5 to 6 for experiments with carbonates. These acids should be responsible for the general larger amount of cations dissolved from the mineral phases compared to experiments using pure CO_2. For pure CO_2 a pH of around 4 was obtained using silicates and anhydrite, and 7 to 8 for carbonates.

Silicates do not exhibit visible alterations during all experiments but released an increasing amount of cations in the reaction fluid during experiments with impure CO_2. Si was obtained in ascending concentrations during experiments with silicates whereas Al and Fe exhibited increasing concentrations only during the beginning of the experiments but were variable towards the end. The amounts of Mg and K in the fluids increased or kept constant during all experiments. Ca behaved variable. Nonetheless, precipitated secondary carbonates could not be identified.

Dissolution of carbonates was observed after both pure and impure CO_2 experiments. The total amount of dissolved constituents in the reaction fluid is at least twice as high for carbonates and anhydrite than for silicates. Anhydrite was corroded by approximately 50 wt.% and gypsum precipitated during experiments with supercritical CO_2+NO_2.

Degassing a rhyolite: are the old Ar-Ar ages real, inherited or excess?

WILKINSON, C. M. [1*], KELLEY, S. P. [1], SHERLOCK, S. C. [1], WILSON, C. J. N.[2], CHARLIER, B. L. A. [1]

The aim of this project is to test the resolution of Ar-Ar dating and understand some of the minor anomalies that can affect the fidelity of resulting eruption ages. Few reliable age data exist for post-caldera rhyolitic lavas and domes of the Snake River Plain, USA. The Sheridan Reservoir dome (SRD) has previously been dated by U-Pb geochronology and the published age (~2.07 Ma [1]) overlaps with the generally accepted age of the Huckleberry Ridge Tuff (HRT) (~2.05 Ma [2]). New $^{40}Ar/^{39}Ar$ age data has uncovered possible contamination and higher than expected Ar-Ar apparent ages in feldspar crystals. The SRD post-dates the HRT (C. Wilson, 2011 pers. comm.), but new Ar-Ar ages are older than both the existing U-Pb age for the dome and the generally accepted Ar-Ar age of the HRT.

Extraneous argon, artificially elevating ages may either reflect **1.** excess argon ($^{40}Ar_E$) incorporated into a mineral during crystallization (via diffusion into the mineral lattice or hosted within inclusions) or **2.** inherited radiogenic argon (sourced from a component older than the age of eruption) [3].

To further our understanding of extraneous argon contamination of the SRD phenocrysts, we carried out $^{40}Ar/^{39}Ar$ single-grain fusion dating of feldspar and rhyolitic groundmass. Here we present new age data, where initial results show feldspar ages to be variable and too old, whereas $^{40}Ar/^{39}Ar$ ages obtained from the groundmass are less affected. Diffusion modelling (using DIFFARG [4]) has been carried out to show that these older ages are a consequence of radiogenic argon residing in incompletely outgassed feldspar xenocrysts caught up in the SRD eruption..

Mass-dependent molybdenum isotope variations in ocean island basalts

MATTHIAS WILLBOLD*, TIM ELLIOTT, AND COREY ARCHER

University of Bristol, School of Earth Sciences, Bristol, United Kingdom, M.Willbold@bristol.ac.uk (* presenting author)

Systematic differences in the mass-dependent molybdenum (Mo) isotopic composition of chemical sediments have recently been used to infer the oxygenation state of past and present oceans [1-4]. Sediments deposited under oxic conditions (i.e. Fe-Mn-oxides) are marked by overall light isotopic compositions (δ^{98}Mo<0.5‰ [1,3]), whereas sediments deposited in euxinic environments (i.e. black shales) have heavier isotopic compositions (δ^{98}Mo >0.5‰ [1,5]) relative to the convecting mantle value (δ^{98}Mo ~ 0; [1-3]). In contrast, it is generally accepted that magmatic processes do not induce any mass-dependent Mo isotope fractionation [6].

Here we investigate the use of mass-dependent Mo isotope data as a tracer for recycled crustal components in the source of ocean island basalts. The Mo isotopic compositions of samples from the ocean islands of La Palma, Hawaii, Iceland, Tubuaii, and Mangaia were determined by MC-ICPMS using a double spike (^{97}Mo-^{100}Mo) approach. Repeated measurements of the USGS basaltic reference material BHVO-2 over a period of two years yielded a δ^{98}Mo reproducibility of ca. 0.06‰ (2σ; N=62).

Samples from Iceland, Tubuaii, and Mangaia have similar values with δ^{98}Mo = -0.02 to +0.07‰. In contrast, samples from La Palma show an offset to more negative values in δ^{98}Mo (0.00 to -0.25‰), whereas samples from Hawaii display a much larger spread in δ^{98}Mo extending from -0.25 to +0.18‰ with the majority of data ranging between δ^{98}Mo -0.04 to +0.18‰.

Thus ocean island basalts record significant mass-dependent Mo isotopic heterogeneity in the Earth's mantle. We interpret the Mo isotopic variability as reflecting different contributions of crustal-derived components that have recycled into the mantle, although further work is required in more precisely constraining the Mo isotope composition of different deep subducted protoliths. However, it appears that mass-dependent Mo isotopic compositions of oceanic basalts can be used as a sensitive tracer of recycled component in the convecting mantle.

Fractionation of iron stable isotopes by magmatic processes: progress and potential

HELEN M. WILLIAMS[1]*, MICHAEL BIZIMIS[2], STEPHEN MOORBATH[3] & KATRINA E. J. HIBBERT[4]

[1]Department of Earth Sciences, Durham University, Durham, UK (* presenting author; h.m.williams2@durham.ac.uk)

[4]Bristol Isotope Group, Department of Earth Sciences, University of Bristol, Bristol, UK

The last five years have seen unprecedented advances in the measurement and application of non-traditional stable isotope systems, including the transition metals and elements such as Li, Mg, Si, Tl and U. Improvements in analytical precision have facilitated the application of these isotope systems to magmatic processes, where the magnitudes of stable isotope fractionation ($\propto 1/T^2$) are expected to be small. Previous studies have shown that Fe stable isotopes in igneous rocks are a potential tracer of changes in mantle oxidation state [1, 2]. Variations in the Fe isotope composition of the mantle may, therefore, provide an independent means of monitoring secular variations in mantle oxygen fugacity (fO_2) complimenting information from other tracers, such as V/Sc ratios [3], V partitioning data [4], and Fe^{3+}bearing mineral equilibria. However, it has also been shown that Fe isotopes are fractionated by processes such as metasomatism [5] and magma differentiation [6, 7] and it is important to be able to distinguish these effects from fractionation induced by melting and variations in fO_2. In order to investigate this further, a series of highly characterised peridotite xenoliths from Salt Lake Crater, Oahu, Hawai'i [8], which display extreme variations in fO_2 [9], were analysed for their Fe isotope compositions. The Fe isotope compositions of both separated minerals and bulk samples display striking negative correlations with indicators of melt extraction such as Mg/Mg+Fe as well as Hf isotope compositions. No correlation exists between Fe isotopes and fO_2, Sr or Nd isotopes or highly incompatible elements such as the LREE, which are all considered to have been reset by metasomatic processes. Iron stable isotopes therefore have the potential to "see through" metasomatic events and record primary melt extraction processes.

The Fe isotope compositions of metabasalts and ultramafic rocks from Isua (3.6 Ga) and komatiites from Belingwe (2.7 Ga), Vetreny (2.4 Ga) and Gorgona (0.089 Ga) define clear arrays with Mg/Mg+Fe and redox-sensitive trace element ratios such as V/Sc [10, 11]. These data provide evidence for the fractionation of Fe isotopes during melting, with the partitioning of Fe^{3+} and isotopically heavy Fe into the melt phase and, critically, demonstrate that the nature of this fractionation appears has remained more or less constant over the last 3.6 Ga. This observation implies that the Earth's mantle has been oxidised since the Archean, in agreement with other studies.

Iron isotope variations in Icelandic soil profiles and fractionation of Fe isotopes during weathering

HELEN M. WILLIAMS[1]*, SOPHIE OPFERGELT[2,3], CHRISTOPHER SIEBERT[3], REBECCA NEELY[3] & KEVIN W. BURTON[1]

[1]Department of Earth Sciences, Durham University, Durham, UK (* presenting author; h.m.williams2@durham.ac.uk)

[2]Earth and Life Institute, Université catholique de Louvain, Louvain-la-Neuve, Belgium

[3]Department of Earth Sciences, University of Oxford, Oxford, UK

Iron stable isotopes have considerable potential as a new geochemical tool that can be used to address the bioavailability and biogeochemical cycling of Fe in soils and the behaviour of Fe during weathering processes. The degree to which Fe isotopes may be fractionated during pedogenic and weathering processes is, however, controversial [e.g. 1-4]. This study investigates the distribution of Fe stable isotopes in four typical Icelandic soil profiles from a basaltic catchment (Borgarfjördur): Histic Andosol (HA), Histosol (H), Gleyic Andosol (GA), Brown andosol (BA). Among the soil profiles, the weathering degree increases following the sequence BA<GA<H<HA, as supported by a decreasing Total Reserve in Bases (TRB, the total content in Ca+Na+Mg+K) or an increasing content in crystalline Fe-oxides with increasing weathering. These soil profiles are all derived from the same parental basalt and hence provide an ideal opportunity to investigate the response of Fe stable isotopes to pedogenic and weathering processes. Bulk soil samples, pore waters, oxalate extracts (Fe_O, specific for short range ordered Fe-oxide and humus-bound Fe) and dithionite–citrate–bicarbonate extracts (Fe_d, including Fe_O and crystalline Fe oxides, thus excluding Fe bound in silicates) were analysed for their Fe isotope compositions by MC-ICP-MS (Thermo Neptune) at Durham University using standard Fe purication and mass spectrometry procedures (long-term reproducibility: 0.03‰/amu 2 S.D.; blanks < 1ng Fe) [5]. Bulk soil Fe isotope compositions (δ^{57}Fe, relative to the IRMM014 Fe standard) are correlated with the TRB weathering index: the most weathered soil profiles (e.g. HA) display isotopically light and variable Fe isotope compositions (-0.55 ± 0.08‰ to 0.20 ± 0.04‰ 2 S. D.) relative to the parental Icelandic basalt (0.07 ± 0.08‰), providing direct evidence for the fractionation of Fe isotopes during weathering to progressively lighter values. In contrast, poorly weathered soils (e.g. BA) display relatively invariant Fe isotope compositions (0.01 ± 0.07‰ to 0.20 ± 0.06‰) within error of the δ^{57}Fe value of the parental basalt. In these poorly weathered soil profiles, pore waters, Fe_O and Fe_d also show minimal deviations in δ^{57}Fe value with respect to the parental basalt, whereas in the highly weathered HA soil profile the Fe isotope compositions of pore waters, Fe_O and Fe_d are highly fractionated. In HA, the Fe isotope compositions of Fe_d are extremely similar to those of the bulk soils, reflecting the large proportion of crystalline Fe oxides in this soil profile. In contrast, Fe_O from the near-surface horizons in HA (0.34 ± 0.08‰ to 0.66 ± 0.06‰) are heavier than the bulk soil and become increasingly lighter than the bulk soil with depth. This pattern is also displayed by the soil pore waters, which suggests that the cristallinity of Fe-oxides in soils partly controls the fractionation of Fe isotopes in dissolved Fe in pore waters.

The Permian-Triassic Boundary (PTB) extinction is considered the largest extinction in earth's history. However interpreting paleo-environmental conditions from sedimentary records may prove difficult due to the occurrence and preservation of PTB sections. The PTB sediments of the Spiti Valley (Himchal Pradesh, Himalaya, India) have been subjected to diagenesis and low-grade metamorphism. These two processes potentially alter the original geochemical signatures. In Spiti Valley, PTB sections consist of Permian Gungri Formation (Kuling Group) black shale unconformably overlain by an iron-rich pebbly layer ("ferruginous layer") which marks the PTB. Overlying the ferruginous layer is the Triassic Mikin Formation, a limestone inter-bedded with calcareous and black shales. In this study we assessed the post-depositional overprint on the geochemistry of Spiti Valley Muth PTB section using methods geochemical and chemometric approaches to identify original signatures preserved in this section. The results show that the section does preserve original signatures useable for paleoenvironmental reconstruction. More importantly we show evidence of depositional events preceding the Neo-Tethyan main regression associated with the timing of the extinction.

Microbial reduction of U(VI) at alkaline pH relevant to geological disposal

ADAM J. WILLIAMSON,[1*] KATHERINE MORRIS,[1] GARETH T. W. LAW,[2] SAMUEL SHAW,[3] AND JONATHAN R. LLOYD[1]

[1] Research Centre for Radwaste and Decommissioning and Williamson Research Centre, School of Earth, Atmospheric and Environmental Sciences, The University of Manchester, adam.williamson-2@postgrad.manchester.ac.uk (* presenting author), katherine.morris@manchester.ac.uk, and jon.lloyd@manchester.ac.uk

The UK's intermediate level radioactive wastes (ILW) will be disposed of in a deep geological disposal facility (GDF) [1]. Here, one likely scenario for disposal in the UK GDF is mixing ILW with cement, grouting into stainless steel canisters followed by further backfilling with cement. Post-closure, re-saturation of the cementitious GDF over time will form a hyperalkaline chemically disturbed zone (CDZ) within the host rock.

Microbial processes, especially Fe(III) reduction, may immobilise redox active radioactive contaminants in the waste either through direct enzymatic reduction or via interactions with biogenic Fe(II) [2]. Here, we explore the extent of microbiologically-mediated U(VI) reduction under GDF relevant alkaline conditions. Microcosms were set up using sediments taken from legacy lime works, adjusted to pH 10, augmented with electron donor (organic acids with yeast extract) and systems were run with and without added Fe(III) oxyhydroxides. Systems were established with lower (20 ppm) and higher (100 ppm) concentrations of UO_2^{2+} and allowed to progress through a series of redox processes, potentially including metal reduction, and to assess sorption of U(VI), uranium biotransformations and to prepare samples for XAS analysis.

A cascade of microbial redox processes occurred at high pH in all microbially active systems with U(VI)-removal occurring in sediments with and without added Fe(III) oxyhydroxides. In Fe(III) augmented systems, which displayed high levels of Fe(III)-reduction, magnetite was the dominant Fe(II) bearing bio-mineral product. XANES analyses of all microbially active sediment end-members confirmed reduction of U(VI) to U(IV). Interestingly, controls using pre-reduced, autoclaved sediments showed no sign of U(VI) reduction, suggesting that U(VI) reduction in these systems is predominantly enzymatic. Overall, these results show that microbial metal reduction can occur in a high pH environment analogous to that of an evolved GDF and demonstrates the reductive removal of U(VI) from solution in such systems is likely mediated by direct enzymatic processes.

SIMS carbon isotope analysis of Proterozoic microfossils

KENNETH H. WILLIFORD[1*], TAKAYUKI USHIKUBO[1], J. WILLIAM SCHOPF[2], KEVIN LEPOT[1], KOUKI KITAJIMA[1], JOHN W. VALLEY[1]

[1]WiscSIMS, NASA Astrobiology Institute, Dept of Geoscience, University of Wisconsin, Madison, WI, USA, kwilliford@geology.wisc.edu (* presenting author)

[2]Dept of Earth and Space Sciences, University of California, Los Angeles, CA, schopf@ess.ucla.edu

We present new in situ carbon isotope ($\delta^{13}C$) data from permineralized microfossils in the stromatolitic cherts of the Gunflint (~1880 Ma), Bitter Springs (~830 Ma), Chichkan (~775 Ma), and Min'yar (~740 Ma) Formations. Specimens were selected for their excellent preservation and analyzed in thin section with a reproducibility of 1–2‰ (2 SD) using secondary ion mass spectrometry (SIMS). The range of $\delta^{13}C$ values (–34.6 to –22.1‰ VPDB) exhibited among the 46 specimens is consistent with photoautotrophic carbon fixation by ribulose bisphosphate carboxylase (RuBisCO), the acetyl-CoA pathway, or heterotrophic assimilation. In light of the morphologies, however, the $\delta^{13}C$ values support taxonomic assignments of these specimens as photoautotrophs using RuBisCO. Fossil cyanobacteria from the Gunflint, Bitter Springs, and Min'yar Formations, for which available carbonate $\delta^{13}C$ data can be used to estimate $\delta^{13}C$ of dissolved organic carbon (DIC), exhibit a consistent ~20‰ total fractionation ($\delta^{13}C_{DIC} - \delta^{13}C_{org}$) similar to that observed in living cyanobacteria. Morphologically diverse microfossils in a ~1 mm^2 part of a microbial mat from the Min'yar Formation exhibit $\delta^{13}C$ values that correlate with morphology-based taxonomy and cellular anatomy, suggesting that isotopic signatures of their original biosynthetic processes are preserved. Carbon isotopic compositions consistent with the different fractionations observed in modern cyanobacterial and eukaryotic RuBisCO are preserved in a colonial cyanobacterium and a phytoplanktonic protistan acritarch situated < 1 cm apart in in the stromatolitic Chichkan chert.

Due to the low total organic carbon (TOC) of permineralized microfossils, analyses were conducted using a relatively large (15 µm) spot, high (2.5 nA) intensity primary beam, an electron multiplier to collect ^{13}C, and standardized with a low TOC carbonaceous chert PPRG 215-1 [1,2]. This is distinct from our technique for $\delta^{13}C$ analysis of high TOC materials (e.g., kerogen in shales) which employs a 6 µm spot, two faraday cup collectors, an anthracite coal standard, and has a reproducibility of 0.4‰ (2 SD) [3]. Standardization of microfossils with kerogen in a low TOC carbonaceous chert avoids potential barriers to accuracy (different instrumental bias) presented by standardization with crystalline materials that have a high C content (e.g., graphite), and along with analyses of microfossils from the Gunflint and Bitter Springs Formations, the PPRG 215-1 standard enables a direct interlaboratory comparison with the first study of this kind [2].

Results from these exceptionally well-preserved Proterozoic microfossil specimens provide a baseline for a more extensive study of the effect of organic matter preservation on carbon isotope composition in a large suite of Proterozoic microfossils [4], and they demonstrate that it is possible to distinguish subtle differences between metabolic (e.g., eukaryotic vs. bacterial RuBisCO) and biosynthetic (e.g., peptidoglycan vs. lipid synthesis) pathways in individual ancient microbial fossils [5].

Anaerobic methanotrophy in Cretaceous methane seep deposits, Canadian High Arctic

K.WILLISCROFT[1*], B. BEAUCHAMP[2], S. GRASBY[3], D. BIRGEL[4]

[1]University of Calgary, Calgary, Canada, krwillis@ucalgary.ca (* presenting author)
[2]University of Calgary, Calgary, Canada, bbeaucha@ucalgary.ca
[3]Geological Survey of Canada, Calgary, Canada, steve.grasby@nrcan.gc.ca
[4]University of Vienna, Vienna, Austria, daniel.birgel@univie.ac.at

Over 120 ancient methane seep deposits have been found on Ellef Ringnes Island, Canadian high Arctic, within the Early Cretaceous marine shale of the Christopher Fm. The seep deposits range in size from less than 0.3 m to over 7 m height and are composed of varying proportions of background sediment and authigenic calcite. Many mounds are highly fossiliferous, including abundant bivalves, ammonites and tubeworms.

The $\delta^{13}C_{carbonate}$ values range from -55‰ to -30‰, implying an origin through oxidation of methane and subsequent carbonate deposition. The seep mounds are largely confined to one stratigraphic horizon indicating a major methane flux from the basin occurred at that time. This timing is consistent with the basin burial history and onset of thermogenic methane production, suggesting gas migration to the sea floor was synchronous with methane generation.

Mo/Al ratios of the seep deposits, in comparison to the surrounding Christopher shale host, suggests seep deposits formed in an isolated anoxic setting in an otherwise oxic environment. Biomarker analysis is consistent with this model and suggests anaerobic oxidation of methane (AOM) was most likely carried out by both ANME -1 and -2 archaea, which may represent various consortia active either temporarily or spatially. The low contents of SRB-derived biomarkers may point to a predominance of ANME-1, which are not closely tied to sulphate reducing bacteria (SRB).

Due to the local anoxic conditions during deposition, many early diagenetic carbonate phases preserve organic matter, with the exception of high magnesium botryoidal calcite, which is completely devoid of organic material. There are no hopanoids or steroids preserved in any of the methane seep deposit phases to support aerobic methanotrophy, indicating that these cements do not represent a switch to more oxic conditions as originally interpreted. Instead it is proposed that the waxing and waning of methane/nutrient flux and its ability to move through the sediment is controlling the precipitation of the two cement phases. Alternatively, it is also possible the rate of microbial growth and methanotrophy during cementation effects the formation of the two cements.

Imposed redox frequency and amplitude flux in the study of iron biogeochemical dynamics

[4]University of California Berkeley, Environmental Science, Berkeley, USA, stevenhall@berkeley.edu

The chemical stability and microbial bioavailability of iron (Fe) oxides in soils, and the coupling between carbon (C), Fe and phosphorous (P) cycles, depends on biogeochemical conditions and their temporal variability. To assess the impact of periodic redox fluctuations commonly found in variably saturated soils, a custom bioreactor system was developed in which redox fluctuations (i.e. Eh frequency and amplitude) were imposed via N_2 and O_2 gas exchange with Bisley, Puerto Rico, (CZO) soil suspensions while allowing for sub-sampling of Fe, P, CO_2 and microbial DNA. Characterization of Bisley site soils included variable temperature ^{57}Fe-Mössbauer spectroscopy (at 298, 140, 70, and 15K), X-ray diffraction (XRD) and chemical extractions of operationally defined Fe pools to evaluate Fe phase heterogeneity. Extraction data show that 20% of the total Fe oxide pool is associated with the dithionite-citrate-bicarbonate (DCB) fraction, of which half is associated with the citrate-ascorbic acid (CA) fraction. Mössbauer spectra show quadrapole distribution sites for Fe^{II}/Fe^{III} in clay and a hyperfine distribution site (sextet) that closely resembles that of nano-goethite. The difference between averaged sextet spectral areas at 70 and 15K (11.7% relative abundance) may correlate with the % abundance of CA extracted Fe. Currently, microbial fingerprinting techniques (i.e. denaturing gradient gel electrophoresis (DGGE) and ribosomal intergenic transcribed spacer analysis (RISA)) are being used to characterize changes in bacterial community composition in response to bioreactor redox oscillations. Finally, process-based kinetic model simulations have been used to describe and test mechanisms of Fe reduction, abiotic transformations, phase partitioning, and microbial population growth in the Bisley (CZO) soils. Preliminary simulations show that Fe concentrations can be reproduced closely by adjusting the time period in oxic and anoxic cycles in accord with experimental conditions.

[5]Geological Institute, Climate Geology, ETH Zürich, Zürich, Switzerland

The Subarctic North Pacific is one of the three primary high-nutrient-low chlorophyll regions of the modern ocean, where the biological pump is relatively inefficient at transferring carbon from the atmosphere to the deep sea. The system is thought to be iron-limited. Atmospheric dust is an important source of iron and other trace elements that are essential for the health of marine ecosystems and potentially a controlling factor of the high-nutrient-low chlorophyll status of the Subarctic North Pacific. However, spatial patterns of dust fluxes in the present and in the past are poorly known for this region.

We trace and quantify the supply of sedimentary phases across surface sediments from 37 multi-core core-top sediments from the Subarctic North Pacific, obtained during the SO202/INOPEX cruise in 2009, in order to obtain a robust representation of the spatial pattern in the supply of dust. To this end, we map the spatial patterns of Th/U isotopes, helium isotopes and rare earth elements in. In order to deconvolve the detrital endmembers in regions of the North Pacific affected by volcanic material, IRD and hemipelagic input, we use a combination of trace elements with distinct characteristics in the different endmembers. This approach allows us to calculate the relative eolian fraction, and in combination with ^{230}Th-normalized mass flux data, to quantify the dust supply.

We compare the spatial patterns of the reconstructed dust fluxes to results of published reconstructions of modern dust trajectories, model output and water column based estimates. The results from this study will be used for future research focusing on dust flux and productivity changes during the abrupt climate change sequence of the last deglaciation: the sequence from the cold and dusty Heinrich Stadial 1, through the dust-poor Bølling-Allerød warm period and a return to the near-glacial conditions of the Younger Dryas stadial. Ultimately, our results will allows us test the traditional hypothesis of eolian iron input primarily controlling the biological productivity in the Subarctic North Pacific and to evaluate how the Subarctic North Pacific's ecosystem mediates climate change.

Origin and evolution of Red Sea brines - Insights from noble gases

GISELA WINCKLER[1,2*], WERNER AESCHBACH-HERTIG[3], ROLF KIPFER[4], REINER BOTZ[5], MARK SCHMIDT[6] AND ENRICO BONATTI[1]

The Red Sea represents a unique setting where an oceanic basin is actively forming and, thus, is an ideal natural laboratory to study young rifiting processes and to test models of hydrothermal circulation. The central rift zone of the Red Sea is known to contain more than twenty morphological depressions filled by highly saline brines. Historically, one of these deeps, the Atlantis II brine, provided the first geochemical evidence for the existence of hydrothermal vents on the ocean floor [1].

Due to their conservative nature, noble gases represent powerful tools to study the dynamics of fluid systems. They have proven to be useful to decode the complex geochemical processes underlying the origin and formation of the Red Sea brines and their relation to the tectonic setting of the Red Sea. Atmospheric noble gas data are used to reconstruct dynamic processes such as bubble formation and degassing within the brine layer and at the brine/seawater interface or boiling. Non-atmospheric noble gas isotope data, i.e. helium and argon isotopes, are applied to interpret the origin of the brines in the tectonic context of the Red Sea.

Here, we present a compilation of atmospheric and non-atmospheric noble gas data from several brine basins, the Kebrit, Discovery and Atlantis II Deep [2,3] as well as new noble gas data from the Shaban Deep, the northernmost Deep of the Red Sea [4]. The noble gas data provide unique insights into the development of sea floor spreading in this active region. Placing the new data in the context of the previous studies, the Shaban Deep appears to be an isolated seafloor spreading cell similar to, but less developed than the Atlantis II Deep.

Geochemical and bacterial evidence for 9800 years of meromixis and euxinia in alpine Lake Cadagno

Lake Cadagno is a meromictic high-alpine lake in the southern Alps of Switzerland (1921 m asl, 0.26 km^2, max. water depth 21 m). The inflow of sulfate-rich waters from subaquatic springs located in dolomitic bedrock results in a permanent chemocline at 10 to 13 m water depth with sulfidic conditions in the hypolimnion [1]. As yet, it is unknown how far back in time euxinia has prevailed in the Lake Cadagno water column, maintaining a diverse anaerobic community of bacteria at and below the redox-transition zone.

Here, we present results documenting the lake's redox-state evolution through the Holocene period using sediment cores (10.5 m) that cover the past ~12,000 years and applying sedimentological, geochemical and molecular analyses.

Trace metal analysis by XRF core scanning and ICP-MS measurements documents the transition from oxic conditions after the lake formation (~12,000 cal yr BP) to sulfidic conditions at 9800 cal yr BP. Part of this transition is a ~1000-year period with enhanced accumulation of Mn (up to 5.9 wt% of Mn) in the sediments, indicating an intermediate oxygenation state with fluctuating redox conditions. We propose that the high Mn concentrations are the result of Mn^{2+} leaching from the sediments during reducing conditions and subsequent rapid precipitation of Mn-oxide minerals during episodic and short-term mixing events. Thereafter, a stable chemocline formed and sulfidic conditions, documented in the sediments by high Mo burial rates (Mo concentrations of up to 470 ppm) [2], prevailed until modern times without any lasting hypolimnetic oxygenation. The onset of euxinia probably corresponds in time to the actuation of the subaquatic springs after the last glacial termination.

The evidence of a stable and persistent chemocline over ~10 kyr in Lake Cadagno offers the framework to study the evolution of anaerobic bacterial communities in an extreme lacustrine environment that could serve as an equivalent for conditions in ancient oceans.

A general quasi-chemical solution model for ordered many-component systems

AARON S. WOLF[1*], PAUL ASIMOW[1], AND RAZVAN CARACAS[2]

[1]California Institute of Technology, Geological and Planetary Sciences, Pasadena, USA, awolf@caltech.edu (* presenting)
[2]Ecole Normale Superieure de Lyon, Laboratoire de Sciences de la Terre, Lyon, France

As first principles quantum mechanical techniques have developed to take advantage of increasing computational power, theoretical mineral physicists have begun to turn their attention toward more realistic systems with greater compositional complexity. While it is now possible to use density functional theory to calculate Gibbs energies of both crystal and liquid solutions composed of many compositional end-members, we will forever be limited by the exponential growth of the parameter space with each added component. Resigned to only sparsely sampling such large many-dimensional composition spaces, we must therefore rely on accurate, and ideally predictive, solution models to interpolate into the large intervening spaces between data points.

In this talk, we will present a new quasi-chemical model that can be used to accurately describe the Gibbs energy surface for many component solutions in addition to providing a physically-based method for projecting into the interior of the many-component space. Our model is a union and extension of the work presented on the polynomial solution model in Saulov (2006) and on the modified associates model in Saulov (2009) [1, 2]. In particular, we have adapted this quasi-chemical model, which is carefully constructed to avoid violating entropy constraints, and applied it to describe the locally ordered regions of solutions. By fitting the model to data along the bounding binaries of the system, we can estimate the non-ideal Gibbs energy cost associated with having local n-body regions in the solution of mixed composition. We have further developed and fully generalized a probabilistic projection method, extending Saulov (2006) to many dimensional systems with Gibbs energy surfaces of realistic complexity, which uses the derived set of binary models to project inside the ternary, quaternary, or higher dimensional space. Because the model is physical rather than merely geometric, it has considerably more predictive power than other commonly used projection methods like the Kohler or Muggianu models [3]. Also, we incorporate a statistically rigorous probability weighting scheme, which straightforwardly produces error estimates on the resulting Gibbs energy surface while enabling mixed compositional data to be incorporated and later used to update model parameters.

We will also discuss the strengths and limitations of the model, by applying it to a number of example solid and liquid solutions. For the liquid solutions, we discuss the difficulties posed with deciding what to choose as the basic "atomic unit" of mixing. For the more straightforward case of solid solutions, we will apply the model to our own DFT calculations and use it to understand the role of spin state in iron-bearing magnesium silicate perovskite.

Fluorite (U-Th)/He thermochronology

R. WOLFF[1*], I. DUNKL[2], H.V. EYNATTEN[3]

[1]University of Göttingen, GZG-Sedimentology, Göttingen, Germany, rwolff@gwdg.de
[2]University of Göttingen, GZG-Sedimentology, Göttingen, Germany, idunkl@gwdg.de
[3]University of Göttingen, GZG-Sedimentology, Göttingen, Germany, heynatt@gwdg.de

Why fluorite?

The (U-Th)/He method is a low-temperature thermochronometer dating single crystals. It uses the ^{4}He accumulation from the radioactive decay of U, Th and Sm. The most used U and Th bearing accessory minerals are apatite and zircon with closure temperatures of 60 - 70 and ~180 °C. However, more minerals are suited for (U-Th)/He chronology. Fluorite is one of these because it is quite common all over the world, occurs in high- and low-temperature felsic hosted hydrothermal veins and Mississippi Valley Type (MVT) ore deposits. Moreover, its geochemistry is well studied. Consequently, fluorite (U-Th)/He chronology is promising for dating hydrothermal events, secondary fluorite formation in limestones, or regional cooling events.

First results indicate the potential of this method [1,2,3,4,5]. However, the reported diffusion parameters and closure temperatures differ greatly. According to [3] the parameters are E_a = 30.5 ± 3.9 kcal/mol, $\log(D_o/r^2)$ = 4.9 ± 0.6 s^{-1} and T_c = 90 ± 10 °C (10°C/Ma, 1 - 3 mm) but [4] reports a closure temperature of T_c = 200 °C. Thus we decided to follow a two-fold strategy.

Approach and Results

On the one hand we perform a regional study in the Erzgebirge, Germany, that combines analysis of fluorite with the thermal history of the study area constrained by well established thermochronometers. The comparision of the results will indicate the closure temperature of fluorites for this case study. Diffusion experiments on the other hand give laboratory based information on the closure temperature and the diffusion parameters.

Our fluorite (U-Th)/He data fit well into the independently measured Upper Cretaceous to Paleocene regional cooling history of the Erzgebirge and the diffusion experiments suggest a behaviour of fluorite similar to Durango apatite.

Conclusions and Outlook

The results show that fluorite is suitable for low-temperature thermochronology. This opens a window into the chronology of hydrothermal systems, limestones and MVT ore deposites. Additional attention has to be turned on fluorite because it occurs in a variety of colors (colorless, yellow, pink, brown, green, blue, black, fetid fluorite). Due to changes in chemistry and REE patterns they may show also changes in diffusion kinetics.

Calcite growth kinetics and solution stoichiometry

M. WOLTHERS[1,2*], G. NEHRKE[3], P. VAN CAPPELLEN[4]

The influence of solution stoichiometry on calcite crystal growth kinetics has recently attracted increasing attention. Here we present a process-based calcite growth model (Figure, adapted from [1]) that is founded in a surface structural model for the calcite–aqueous solution interface [2] and extends the growth model for binary symmetrical electrolyte crystals [3]. The model combines kinetic descriptions of the incorporation of calcium, carbonate and bicarbonate ions at kink sites along step edges, with equilibrium calculations of the surface chemical structure of the calcite–aqueous solution interface under variable chemical conditions. Key model parameters are calibrated by fitting the model to a selected set of step velocities on calcite surfaces measured by Atomic Force Microscopy [4-5]. Without any further adjustment of the parameter values, the model reproduces the observed dependence of the macroscopic growth rate of single calcite crystals on the solution activity ratio of calcium and carbonate ions under alkaline conditions. A variable surface roughness factor is introduced in order to reconcile the new process-based growth model with bulk precipitation rates measured in seeded calcite growth experiments. For practical applications, we further present empirical parabolic rate equations fitted to bulk growth rates of calcite in common background electrolytes and in artificial seawater-type solutions. Both the process-based and empirical growth rate equations agree with measured calcite growth rates over broad ranges of ionic strength, pH, solution stoichiometry and degree of supersaturation.

Experimental investigation of mass-(in)dependent cadmium isotope fractionation during evaporation

FRANK WOMBACHER[1]*, VICTORIA KREMSER[1], WERNER ERTEL-INGRISCH[2], DON B. DINGWELL[2], CARSTEN MÜNKER[1], AND ALEXANDER HEUSER[3].

[1]Universität zu Köln, Institut für Geologie und Mineralogie, 50674 Köln, Germany, fwombach@uni-koeln.de (* presenting author).

[3]Rheinische Friedrich-Wilhelms-Universität Bonn, Steinmann Institut, 53115 Bonn, Germany.

Evaporation experiments for volatile elements provide insight into stable isotope fractionation mechanisms and therefore aid in interpreting results from e.g. volcanic or meteorite samples.

We present data from two types of experiments: i) evaporation of molten Cd into vacuum at 10^{-4} mbar and ~180°C [1] ii) evaporation of Cd and other volatile elements from silicate melts at ~1300°C, atmospheric pressure and variable logfO2 using a mechanically assisted equilibration technique [2].

Cadmium stable isotope data were obtained using a Neptune MC-ICP-MS. To resolve small mass-independent anomalies, residual Cd metal samples were analysed at high ion beam intensities (typically > 20V for ^{114}Cd) and long analysis times (30 minutes). Loss of volatile elements from the silicate samples has been quantified using an ElementXR SF-ICP-MS and external calibration.

Residual Cd metal samples from vacuum evaporation experiments are well described by Rayleigh destillation with a vapor-residue fractionation factor $\alpha = 0.9900$ for ^{114}Cd/^{110}Cd (i.e. -10.0 ‰) [1]. This fractionation is much less than predicted from kinetic theory (α_{kin} = (mass ^{110}Cd / mass ^{114}Cd)$^{0.5}$ = 0.9829; i.e. -17.7 ‰), a mismatch that is frequently observed, e.g. [3]. In contrast, α for the high temperature evaportion from silicates under atmospheric pressure is much lower and corresponds to -1.6 and -0.3 ‰ respectively. The supressed Cd isotope fractionation may in part relate to back reaction.

The accurate quantification of mass-independent fractionation (MIF) in residual Cd metals required that the large mass-dependend fractionation is accurately corrected. This is facilitated using the generalized power law and normalization to ^{110}Cd/^{114}Cd of the starting material [1]. After correction, deficits ranging from 8 to 28 ppm were well resolved for ^{111,113,116}Cd/^{114}Cd. This pattern is in accord with predictions from nuclear charge radii and thus constrain nuclear volume effects. The preferential evaporation of ^{111}Cd, ^{113}Cd and ^{116}Cd may result from their more tightly bond 5s electrons and hence weaker metallic bonds in the liquid as previously suggested for Hg [4,5], another group 12 element. The observation of nuclear volume effects thus suggests that (metallic) bonding in the melt results in reduced fractionation factors.

Metal-silicate partitioning of Mo and W: evidence for late S accretion

B. J. WOOD* AND J. WADE

University of Oxford, UK; berniew@earth.ox.ac.uk

Abstract

We have performed experiments to determine the partitioning of Mo and W between liquid Fe-rich metal and liquid silicate at pressures of 1.5-24 GPa and temperatures of 1803-2723K. Experiments performed in MgO capsules at 1.5 GPa/1923 K indicate that Mo is in the +4 oxidation state in the silicate at oxygen fugacities >2 log units below the IW (Fe-FeO) buffer. In contrast W^{6+} is the dominant tungsten oxidation state in the silicate at 1.5 GPa/1923 K and 1.8-3.3 log units below the IW buffer. We find no evidence that W changes oxidation state in the pressure range to 24 GPa.Metal-silicate partitioning of both Mo and W shows strong dependence on silicate melt composition with both elements becoming more siderophile as the melt becomes more SiO2-rich. When our results are considered in terms of a continuous accretion model consistent with the silicate Earth contents of Ni, Co, V, Cr and Nb, W should partition twice as strongly into the core as Mo. This is in stark contrast to the estimated core-mantle partition coefficients of ~40 for W and 90-140 for Mo. Neither changes to the accretionary path nor the assumption of partial disequilibrium alters the result. The cause is one of the light elements in the core.

The calculated Si content of the core (~4%) comes directly from the metal-silicate partitioning behaviour of Si (Tuff et al., 2011) and the P-T- oxidation state path of accretion defined by the refractory elements. This is not the cause of the discrepancy noted above. We therefore investigated the effect of S on our accretionary model by adding 2% of this element (consistent with cosmochemical estimates) to the core. If S is added at constant S/Fe ratio throughout accretion the net effect is negligible. If, however, S is added exclusively during the last 10-20% of accretion DMo and DW become consistent with the silicate Earth contents of these elements. We conclude that the Mo and W contents of the silicate Earth indicate that S (and other moderately volatile elements) was added to the Earth during core formation but only during the last ~20% of accretion. This conclusion is the same as that reached by (Schönbächler et al., 2010) from the Ag isotopic composition of silicate Earth.

Speciation of lead in aqueous solutions

RYAN J. WOOSLEY[1]* AND FRANK J. MILLERO [1]

[1]Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL, USA rwoosley@rsmas.miami.edu (*Presenting author)
fmillero@rsmas.miami.edu

Introduction

Lead (Pb^{2+}) has been widely studied because of its toxicity to organisms. Since it is the chemical form that is important, rather than the total concentration, in determining the bioavailablity, behavoir and fate of the metal in natural waters, an accurate knowledge of speciation is required. Speciation is determined by complexation with organic and inorganic ligands, which is a function of temperature, inonic strength, and media; therefore reliable formation constants over a range of temperature, ionic strangth, and media are essential. In most natural waters, the inorganic speciation of lead is dominated by chloride and carbonate complexes. To date only a limited number of lead formation constatnts (β_i) have been made due to difficulty in their determination as a result of the limited solubitlity of lead. Instead, formation constants have often been estimated from correlations with other metals; direct measurements are limited. Recently serveral studies of lead chloride and lead carbonate complexation have been done over a large range of ionic strength and in several different media [1,2]. We've combined these previous measurements of lead chloride complexes in various media and lead carbonate complexes in $NaClO_4^-$ with new measurements of $PbCO_3$ in NaCl to model the speciation of lead in natural waters using a Pitzer model.

Pitzer Model

The formation constant of $PbCO_3$ in NaCl was measured using a spectrophotometric method since $PbCO_3$ is known to absorb in the ultraviolet, with a peak in the ultraviolet wavelengths. Measurments were made from 0.001-6 m NaCl at various [CO_3^{2-}]. The β_{PbCO3} was determined through nonlinear least-squares regressions using the global curve-fitting function in OrginPro 8.6. These formation constants were combined with earlier measurements of PbCl complexation (critically reviewed by [1]) and recent measurements of $PbCO_3$ in $NaClO_4^-$ [2] into a Pitzer model. These Pitzer coefficients allow for the inorganic speciation of lead to be determined in many natural waters including brines and seawater.

Magnesium isotope cycling within *Acer saccharum* (sugar maple)

S. WORSHAM[1*], C. HOLMDEN[1], AND N. BÉLANGER[2]

[1]Saskatchewan Isotope Laboratory, University of Saskatchewan, Saskatoon, Canada (*correspondence: srw039@mail.usask.ca, ceh933@mail.usask.ca)
[2]Université du Québec à Montréal, Montréal, Canada (belanger.nicolas@teluq.uqam.ca)

Magnesium (Mg) serves as an important macronutrient for plants being involved with metabolic functions, respiration and most importantly, photosynthesis. Previous studies have demonstrated mass dependent fractionation of Mg within laboratory grown vegetation [1,2] while there has been only one confirmed case of plant fractionation in the field [3]. This study builds on previous work by coupling laboratory and field based investigations of Mg isotope fractionation within *Acer saccharum* (sugar maple) plants. Our main objective is to determine whether Mg isotopes might serve as useful tracer of a forest Mg-cycle.

The study site consists of a sugar maple stand within a first-order catchment located in southern Québec, Canada. Significant Mg isotope fractionation has been established between different tree tissues such as roots, stemwood, and leaves (both senescent and photosynthesizing) as well as other reservoirs including soil waters, precipitation, throughfall, and stream water. The total range of $\delta^{26}Mg$ ($^{26}Mg/^{24}Mg$) values within the study plot is $1.37‰_{DSM3}$ (approximately 30% of reported terrestrial variation).

Earlier laboratory based studies of potted plants have demonstrated a light isotope enrichment of Mg in the soil pool, complementing heavy isotope uptake and incorporation into plant material [1,2]. In contrast to these reported data trends, we do not see light isotope enrichment within the soil pool in nature when whole seedlings are analyzed as analogues of adult trees. We are conducting our own pot experiment with sugar maple to investigate this effect, which will guide our interpretations of this field study. Full results will be presented and discussed in detail regarding factors influencing Mg isotope cycling within a sugar maple dominated catchment.

Insights into zircon U-Pb systematics from intercalibration with astronomical time

JÖRN-FREDERIK WOTZLAW[1*], URS SCHALTEGGER[1], SILJA K. HÜSING[2] AND FREDERIK J. HILGEN[3]

[1]Earth and Environmental Sciences, University of Geneva, Geneva, Switzerland joern.wotzlaw@unige.ch (* presenting author)
[2]Paleomagnetic Lab., Department of Earth Sciences, Utrecht University, Utrecht, Netherlands
[3]Stratigraphy and Paleontology, Department of Earth Sciences, Utrecht University, Utrecht, Netherlands

High-precision U-Pb geochronology of accessory minerals is an integral part of various Earth Science disciplines. Recent advances in U-Pb geochronology by isotope dilution – thermal ionization mass spectrometry (ID-TIMS) allow dating of high uranium accessory minerals (most commonly zircon) at permil precision and external reproducibility. Such high temporal resolution may result in complex zircon age populations, reflecting prolonged growth, magma residence and/or zircon recycling, previously only resolvable by in-situ U-Th dating in Pleistocene magmatic systems. This allows to track the evolution of Cenozoic magmatic systems at unprecedented resolution and to add absolute time constraints to thermal and petrogenetic models. However, these complexities have also been considered to systematically bias zircon U-Pb derived eruption ages, to compromise chronostratigraphic applications of high-precision zircon U-Pb geochronology and to contribute to systematic offsets between the K-Ar and U-Pb systems [1,2].

Orbitally tuned Miocene sedimentary sequences around the Mediterranean contain abundant intercalated zircon-bearing ash beds. These sequences provide the rare opportunity to compare ash-bed zircon U-Pb dates with independent and accurate deposition ages derived from orbital tuning. This allows us to evaluate effects of prolonged crystallization and zircon recycling on zircon U-Pb derived ash bed deposition ages. We present a large data set (*N=18, n>200*) of high precision zircon U-Pb dates for ash beds from an almost continuous Messinian to Langhian (6.2-15.4 Ma) sedimentary sequence near Ancona, Italy [3, 4]. The majority of ash beds contain abundant zircons that predate eruption by several 10s to 100s of ka. However, considering only the youngest single zircon dates to interpret ash bed deposition, results in stratigraphycally consistent deposition ages that, for most of the section, agree with the astrochronologic age model. In the upper part of the section, we find an increasing offset between zircon U-Pb dates and astrochronologic age model within an ~8 m thick ash-rich interval. This may suggest that prolonged zircon growth and zircon recycling is more likely to bias U-Pb dates over short, ash-rich intervals where ash beds are likely derived from a repeatedly tapped, common magmatic source.

Temperature dependent structural changes in aluminoborosilicate melts with different modifier cations (Na, Ba, Ca)

JINGSHI WU[1*], JONATHAN F. STEBBINS[1]

[1]Stanford University, Department of Geological & Environmental Sciences, Stanford, California, USA, jswu@stanford.edu (* presenting author), stebbins@stanford.edu

Introduction

Borosilicate glasses and melts are critical in technology. Because of the ease of transition among three- and four-coordinated boron with composition, temperature and pressure, they may also serve as analog system for silicates at high pressure. The effect of temperature on the structure of aluminoborosilicate liquids has been studied by ^{11}B, ^{17}O and ^{27}Al MAS NMR spectroscopy using glass samples prepared with different cooling rates and thus different fictive temperatures (T_f). The abundances of BO_3 groups and of non-bridging oxygens (NBO) increase with increasing T_f, indicating that the reaction $BO_4 \leftrightarrow BO_3$+NBO shifts to the right at a higher T. The modifier cation with higher cation field strength (Valence/square of ionic radius) promotes formation of BO_3 and NBO.

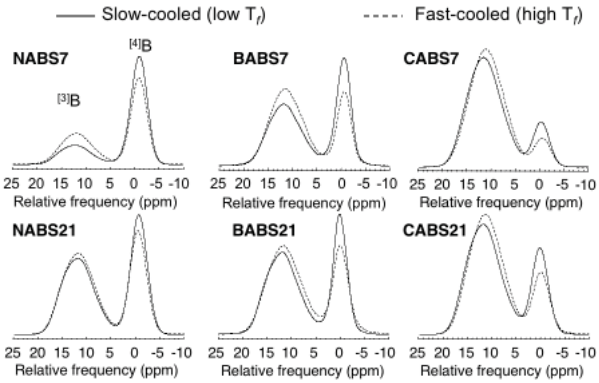

Figure 1: ^{11}B MAS NMR spectra at 14.1 Tesla. Dashed lines are samples with higher cooling rates. Solid lines are samples with low cooling rate. The peak centred around 12ppm is 3-coordinated boron, and the one centred around 0 ppm is 4-coordinated boron. The peak heights are normalized to constant total peak areas. The peak intensities are obtained by peak area integration. All the samples have 20 mol% of modifier cations (N for Na_2O, B for BaO, C for CaO), 8 mol% of Al_2O_3. The samples in first row have 7 mol% of B_2O_3, and 65 mol% of SiO_2; in the second row have 21 mol% of B_2O_3, and 51 mol% of SiO_2.

Conclusion

The observed T dependence of BO_4 species abundance allows us to estimate the enthalpy (ΔH) of the reaction $BO_4 \leftrightarrow BO_3$+NBO to be 20 to 50 kJ/mol in different glass compositions and closely related with the amount of NBOs in the glass. The ΔH is lower for the higher field strength network modifier cations ($Ca^{2+} > Ba^{2+} > Na^{+}$). This observation suggests that the divalent cations promote the formation of NBO much more effectively (lowers their enthalpy and thus free energy), which in turn helps to stabilize the modifier cation in the melt networks.

Stable iron isotope fractionation between aquoeus Fe(II) and smectite

LINGLING WU[1,2,3*], BRIAN L. BEARD[1,2], ANKE NEUMANN[4], MICHELLE M. SCHERER[4], ERIC E. RODEN[1,2], AND CLARK M. JOHNSON[1,2]

[1]University of Wisconsin-Madison, Madison, USA, lwu@geology.wisc.edu (* presenting author)

[3]University of Waterloo, Waterloo, Canada
[4]University of Iowa, Iowa City, USA

Redox transformations of Fe-bearing phyllosilicate minerals play an important role in Fe cycle in the subsurface environments. This experimental study determined the stable Fe isotopic exchange and fractionation factor between a ^{57}Fe-enriched aqueous Fe(II) and an isotopically "normal" smectite SWa-1 (iron oxide impurities stripped off by purification) using a three-isotope method. Leaching of solid with 0.5 M HCl for 0.5 hr, following separation with aqueous Fe(II) at different time points, yielded mostly Fe(II) in extract 1 and subsequent leaching with 0.5 M HCl for 24 hrs yielded mostly Fe(III) in extract 2.

Isotopic exchange between different components was monitored by changes in their $\delta^{57/56}$Fe values. Isotopic exchange was limited between aqueous Fe(II) and bulk smectite. When excluding bulk smectite from the system, however, about 90% of exchange was achieved between aqueous Fe(II) and extract 1 (a weakly sorbed component) in the beginning of the experiments and leveled off with time, suggesting a steady-state condition was reached early on in the experiments between aqueous Fe and extract 1. Fraction of isotopic exchange (F) reached ~50% between aqueous Fe(II) and extract 2. The equilibrium fractionation factor betweem aquoues Fe(II) and extract 2 has been determined to be ~ –2.4‰ (below figure represents one of the duplicate experiments). Extract 2 could be an iron oxide phase as observed during eletron transfer between aqueous Fe(II) and smectite [1] and the mineralogy nature of extract 2 will be further identified using Mössbauer spectra. Nevertheless, the equilibrium Fe isotope fractionation between aqueous Fe(II) and smectite, driven by redox changes, has important implications for understanding redox processes in subsurface environments that is enriched in ferrous iron and clay minerals.

Multiple sulfur isotopic composition of carbonate associated sulfate in Carboniferous brachiopods: oceanic sulfur cycling and its implications

NANPING WU[1*], JAMES FARQUHAR[1, 2], HARALD STRAUSS[3]

[1]Deparment of Geology, University of Maryland, College Park, Maryland, USA, 20740 (*Correspondence: npwu@umd.edu)
[2]Earth System Science Interdisciplinary Center, University of Maryland, College Park, Maryland, USA, 20740
[3]Institut für Geologie und Paläontologie, Westfälische Wilhelms-Universität Münster, Germany

We present multiple sulfur isotopic records of carbonate associated sulfate from Carboniferous rocks in the Ukraine, Belgium and Moscow Basin [1, 2]. The most significant feature of this data is that the values of δ^{34}S change from higher values (18.4±3.5‰) in the early Carboniferous to lower values (12.6±1.8‰) in the late Carboniferous. In contrast, Δ^{33}S remains similar throughout the early and late Carboniferous (-0.003±0.028‰ and -0.006±0.027‰, respectively). These sulfur isotope records also show evidence for shorter timescale variations that are superimposed on the first order observations in δ^{34}S and Δ^{33}S.

The decline in δ^{34}S is concurrent with a 3‰ increase in δ^{13}C observed in Carboniferous brachiopod shells of the Russian platform [3]. This negative correlation between δ^{34}S and δ^{13}C is similar to the long term linkage between the carbon and sulfur cycles throughout the Phanerozoic. The favored interpretation of carbonate δ^{13}C is that higher δ^{13}C reflects an increasing fraction of organic matter burial. In line with this, we hypothesize that the perturbation of the terrestrial organic carbon cycle plays a more prominent role in the global carbon cycle, based on the observation of significant coal deposits in the late Carboniferous. In this context, the shift in δ^{34}S may reflect the decreasing burial of marine organic matter and reduced burial of pyrite and/or a change in the quality of organic matter that can be used for sulfate reduction because of an increasing fraction of terrestrial organic carbon in the marine sediments, and/or enhanced delivery of sulfate with low δ^{34}S to the late Carboniferous oceans coupled to increasing sulfate levels.

The relatively constant Δ^{33}S record, in conjunction with falling δ^{34}S, may be attributed to a decrease in the sulfur isotope fractionation between sulfate and pyrite with a constant fraction of pyrite burial, and no change in the parameter λ that relates ^{34}S/^{32}S to ^{33}S/^{32}S. Alternatively, it could implicate a change in λ but with constant ^{34}S/^{32}S fractionation associated with pyrite burial to compensate for an increasing influx of sulfur to oceans. The changes in λ would imply that sulfide re-oxidation played a smaller role in the sulfur cycle. Ongoing work will further explore the implications of the high-order variation in these sulfur isotopic records.

Chemical weathering of large river catchments in China and the global carbon cycle

WEIHUA WU [1*], HONGBO ZHENG [1], JIEDONG YANG [2] AND CHAO LUO [1]

[1] Institute of Surficial Geochemistry, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China. wuwh@nju.edu.cn (* presenting author)

[2] Center of Modern Analysis, Nanjing University, Nanjing 210093, China.

Analyzing chemical compositions of river waters, rain waters, sediments, and rocks of large river catchments in China and combining with hydrological information, we use the forward model to generally assess the chemical weathering rates and capacity and mechanism of the atmospheric CO_2 consumption, and discuss the variation trend of chemical weathering and their controlling factors in different environments of climate, lithology, topography, and vegetation. The atmospheric CO_2 consumptions derived from silicate and carbonate weathering are 421~ 627×10^9 mol/y and 1323×10^9~ 2025×10^9 mol/y, which accounts for about 4.8 ~ 7.1 % and 11.1 ~ 16.1 % of the total consumption from the global rivers, respectively. The results show that China as a country of karst wide distribution, the influence of carbonate weathering on the global carbon cycle is more important. The atmospheric CO_2 consumptions from silicate and carbonate weathering in the Yangtze River, Yellow River, and Pearl River catchments account for about 2/3 and 90 % of river catchments in China.

By comparing the characteristics of chemical weathering in some small river catchments draining the typical silicate rock regions, the Nandujiang River flowing on basalt formations in tropical climate zone has the highest silicate weathering rates (7.2×10^5 mol/km^{2}a), and followed by the Beijiang River (6.99×10^5 mol/km^{2}a) and Dongjiang River (5.39×10^5 mol/km^{2}a) flowing on granite formations in tropical climate zone, which close to those rivers in New Guinea near the equator. Under similar lithology conditions, atmospheric CO_2 consumption rates have positive correlation with temperature and rainfall and negative correlation with elevation.

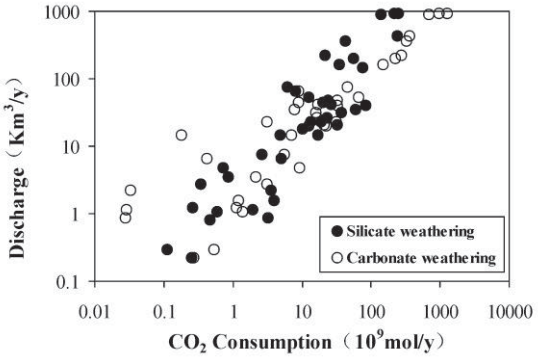

Figure 1: Scatter plots of atmospheric CO_2 consumptions resulted from silicate and carbonate weathering vs. water discharge. Good positive correlation indicates that discharge is an important factor affecting CO_2 consumption flux.

Biomineralization of deep-sea iron reducing bacteria *Shewanella piezotolerans* WP3

WENFANG WU[1,2*], YONGXIN PAN[1,2]

[1]Key Laboratory of the Earth's Deep Interior, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China

[2]Franco-Chinese Biomineralization and Nano-Structures Laboratory, Chinese Academy of Sciences, Beijing 100029, China wuwenfang@mail.iggcas.ac.cn(* presenting author) yxpan@mail.iggcas.ac.cn

Introduction

Iron reducing bacteria (IRB) that can utilize Fe(III) as its terminal electron acceptor are ubiquitously distributed on earth surface and subsurface. They are of great significance in iron biogeochemical cycling, environmental bio-remediation and magnetic nanoparticle bio-synthesis. However, the biomineralization of deep-sea IRB is rarely studied, whereas the deep-sea environment is quite different, for example, dark, microaerobic or anaerobic, oligotrophic. Besides, bacteria live in deep sea often tolerate great high hydrostatic pressure and quite low temperature, which can exert great influence on microbes.

Here we investigated the laboratory iron reduction and biomineralization behavior of a deep-sea IRB *Shewanella piezotolerans* WP3 under various hydrostatic pressures (0.1, 5, 10, 20 and 50 MPa) at 4°C and 20°C, in the aim of understanding pressure and temperature effects on microbial mineralization.

Results and Conclusion

S. piezotolerans WP3 was isolated from West Pacific deep-sea sediments at a water depth of ~1,914 m. It is a Gram-negative, facultative anaerobic psychrotolerant and piezotolerant bacterium, highly adaptive to dynamic environments. Ferrihydrite was quickly reduced by *S. piezotolerans* WP3 with an initial iron reduction rate of 175 μM/h at 20°C and 0.1 MPa. During iron bio-reduction, the pH increased while the Eh (redox potential) decreased greatly, which were favorable for magnetite formation and precipitation. During biomineralization, room-temp and low-temp magnetic parameters (e.g., M_s, M_{rs}, B_{cr}, B_c and T_p) of the bio-products changed systematically, corresponding to the mineral transformation from ferrihydrite to magnetite. The final bio-products are well crystalline superparamagnetic magnetite nanoparticles (<10 nm) [1].

Under all the tested pressures *S. piezotolerans* WP3 can reduce ferrihydrite and induce magnetite biomineralization. A slower iron reduction and magnetite formation accompany with diminished cell growth were observed at elevated pressures. Under the same pressure, it was slower at 4°C for the iron bio-reduction and mineralization as well as the cell growth than that at 20°C. Low-temp magnetic characterization showed a smaller average particle size for the magnetite biominerals at either higher pressure or lower temperature.

As *S. piezotolerans* WP3 can reduce Fe(III) and mediated magnetite biomineralization at high hydrostatic pressure and low temperature, this study suggests that IRB like WP3 can play an important role in deep-sea iron cycling and sedimentary magnetism that we might have previously overlooked.

Cr(VI) Adsorption on organic rich soil from Kleinstuck Marsh, Kalamazoo, MI

Davina Wyman[1*], Carla M. Koretsky[2], and Michelle L. Barger[3]

[1]Western Michigan University, Geosciences Department, davina.a.wyman@wmich.edu (* presenting author)

[2]WMU, Geosciences Dept., carla.koretsky@wmich.edu

[3]University of Iowa, IIHR-Hydroscience & Engineering, michelle-barger@uiowa.edu

Abstract

Chromium is a highly toxic chemical species that has leaked into natural systems via many industrial processes. There is much about Cr(VI) biovailability and mobility that remains poorly understood, but past studies have demonstrated that Cr(VI) is typically mobile in the environment. Cr(VI) mobility can be diminished via adsorption onto sediments, especially sediments containing reduced organic matter, iron (FeII) or manganese (MnII) because these can reduce Cr(VI) to Cr(III) which is more readily sorbed. The objective of this study is to measure the adsorption of Cr(VI) onto organic-rich sediment as a function of pH, time and after step-wise removal of operationally defined sediment fractions.

Sediment cores (10 replicates) were collected to a depth of 50 cm with a Russian peat corer from Kleinstuck Marsh, a minerotrophic fen in Kalamazoo, MI. The upper 10 cm and the lower 10 cm of each core was separated and combined with the same depth interval from the other cores, homogenized in ziplock bags, and promptly freeze-dried. A 4-step sequential extractions procedure [1] was used to selectively remove exchangeable, carbonate, reducible, and oxidizable fractions. Supernatants from each extraction step were analyzed for a suite of metals via ICP-OES. The bulk sediment, together with sediment remaining after each progressive sequential extraction were used to measure Cr(VI) adsorption as a function of pH and time. Adsorption was tested using kinetic edge experiments in which 1 g/L sediment, 10^{-5} M Cr(VI), and 0.01 M $NaNO_3$ were combined in 15 mL plastic centrifuge tubes. Each tube was titrated to a particular pH (spanning 3-10) and placed on a shaker. After 24 hr, 48 hr, 1 week, and 2 weeks, pH was retested in each tube and subsamples (~15 mL) were removed, centrifuged, syringe-filtered (0.2 μm) and the supernatant tested for Cr(VI) and total Cr, using the colorimetric diphenylcarbazide procedure and ICP-OES, respectively. For all sediments except those with the oxidizable fraction removed, Cr(VI) sorption edges are very similar, with nearly 100% sorbed below pH 4, decreasing to less than 5% sorbed above pH 7. In contrast, adsorption is greatly diminished with removal of the oxidizable fraction: after 2 weeks, a maximum of 50% Cr(VI) is sorbed at pH 3, with <20% sorbed between pH 4 and 7. This suggests that much of the Cr(VI) binds to organic matter or other reduced fractions of the soil (e.g. Fe(II)-bearing clays). For all experiments, sorption increased significantly for the first week, with much smaller increases beween 1 and 2 weeks. For pH 3-6.5, agreement between colorimetric and ICP data suggests that Cr in solution was primarily Cr(VI). Above pH 6.5, however, there is an increasing divergence between ICP and colorimetric data, demonstrating that up to 40% of the Cr at alkaline pH is reduced to Cr(III) and released into solution. These data will be used to develop surface complexation models, based on both the component additivity and composite sediment approaches.

[3]State Key Lab.of Oil&Gas G&E Engineering,Chengdu,China rex_swpu2005@126.com

Dunhua Basin is located in the middle of Dunhua Mishan Graben in Northeastern China. And it is a rift-fault depression superposed basin which is controlled by the Dunhua Mishan fracture zone. A series of tectonic system transitions happens during the Mesozoic and Cenozoic period in the Dunhua Mishan fracture zone （Zhang et al.,1994; Yin ,1993; Li,1994）.The transitions starts in the Late Triassic. In the Late Jurassic, it is compressional; during the Cretaceous–Paleogene, it has a left-lateral displacement and a certain scale of extension; there is a compression in the late Paleogene, which then turns into the extension state again after Neogene. The evolution of Dunhua Mishan fracture zone plays a controlling role in the generation,development and evolution of the Dunhua basin. The evolution of the Dunhua Basin in the Mesozoic–Cenozoic period is: the compressional orogeny, strike slip & pull-apart and the initial rifting stage in Late Jurassic–Early Cretaceous (rift development stage); the inversion, uplifting and exhumation stage in Late Cretaceous-Paleocene;rift basin development stages in the Eocene–Oligocene period and Depression and basalt eruption stage after the Neogene. Different evolution stages have different deposition response characteristics.

ANAMMOX ACTIVITY IN CONTAMINATED GROUNDWATER HAVING HIGH AMMONIUM AND NITRATE CONCENTRATIONS

YANGPING XING[1]*, ELIF TEKIN[1], DANIELLE FORTIN[1], ROBERT TIMLIN[2], IAN D CLARK[1]

[1]University of Ottawa, Department of Earth Sciences, Ottawa, Canada, yxing@uottawa.ca (* presenting author)

[2]SNC-Lavalin Environment, Ottawa, Canada, robert.timlin@snclavalin.com

Abstract

Anaerobic ammonium oxidation (anammox) has been recognized as a critical process for removing nitrogen components in marine and surface aquatic systems, and recent studies suggest that anammox appears to be ubiquitous in natural and engineered environments. However, the activity and reaction rates of anammox in contaminated groundwater environments have never been directly quantified and their relative importance is still unknown. In our study, microcosm tracer incubation experiments with $^{15}N\text{-}NH_4^+$, $^{15}N\text{-}NO_3^-$, and $^{15}N\text{-}NO_2^-$ were performed with groundwater and sediment samples from a contaminated aquitard near Elmira, Ontario, Canada, in order to measure the potential reaction rates and assess the respective contribution of anammox and denitrification activities. The tracer experiments showed that the potential anammox reaction rates ranged from 71.5 to 148.1 nmole N_2 L^{-1} d^{-1} which are very comparable to those reported in freshwater lakes. A comprehensive mathematical calculation suggested that 32 to 48% of N_2 production was attributed to anammox at the Elmira site.The measurements of NH_4^+ and NO_3^- before and after incubation and elevated $\delta^{15}N\text{-}NO_3^-$ indicated a complex and interactive ammonium attenuation mechanism including anammox and both microaerobic and anaerobic ammonium oxidation. Together with fluorescence *in situ* hybridization (FISH) results, our study points to anammox as an active process in the highly contaminated Elmira groundwater and to the fact that anammox organisms show a strong adaptability to heavy total nitrogen loads up to 46.5 mmol L^{-1} and relatively high dissolved oxygen concentrations up to 65.3 µmol L^{-1}.

Pairing Re-Os systematics with geochemical proxies – environmental conditions and seawater chemistry

G. XU[1,2*], J. L. HANNAH[1,2,3], B. BINGEN[2] AND H. J. STEIN[1,2,3]

[1]AIRIE Program, Department of Geosciences, Colorado State University, Fort Collins, CO 80523-1482 USA (*presenting author: Guangping.Xu@colostate.edu)
[2]Geological Survey of Norway, 7491 Trondheim, Norway
[3]Physics of Geological Processes, University of Oslo, 0316 Oslo, Norway

Re-Os systematics of black shales provide depositional ages and syndepositional seawater $^{187}Os/^{188}Os$ ratios. The seawater Os-isotope record is a proxy for short-term changes in continental weathering rates. Additionally, both Re and Os are redox sensitive elements, and can be used with other redox sensitive trace metals to infer depositional conditions and seawater chemistry. Here we report Re-Os data, trace metal concentrations and sizes of pyrite framboids for Triassic black shale from Svalbard, Svalis Dome and Kong Karls Land across the Barents Shelf, spanning the Olenekian to early Carnian stages. Using these data, we discuss the evolution of Triassic environmental conditions.

Seawater $^{187}Os/^{188}Os$ ratios in the Barents Sea region decrease from ca 0.85 in the Olenekian to 0.65 in the late Ladinian and then increase to 0.73 in the early Carnian. These variations are synchronous with the decrease of $^{87}Sr/^{86}Sr$ ratios through the middle Triassic and a subsequent increase in the Carnian [1]. Decreasing Os and Sr isotope ratios reflect decreasing global continental weathering rates from Olenekian to late Ladinian.

Olenekian black shales from Svalbard and Svalis Dome have higher Mo contents for a given TOC content than younger late Anisian black shales. The decrease in [Mo]/TOC ratios suggests increasing restriction as the Panthalassa ocean retreated from Svalbard and Svalis Dome [2]. Olenekian black shales from Svalbard and Svalis Dome also have low Re/Mo and V/Mo ratios and small pyrite framboids, indicating euxinic conditions, whereas early Carnian shales from Kong Karls Land have low Mo contents and high Re/Mo and V/Mo ratios suggesting suboxic – oxic conditions.

In summary, from the Olenekian to the latest Ladinian in the Barents Sea region, continental input to the oceans decreased, and the depositional environment on the Barents shelf changed progressively from euxinic, deep, open marine to a shallow, water-restricted anoxic embayment.

Sweet Spot for the Formation of Sedimentary Dolomite

HUIFANG XU*

NASA Astrobiology Institute, Department of Geoscience, The University of Wisconsin, Madison, WI 53706, USA, hfxu@geology.wisc.edu

8i. Interactions at the interface between organic components and minerals

The roles of organic matters in dolomitization were considered important, although their precise functions remain unclear. There are four proposed mechanisms for explaining the roles of organics and microbes in dolomitization: (1) Organic bounded Mg was released during decay of the organics; (2) extracellular polymeric substance may serve as nucleation sites; (3) Removal of sulphate (believed to be an inhibitor) through sulphate-reducing bacteria promotes dolomite crystallization, and (4) Oxidation of organics and proteins increases pH and alkalinity. However, laboratory experiments based on the proposed mechanisms failed to synthesize dolomite inorganically at room temperature. Mg^{2+} ions, which form one of the strongest bonds with water molecules among the divalent ions may only be partially dehydrated when incorporated into a growing nucleus of calcite or dolomite. The residual hydration sphere of the incorporated Mg^{2+} ions would then inhibit the further growth of the crystal. Dolomite crystals preferentially associated with organic rich layers / lamina in some partially dolomitized limestone and stromatolites. Early formed Mg-calcite or calcite crystals served nucleation sites for the dolomite. Synthesis experiments indicate polysaccharides in extracellular polymeric substance (EPS) of certain anaerobic bacteria can promote dolomite nucleation and growth. The polysaccharides adsorbed on surfaces of calcite or dolomite through hydrogen bonding with surface carbonate anions will lower the kinetic energy barrier for dehydration of metal complexes between H_2O and surface Mg^{2+}. Author acknowledges supports from NSF and NASA Astrobiology Institute.

CO_2-rich fluids in lode gold deposits at the Sarekoubu- Qiaxia area, southern Altaides, China

XU JIUHUA*, LIN LONGHUA, XIAO XING, AND YANG RUI

Resource Engineering Department, University of Science and Technology Beijing, Beijing 100083, China
jiuhuaxu@ces.ustb.edu.cn (* presenting author)

Geological Setting

The Sarekoubu and Qiaxia lode gold deposits, located in the southern margin of Altaides, occur in metamorphic volcano clastic rocks of the lower Devonian Kangbutiebao Formation ($D_1k_2^2$) [1]. There are two groups of gold(copper)-bearing quartz veins(Fig.1): 1) lentoid or streaked quartz veins (QI) which are parallel to the foliated structure of the biotite-chlorite or garnet-chlorite schist; 2) sulfide quartz veins (QII) cutting across chlorite mica schist .

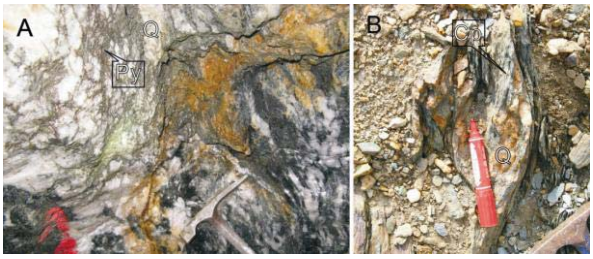

Figure 1: Au-Cu-quartz veins in the Sarekoubu and Qiaxia area

Fluid Inclusion Study

Carbonic fluid inclusions that are free of water are often found in the Sarekoubu deposit. They are of primary origin in QII veins, while a large number of these inclusions are of secondary origin in QI. There are two instances for $T_{m,CO2}$ and $T_{h,CO2}$: 1) $T_{m,CO2}$ = -60℃ ~-56.5℃ and $T_{h,CO2}$ =-23℃~+31℃; 2) $T_{m,CO2}$ <-57℃, to a minimum of -78.1℃, and $T_{h,CO2}$ =-33.7℃~-17.7℃. The $T_{h,TOT}$ of CO_2-H_2O fluid inclusions in vein quartz of the Sarekoubu deposit are 227~374 ℃(QI) and 205~370℃(QII). In this situation the lowest trapping pressures of CO_2–rich fluids can be estimated to be 110~ 300MPa based on CO_2 densities and CO_2 phase diagram at high *P-T* of Van den Kerkhof [2]. The ^{18}O delta values of fluid inclusions in quartz are 7.54~11.84‰ (QI) and 3.82~7.82‰ (QII), whereas the D delta values are -84.7~-98.2 ‰ (QI) and -75.8~-108.8 ‰ (QII) respectively.

CO_2-H_2O fluid inclusions composed of a liquid CO_2 phase and a H_2O phase are commomly observed in the Qiaxia deposit. The melting temperatures of frozen CO_2 ($T_{m,CO2}$) range from -63~ -56.6 ℃ for QI, and from -62.6~-58.6℃ for QII; the homogenization temperatures of CO_2 ($T_{h,CO2}$)= 19.6~28.9℃ for QI, and 25.2~27.9℃ for QII. The final homogenization temperatures ($T_{h,TOT}$) of these inclusions are mostly 180~380℃ (QI) and 180~360 ℃ (QII).

Conclusions

Gold and copper mineralization in the Sarekoubu and the Qiaxia area has a close relationship with CO_2-rich fluids and belongs to orogenic. The source of ore-forming fluids is related with regional metamorphism and associated magmatism.

Geochemical Characteristics of Heavy Metals in Water-Sediment Media in Panzhihua V-Ti-Magnetite Zone，China

ZHENGQI XU[1,2*], SHIJUN NI[1], YANGUO TENG[2], CHENGJIANG ZHANG[1]

[1]Chengdu University of Technology, Chengdu, China , xuzhengq@163.com (* presenting author)
[2]Beijing Normal University, Beijing, China,xuzhengqi@cdut.cn

Sulphide mines have always been the concerns of people because of their various forms and the resultant environmental problems, whereas oxide mines are paid less attention and not studied much because they do not cause obvious environmental problems such as acid mining drainage（AMD）. However, the potential environmental problems caused by oxide mines can not be ignored.

The author chooses Panzhihua V-Ti-Magnetite, a famous oxide mine in China, as the subject of research. In this thesis, the geochemical characteristics of heavy metals in water-sediment environmental media in the zone during the process of mining are systematically studied by using those media as research carriers and employing the analyzing methods of ICP-MS and ICP-OES. The research results are shown below:

The research on the geochemical characteristics of heavy metals in the system of water-suspended solid-sediment in the mining zone show that: the contents of heavy metals in water are very low, while those in suspended solids and sediments are relatively higher; the contents of Cu, Zn, Co, Ni, Fe and As in suspended solids are higher than those in sediments; the contents of Pb, V, Ti and Cr in sediments are higher than those in suspended solids. The partition coefficients show that: Hg is most active, As and Ni are less active, and Ti is least active. The morphological analyzing results of sediments show that in the sediments in Panzhihua Mining Zone, Ti is most stable, V, Cu and Cr are relatively stable, and Zn, Mn, Co and Ni are more active. The index evaluation on potential ecological risk shows that most heavy metal elements in the sediments are contaminated, whether heavily or in a medium degree, in which Cu, Co, V and Ti are contaminated heavily or even more severely. The potential ecological risk index shows that all places are in light ecological risk and generally the potential ecological risk of heavy metals in the sediments are not high and they have limited influence on environment.

Coupled-Process Modeling of a Uranium Bioremediation Field Experiment

STEVEN B. YABUSAKI [1*], YILIN FANG [1], MICHAEL J. WILKINS[1], AND PHILIP E. LONG[2]

[1]Pacific Northwest National Laboratory, Richland, Washington, USA
yabusaki@pnnl.gov,yilin.fang@pnnl.gov, michael.wilkins@pnnl.gov
[2]Lawrence Berkeley National Laboratory, Berkeley, California, USA
pelong@lbl.gov

Field biostimulation experiments at a former uranium mill tailings site are being used to better understand the processes, properties, and conditions controlling engineered bioremediation of uranium contaminated groundwater. A key component of the research is the development of a mathematical model that incorporates three-dimensional variably saturated flow through physically and chemically heterogeneous sediments, as well as the interaction of biologically-mediated reaction products with the subsurface geochemical environment. We present the modeling of the 2008 uranium bioremediation field experiment, in which pulsed acetate groundwater amendment was used to stimulate indigenous metal-reducing bacteria to transform aqueous U(VI) to immobile solid-associated U(IV).

Uranium mobility is sensitive to pH, Eh, alkalinity, calcium, and reactive surface area, as well as aqueous uranium concentrations. In the model, these geochemical conditions are impacted directly by the terminal electron accepting process (TEAP) reactions and indirectly by subsidiary reactions induced by the biologically-mediated reaction products. For example, uranium surface complexation is directly affected by the large amount of bicarbonate produced by the acetate-oxidizing microorganisms but also indirectly by changes in the pH from mineral reactions induced by sulfide. The modeling also addresses site-specific issues such as the continuous influx of actionable levels of U(VI) into the treatment zone, seasonal water table variation, spatially variable physical (hydraulic conductivity, porosity) and geochemical (reactive surface area) material properties, and competition for the acetate electron donor by sulfate reducing bacteria.

Findings include: 1) uranium bioreduction is most effective when acetate concentrations are engineered to exceed the sulfate-reducing bacteria demand; 2) biogenic sulfide promotes the dissolution of Fe(III) minerals leading to an abiotic but biologically mediated Fe(II) source; 3) falling water table sequesters residual reactants and products in the newly unsaturated pores; 4) preferential flow paths for acetate delivery create local zones of enhanced TEAP reactivity and subsidiary reaction; and 5) predicted central metabolic pathway reaction fluxes from a genome-scale metabolic ("*in silico*") model of *Geobacter metallireducens,* correlate well with proteomics data from the field experiment.

The eSTOMP subsurface simulator was used to exploit the large memory and high-performance of massively parallel computers needed to address the high spatial and temporal resolution, large number of reactive species and minerals, and detailed process models.

Cretaceous *P–T–t* evolution of the Fosdick migmatite–granite complex, West Antarctica: orogenic collapse along the East Gondwana margin

CHRIS YAKYMCHUK[1*], FAWNA J. KORHONEN[2], MICHAEL BROWN[1], PHILIP M. PICCOLI[1] AND CHRISTINE S. SIDDOWAY[3]

[1]Laboratory for Crustal Petrology, Department of Geology, University of Maryland, College Park, MD 20742, USA, cyak@umd.edu (* presenting author)
[2]Geological Survey of Western Australia, Department of Mines and Petroleum, East Perth, Australia
[3]Department of Geology, The Colorado College, Colorado Springs, CO 80903, USA

The Fosdick migmatite–granite complex in West Antarctica represents a rare exposure of the anatectic middle crust from along the former active margin of East Gondwana. The complex preserves a polyphase metamorphic history and contains a detailed record of crustal differentiation during a Cretaceous transition from oblique tectonic convergence to divergence across the most long-lived and extensive active plate margin in the Phanerozoic. Migmatites that crop out in the complex preserve evidence of Lower Cretaceous high–*T* metamorphism and anatexis, and subsequent retrograde decompression inferred to record orogenic collapse early during the Upper Cretaceous breakup of the East Gondwana margin. Migmatites collected from the eastern and western extents of the complex contain peak metamorphic assemblages that include garnet, garnet + cordierite or cordierite associated with leucosomes. Sillimanite is preserved as inclusions in garnet, cordierite, and biotite. Phase equilibria modelling constrains prograde heating into the sillimanite + garnet + liquid stability field at temperatures of 850–900°C and pressures of 0.7–1.1 GPa, which was followed by decompression into a cordierite + liquid stability field immediately above an elevated solidus at conditions of metamorphism of temperatures of 850–880°C and pressures of 0.6–0.7 GPa. Melt reintegration along a model isobaric heating path at 0.7 GPa suggests that the metasedimentary protoliths could have produced up to 24 mol.% melt, most of which must have been extracted in order to preserve the garnet– and cordierite–bearing mineral assemblages. This melt was emplaced at higher crustal levels, as represented by Cretaceous peraluminous granites exposed in the periphery of the Fosdick complex—a process that contributed to the differentiation and ultimate stabilization of the East Gondwana active margin now exposed in West Antarctica.

In situ SHRIMP U–Pb isotope analysis of monazite from stromatic metatexite migmatites yield dominantly Cretaceous ages of c. 111–96 Ma. Individual Cretaceous monazite grains show variable zoning patterns in Y and Th, but most contain low-Y cores and high-Y rims. This is consistent with progressive monazite growth associated with garnet breakdown during near-isothermal decompression. These data suggest orogenic collapse and exhumation of the Fosdick complex as a gneiss dome was underway by c. 111 Ma, which supports geophysical studies in West Antarctica and regional studies in the outboard part of the once contiguous margin of East Gondwana that suggest breakup had begun by c. 110–100 Ma.

Pu isotopes in water columns of the northern North Pacific

MASATOSHI YAMADA[1*], JIAN ZHENG[2]

[1]Department of Radiation Chemistry,Institute of Radiation Emergency Medicine, Hirosaki University, Hirosaki, Japan, myamada@cc.hirosaki-u.ac.jp (* presenting author)

[2]Research Center for Radiation Protection, National Institute of Radiological Sciences, Chiba, Japan, jzheng@nirs.go.jp

Introduction

Anthropogenic radionuclides such as ^{239}Pu (half-life: 24,100 yr), ^{240}Pu (half-life: 6,560 yr) and ^{241}Pu (half-life: 14.325 yr) mainly have been released into the environment as the result of atmospheric nuclear weapons testing. In the North Pacific Ocean, two distinct sources of Pu isotopes can be identified; i.e., the global stratospheric fallout and close-in tropospheric fallout from nuclear weapons testing at the Pacific Proving Grounds in the Marshall Islands.[1] The objectives of this study are to measure the ^{240}Pu/^{239}Pu atom ratios in seawater from the northern North Pacific Ocean and to discuss the transport processes of Pu.

Materials and methods

Seawater samples were collected at Stn. DR-10 in the northern North Pacific and Stn. DR-13 in the Bering Sea with a double barrel PVC large-volume sampler.[2] The ^{240}Pu/^{239}Pu atom ratios were measured with a double-focusing SF-ICP-MS, which was equipped with a guard electrode to eliminate secondary discharge in the plasma and to enhance overall sensitivity. [3]

Results and discussion

The total (water + sediment) inventory of 53.8 Bq m^{-2} at Stn. DR-10 in the northern North Pacific was mostly the same as that (58.1 Bq m^{-2}) of the expected cumulative deposition density of atmospheric global fallout at the latitude of 40 – 50°N. The atom ratio of ^{240}Pu/^{239}Pu showed no notable variation from subsurface water of 100 m depth to deep water of 2000 m depth, then increased with depth to 0.255 at the bottom layer. The atom ratios in water column of the northern North Pacific were significantly higher than the mean global fallout ratio of 0.18.[4] High atom ratios of ^{240}Pu/^{239}Pu in the northern North Pacific prove the presence of close-in tropospheric fallout from nuclear weapons testing at the Pacific Proving Grounds.

Negative growth of the continental crust at present: Significance of arc subduction

S. YAMAMOTO[1]*, S. MARUYAMA[2]

[1]Department of Earth Science and Astronomy, The University of Tokyo, Komaba, Meguro, Tokyo, 153-8902, Japan (*correspondence: syamamot@ea.c.u-tokyo.ac.jp)

[2]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan

Subduction and recycling of differentiated material into the mantle are of significance not only for continental growth but also for creating mantle heterogeneities. Continental crust is predominantly created by arc magmatism and returned to the mantle via sediment subduction, subduction erosion and continental subduction [1]. Oceanic arcs, primary form of continental crust, have been thought to be entirely accreted during arc-collision due to its buoyant nature. Modern oceanic arcs are, however, mostly subducted into the mantle. The best examples of arc subduction are observed around the Japan islands [2,3]. Among the more than 15 examples of arc–arc collision in the western Pacific, arc–arc amalgamation is possible only in the case of parallel collision [2,4]. Parallel collision of two arcs is rather rare case, compared to the normal arc–arc collision, therefore these observation imply that the predominant subduction of arc crust is in general and that a majority of the intra-oceanic arc in the Earth history must have been subducted into the mantle.

Geophysical and geological studies document that sediment subduction and subduction erosion move large volumes of continental material toward the mantle, and comprehensive studies for the rate of continental reduction versus production suggest a balance, resulting in no growth of continental crust at present [5,6]. However, these estimates do not take into account the concept of arc subduction. Considering direct subduction of oceanic arcs into the mantle, we conclude negative growth of the continental crust on the Earth at present.

Geochemical and carbon isotopic study in a karst groundwater system on Miyakojima Island, Japan

MASARU YAMANAKA

Nihon University, Department of Geosystem Sciences, Tokyo, Japan, yamanaka@chs.nihon-u.ac.jp

Groundwater $\delta^{13}C$ values and chemical compositions were employed to quantitatively evaluate the controlling processes and sources of dissolved inorganic carbon in a karst aquifer system on Miyakojima Island (MI), southwestern Japan. Most MI groundwater is Ca-HCO_3 type water. The groundwater Ca/HCO_3 ratio was relatively constant, as predicted by the dissolution processes of calcite and of CO_2 in the groundwater. WATEQ4F and PHREEQC calculations demonstrated that all groundwater samples, not only Ca-HCO_3 type groundwater but also groundwater of other types, were strongly influenced by dissolution of calcite and of soil CO_2 in this karst aquifer system. The system was open with respect to CO_2 with mostly around 10–50 matm as gas pressure, and most groundwater was saturated with respect to calcite. Detailed comparison of measured values and PHREEQC calculations for MI groundwater revealed that oxidation of ammonium sulfate (applied as fertilizer) played a key role in the groundwater chemistry by adding H^+, which caused surplus calcite dissolution. Model calculations using the $\delta^{13}C$ values and pH of the groundwater samples with PHREEQC were used to determine the mass fractions of DIC initially from calcite dissolution and from C3 and C4 organic materials, the origin of the soil CO_2. On average, the contributions of calcite and C3 and C4 organic materials were estimated to be 46.4%, 18.5% and 35.1%, respectively. Of these, contribution of calcite was relatively constant in any groundwater, indicating easily occurrence of this process at anywhere in karst aquifer systems. The calculated mixing ratios of C3 and C4 organic materials, which explained the contribution of each to the DIC in the groundwater, were concordant with the land use on MI, that is, the distributions of forest and sugarcane fields. This fact indicates that the calculated mixing ratios from the model can be reasonably used to constrain groundwater information, such as its recharge area and flowpahts, in a specific study area where the distributions of organic materials in soil initially from C3 and C4 plants are clear.

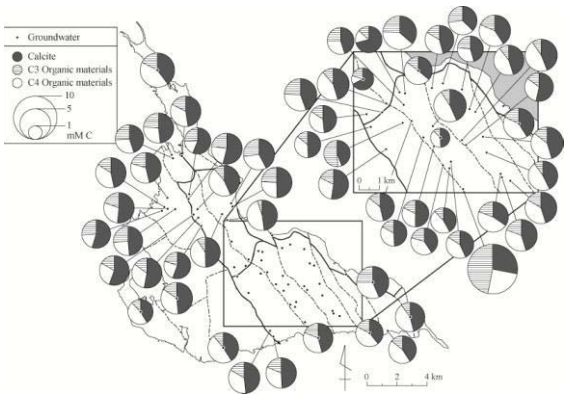

Fig.1: The mass fractions initially from calcite and C3 and C4 organic materials by pie charts within the bubbles, expressing DIC contents in the MI groundwater.

New time constraints on brittle faulting in the Toki Granite, central Japan

S. YAMASAKI [1*], H. ZWINGMANN[2], K. YAMADA[1], K. UMEDA[1] AND T. TAGAMI[3]

[1]JAEA TGC, Gifu, Japan, yamasaki.seiko@jaea.go.jp (* presenting author)
[2]CSIRO ESRE, Perth, Australia, horst.zwingmann@csiro.au
[1]JAEA TGC, Gifu, Japan, yamada.kunimi@jaea.go.jp
[1]JAEA TGC, Gifu, Japan, umeda.koji@jaea.go.jp
[3]KUEPS Kyoto University, Kyoto, Japan, tagami@kueps.kyoto-u.ac.jp

Numerous studies [e.g. [1]] have highlighted the potential for determining the timing of near-surface brittle deformation using isotopic dating of authigenic illites in fault gouge. In recent years, precise size separation combined with mineral characterization of gouge samples has demonstrated the suitability of illite K-Ar dating for constraining the timing of brittle deformation [e.g. [2]], despite analytical difficulties such as contamination.

We discuss new K-Ar and fission-track age data from gouge samples collected from a fault in the Cretaceous Toki granite, central Japan. The fault occurs sub-vertically along the wall of a shaft exposing granite host rock. The minimum age of the fault deformation is estimated to be older than 20 Ma, as the Miocene sedimentary formation is not displaced by the fault. The gouge samples were separated into five grain-size fractions (<0.1, <0.4, <2, 2-6, 6-10 μm) and characterized by laser particle analyses, XRD, SEM, and TEM.

The fine fractions provide younger K-Ar ages, suggesting enrichment in more recently grown authigenic illites. The finest fractions (<0.1 μm) give ages of 46 ±1 and 43 ±1 Ma (±2 sigma). The K-Ar ages of the fractions with no detectable contamination from detrital K-bearing minerals on XRD analysis, range from 53 to 43 Ma. The obtained illite age range is consistent with the stability field of illite and the main temperature field of brittle deformation within the cooling history of the host granite body of the fault, which was evaluated by apatite and zircon fission-track and K-Ar biotite ages from the host rock.

The internal consistency of the ages obtained from K-Ar dating of the two subsurface fault gouges, as well as their consistency with constraints from existing geochronological data demonstrate the potential of gouge dating in providing new data to constrain timing of brittle deformation in the Toki granite.

Denitrification coupled to pyrite oxidation has been observed in many groundwater aquifers, although a direct reaction between nitrate and pyrite can not be detected [1, 2]. Our understanding of the mechanisms of this redox process is, however, still limited. Since Fe(III) is detected as a well-known oxidant for pyrite in the presence of oxygen even at neutral pH [3], we postulate that electron transfer is being mediated through this reaction also in the presence of nitrate as terminal electron acceptor. Microbial catalysis by bacteria, such as Fe(II) oxidizing or sulfide reducing bacteria, is considered to affect the denitrification and pyrite oxidation rates significantly. Therefore, bacteria are supposed to mediate the electron transfer from pyrite to nitrate.

The goal of the work is to understand the mechanism of the anaerobic oxidation of pyrite coupled to nitrate reduction in anoxic groundwater sediments. To this end batch experiments have been set up in which synthesized pyrite is exposed to nitrate-dependent Fe(II)-oxidizer strain ***BoFeN1*** [4] and nitrate-reducing Fe(II)- and sulfide-oxidizing bacteria--***Thiobacillus denitrificans*** [5] testing kinetics of this process--the effect of initial concentration of pyrite and nitrate.

Results

Pyrite was oxidized with nitrate by ***Thiobacillus denitrificans***, but not by ***BoFeN1***. The reaction rate is dependent on the initial conc. of nitrate, in contrast, the initial conc. of pyrite did not show any effect of the rate.

Petrogenesis of the Mesozoic intermediate intrusive rocks in the central North China Craton: Constraints from zircon U–Pb chronology and geochemistry

D.B. YANG, W.L. XU, F.P. PEI, AND D.Y. WANG

College of Earth Sciences, Jilin University, Changchun 130061, China (yangdb@jlu.edu.cn, xuwl@jlu.edu.cn, peifp@jlu.edu.cn, wangdy@jlu.edu.cn)

The nature of the Mesozoic lithospheric mantle in the central North China Craton (NCC) is the key for us to reveal the mechanism of the NCC destruction [1]. However, LA–ICP–MS zircon U–Pb ages and whole rock geochemical data of the Mesozoic alkaline intrusive rocks, including quartz syenite and quartz monzonite, from the Shuiye, Huyanshan, Wanrong, and Erfengshan intrusions in the Shanxi and Henan provinces, central North China, provide insights for the nature of the Mesozoic lithospheric mantle beneath the central NCC.

The analyzed zircons show typical oscillatory growth zoning and striped absorption in CL images, indicating a magmatic origin. LA–ICP–MS zircon U–Pb dating results indicate that the Shuiye, Huyanshan, Wanrong, and Erfengshan quartz syenitie – quartz monzonite intrusions formed in the Early Cretaceous [2], i.e., their weighted mean $^{206}Pb/^{238}U$ ages being 130±5 Ma, 130±3 Ma, 125±2 Ma, and 127±2 Ma, respectively. Several inherited zircon cores yield Paleoproterozoic to Neoarchean ages of 1791 Ma, 2088 Ma, 2208 Ma, 2339 Ma, and 2559 Ma, indicating the presence of Paleoproterozoic and Neoarchean lower crustal basement rocks of the NCC.

These quartz syenite – quartz monzonite, together with the contemporaneous Huanglongnao nepheline syenite and Taershan quartz syenite [3], have SiO_2 = 59.42 ~ 64.98 wt%, MgO = 0.21 ~ 1.38 wt% ($Mg^{\#}$ = 21 ~ 45), and (Na_2O+K_2O) = 7.45 ~ 14.38 wt%. They are enriched in large ion lithophile elements (e.g., Rb, Ba, Sr, and K) and light rare earth elements, depleted in high field strength elements (e.g., Nb, Ta, Zr, Hf, and Ti) and heavy rare earth elements, and display prominent positive Pb anomalies. The initial $^{87}Sr/^{86}Sr$ ratios and ε_{Nd} (130 Ma) values of the Mesozoic intermediate intrusive rocks in the central NCC range from 0.7031 ~ 0.7062 and –13.3 ~ –20.0, respectively.

Based on the presence of the Paleoproterozoic and Neoarchean inherited zircons, whole rock Sr–Nd isotopic compositions, and their prominent positive Pb anomalies, we propose that the primary magma for these Mesozoic intermediate intrusive rocks could been mainly derived from partial melting of an enriched lithospheric mantle modified by the delaminated NCC lower crust. The Early Cretaceous quartz syenite – quartz monzonite intrusions in the Shanxi and Henan provinces could form under an extensional environment related to the subduction of the Paleo-Pacific plate beneath the Eurasian continent.

This research was financially supported by the NSFC (90814003 and 41002018).

Geochronology and kinetics of the Shapinggou porphyry Mo deposit in Jinzhai, eastern Qinling-Dabie orogenic belt

LI YANG [1, 2], FUKUN CHEN [2], YUE QI [2], XI-YAN ZHU [1]

[1] Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China

[2] CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei, 230026, China

The east-west trending Qinling-Dabie orogenic belt formed through the collision of the North China craton and the Yangtze block in early Mesozoic. This belt holds the world's most significant Mo ore province that is mainly situated along the southern margin of the North China craton, including the Jinduicheng, Nannihu-Sandaozhuang, Shangfanggou and Donggou super-large Mo deposits mainly of late Mesozoic in age. Several Mo deposits have been also discovered recently in northern Dabie terrain. This terrain is bordered by the Luanchuan-Gushi fault to the north and by the Xiangfan-Guangji fault in the south. The Shapinggou Mo deposit, being estimated as the largest Mo deposit in China, is one of several newly found Mo deposits in the Dabie region. All the Mo deposits in the Qinling and Dabie areas are directly related to Mesozoic magmatic rocks of different compositions.

In the field observation, we can find that the Mo mineralization occurs in veins and stockworks and is hosted both in granite porphyry and quartz syenite porphyry. Model ages achieved by the Re-Os isotopic analysis on molybdenite and U-Pb ages of zircons from the granite porphyry and quartz syenite porphyry, obtained from the LA-ICP-MS technique, demonstrate that the Mo mineralization is almost simultaneous with the formation of the ore-bearing porphyry, which is consistent with the early to middle Cretaceous Mo mineralization in the eastern part of the Qinling orogenic belt. During this time, the eastern China was characterized by rapid extension, lithospheric thinning, and asthenospheric upwelling. These tectonic activities possibly triggered partial melting of the crust. The Mo mineralization in northern Dabie, represented by the Shapinggou porphyry Mo deposit, likely occurred in such a geodynamic setting. This study is supported by the NSFC grant (No. 41090372).

Global impacts of the Antarctic Circumpolar Current appearance on nutrient distributions and biogeochemistry

SIMON YANG[1]*, ERIC GALBRAITH[2]

[1] McGill University, Montreal, Canada, simon.yang@mail.mcgill.ca (* presenting author)

[2]McGill University, Montreal, Canada, eric.galbraith@mcgill.ca

Abstract

At present, the Southern Ocean is the global nexus for upwelling of deep, nutrient rich waters, and provides the primary supply of nutrients to low latitudes. However, this was not always the case. Prior to the opening of the Drake Passage (DP) ~30 Ma, there was no Circumpolar Current, necessitating a very different return pathway for nutrients from the deep ocean to the surface. Paleo-records therefore provide an opportunity to better understand the global implications of the circumpolar current. However, understanding paleo-records spanning this transition are complicated by the closing of the Panama Isthmus (PI), which appears to have occurred sometime later. Here, we investigate the interactions between these two events, and the implications for marine biogeochemistry, using CM2Mc, a lower resolution version of the standard Geophysical Fluid Dynamics Laboratory (GFDL) fully coupled earth system model, with the BLING biogeochemical module. We carry out four runs : closed PI / opened DP, opened PI / opened DP, opened PI / closed DP, closed PI / shallow DP. The gateways have large impacts on the upwelling flux of nutrients to the Southern Ocean, and their redistribution to low latitudes (as shown in figure 1). They also impact the ventilation of the deep ocean, with implications for re-mineralized nutrients and therefore atmospheric pCO2.

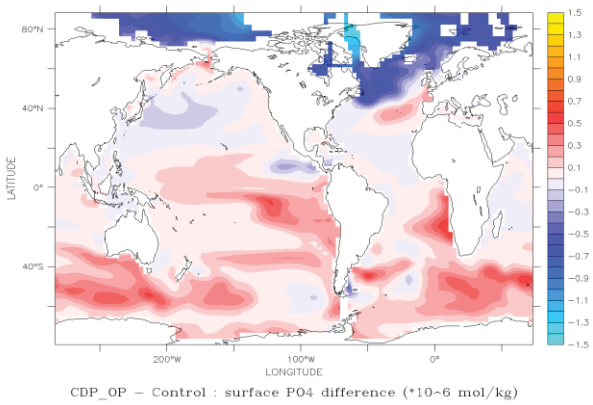

Figure 1: Difference in surface phosphate upon closing the drake passage.

Geochemistry and petrogenesis of dolostone from the Paleogene Shahejie Formation in Qikou depression, Bohaiwan basin, China

Y. YANG[1], F.H. GAO[1*], AND X.G. PU[2]

[1]College of Earth Sciences, Jilin University, Changchun 130061, China (yy_11@mails.jlu.edu.cn, *gaofh@jlu.edu.cn)

[2]Research Institute of Exploration and Development, Dagang Oilfield Company, CNPC, Tianjin 300280, China (puxgang@petrochina.com.cn)

Petrogenesis of dolostones from the Paleogene Shahejie Formation, Qikou depression, Bohaiwan basin, China has been a controversial. This paper reports carbon-oxygen isotopic and, trace element compositions of the dolostones from the Paleogene Shahejie Formation, Qikou depression, Bohaiwan basin, with the aim of revealing petrogenesis of dolostone.

Two major types of dolostones can be recognized as dolomicrite and grainy dolostone in the study area. The $\delta^{13}C$ and $\delta^{18}O$ values from 24 selected samples in the 2th section of the Paleogene Shahejie Formation range from -1.2‰ to 2.4‰ (V-PDB, averaging 0.7‰) and -6.8‰ to -3.9‰ (V-PDB, averaging -5.5‰), respectively. There is a positive relation between their $\delta^{13}C$ and $\delta^{18}O$ values, indicating a closed environment. Based on their minor correlation coefficient (<0.7), it is suggested that an external fluid might have been involved in their formation. Their total rare earth element abundance vary from 45.41 to 151.89 ppm (averaging 83.56 ppm), being higher than those of the marine carbonate. Additionally, their Y/Ho ratios are between 27.7 and 30.7 (averaging 29.7), similar to the average value of the upper crust (27.5). Their Sr/Ca ratios range from 0.0125 to 0.034, yielding an average value of 0.0180, which is located within those of the fresh water. The above results indicate that dolomitization could take place in the continental environment.

Nevertheless, their $^{87}Sr/^{86}Sr$ ratios (0.7092 to 0.7099, averaging 0.7095) are lower than that of fresh water (0.7119) [1] and higher than the average value (0.7080) of the sea-water in the Paleogene [2], indicating that the marine transgression might be the most important factor during formation of the Paleogene dolostones. Based on the empirical formula of Keith and Weber [3], we calculate that Z values (121.7~129.7) of the dolostones are more than 120, similar to ones of the marine carbonates. Combined with their buried depths (from 454m to 903m), we propose that that these Paleogene dolostones could form in a shallow buried diagenetic environment with the high salinity, which is also supported by their positive Gd anomaly showing a seawater source during the dolomitization.

In summary, we conclude that the Paleogene dolostone in the study area formed under a shallow burial condition, which had been influenced by the Rupelian transgression in the Paleogene.

Study on distribution regularities of the soil radionuclide contents in China

Y.X. YANG*, Y. ZHANG, L.S.CAO, Y.M.ZHENG AND X.M.WU

State Key Laboratory Breeding Base of Nuclear Resources and Environment, East China Institute of Technology, Nanchang 330013, Jiangxi, P. R. China, yxyang@ecit.cn(* presenting author)

Radionuclide content in soil is an important component to study the environment natural radioactivity level. It provides a reference for timely detection of radioactive contamination of the environment and has significance for an accurate assessment of environmental radioactive contamination. Therefor, it's necessary to research the contents of ^{238}U, ^{226}Ra, ^{232}Th and ^{40}K by combining with the distribution of uranium resources in China and the geological background of the provinces.

Through this survey, the area-weighted content average values of radionuclides ^{238}U, ^{226}Ra, ^{232}Th and ^{40}K in 28 provinces and cities in China were 39.5, 36.5, 49.1 and 580.0 Bq/kg respectively. The results approximated to the national average. The content of ^{238}U was slightly higher, and the contents of ^{226}Ra, ^{232}Th and ^{40}K were slightly lower. At the same time, the results were higher than the world average values of ^{238}U, ^{226}Ra, ^{232}Th and ^{40}K, but they belonged to the normal background level of the world[1].

By analyzing the changes of the soil radionuclide contents in 28 provinces along with the provinces, it could be seen that the contents of soil ^{238}U, ^{226}Ra and ^{232}Th were basically the same trend, namely one nuclide content in a province was high, the other two nuclide contents were also high, but the content of ^{40}K did not have this trend, which was influenced by human factors, such as burning straw and sowing the potash to the soil.

Through the survey, the contents of soil ^{238}U, ^{226}Ra and ^{232}Th in Fujian, Guangdong, Guangxi, Hunan, Jiangxi, Tibet, Yunnan and Zhejiang provinces were the top eight. In the eight provinces, the soil mother rocks of Fujian, Guangdong, Jiangxi, and Hunan mainly were granite, that of Tibet mainly were sediment and granite, and that of Zhejiang mainly were the quaternary and clay. Thus when soil mother rock was the granite, the contents of natural radionuclides in the soil were relatively high. The extensive granite was one of the reasons for higher levels of radionuclide contents in the soil in China.

By the end of 2008, more than 340 uranium deposits had been proved up. The resources were occupied 90 percents by 10 provinces which were Jiangxi, Inner Mongolia, Guangdong, Xinjiang, Hunan, Guangxi, Hebei, Liaoning, Yunnan and Zhejiang. In the top 8 provinces whose soil radionuclide contents were high, the uranium resources of six provinces were in the top ten. It was obvious that the uranium resources were relative with the soil radionuclide contents.

Geochemistry and geochronology of Cu-bearing adakitic rocks in the Edong-Jiurui area, eastern China

YI-ZENG YANG, FUKUN CHEN, QUN LONG, TING CHENG, YUE QI, JIA-DE WU

CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei, 230026, China

The middle-lower Yangtze River belt in eastern China is characterized by metallization with numerous copper, gold and iron deposits related to the Mesozoic magmatism distributed along this belt. The host magmatic rocks are commonly granodiorites, quartz-diorites and partly granites. However, genesis of the magmatic rocks and the related mineralization is still fully debated. Here we present geochronological and geochemical data of Cu-bearing magmatic rocks exposed in the eastern Hubei and northern Jiangxi area (the Edong-Jiurui area) to understand the origin of the Mesozoic magmatism in the middle-lower Yangtze River belt.

Zircon U-Pb dating using the LA-ICP-MS technique on the copper mineralization-related magmatic rocks yields variable ages ranging from about 152 Ma to 139 Ma, suggesting the earliest magmatic activity in Mesozoic related to metallic mineralization in this belt. These magmatic rocks are characterized by high Sr/Y and La/Yb ratios with high SiO_2, Al_2O_3 contents and are enriched in Sr- and Na_2O contents, light REEs and LILEs, depleted in Nb-, Ta-, Ti-contents. These features are comparable with those of the high-SiO_2 adakitic rocks. Pb isotopic composition of the whole-rocks exhibits feature of the mixture of mid ocean ridge basalts and sediments. Their $^{206}Pb/^{204}Pb$ ratios range 17.75 to 18.17, $^{207}Pb/^{204}Pb$ ratios from 15.51 to 15.63, and $^{208}Pb/^{204}Pb$ ratios from 38.03 to 38.44. Initial ε_{Nd} values of these magmatic rocks vary from -3.4 to -8.5. They have high Th/Yb and low Pb/Ce ratios. These adakitic rocks are further characterized specially by Mg# of 32-60, low Cr- and Ni-contents (<50 ppm and <35 ppm), implying that the magmas underwent quick reaction with peridotites in mantle during the magma ascending. They are enriched in Ba-content, coupled with high Sr/Nd and Ba/La ratios and low K/Rb ratio, indicating existence of slab-derived fluid during the magma formation. From the view of geochemical characteristics of the adakitic rocks in the Edong-Jiurui area, it can be proposed that the origin of the Mesozoic magmatic rocks, including granodiorites, diorites and partly granites, most likely originated from the slab melting with a significant addition of sediments. This study is supported by the NSFC grant (No. 41090372).

Ecological Risk Assessment of Soil Heavy Metals in Fruit Producing Area

Y. Y.YANG[1*], D.Y.WANG[1], Y.F.LI[1], Q. FU[1] AND D.Y.GUO[1]

[1] Jilin University, College of Earth Sciences, Changchun, China, yangyuan52415241@163.com*, wang_dy@jlu.edu.cn, yfli@jlu.edu.cn, fly19881118@yahoo.com.cn, jluguodongyan@163.com

Introduction

With the global agricultural products polluted by heavy metals more seriously, people put more emphasis on the monitoring and evaluation of green food and non-polluted fruit producing soil environment quality.

Material, Method, Results and Discussion

In this paper, the concentrations of 8 heavy metals (As, Hg, Cr, Cu, Ni, Pb, Zn and Cd), collected from 120 surface soil samples of apple-pear main production areas in Longjing-Yanji (LJ-YJ), Sanhe (SH), Tumen (TM), Hunchun (HC)—Yanbian area (in eastern Jilin Province, NE China) are analyzed by means of statistical analysis, the single factor indices, Nemerow soil pollution indices and Hakanson potential ecological risk assessment indices. The results indicate that the accumulations of 8 heavy metals in study area are regionally different and heavy metals are mainly accumulated in SH and TM. The most metal concentrations in SH, in different degrees, do appear higher than soil background values and drastically elevated concentration of As is found in TM contrast with background levels (the ratio of As content and Jilin soil background value is up to 2.64). The metal concentrations in LJ-YJ and HC are not significantly increased compared with background values. The spatial variability of 8 heavy metals is quiet different and the order of metals variability is As > Hg > Cd > Ni > Cr > Cu > Zn > Pb. According to the National Environmental Quality Standard for Soils in China (GB 15618-1995), single factor indexes of 8 heavy metals in Yanbian area are all less than 1, respectively, indicating that soil environment quality is judged as clean and free from pollution and heavy metal concentrations are completely in accordance with the soil quality requirements of nuisanceless agro-food production. Additionally, soil potential ecological risk is mild while it reaches the most serious in SH. The order of average ecological risk indices of 8 heavy metals is Cd>Hg>As>Ni>Cr>Cu>Pb>Zn.

Conclusion

Taken together, we conclude that ecological risk assessment of soil heavy metals could provide the scientific basis data of soil quality in land utilization to get high quality agricultural products and safeguard human health.

Simultaneous precise and accurate measurement of $^{147}Sm/^{144}Nd$ and $^{143}Nd/^{144}Nd$ isotopic ratios in natrual geological samples by MC-ICP-MS without Sm and Nd separation and use of costly spike

Y.-H. YANG*, F.-Y. WU, Z.-Y. CHU, L.-W. XIE AND J.-H. YANG

State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, P. O. Box 9825, Beijing 100029, P. R. China, e-mail:yangyueheng@mail.iggcas.ac.cn (* presenting author)

It's well-known in applications of radiogenic isotopes in the fields of geochemistry and cosmochemistry, not only the determination of isotope ratios of radiogenic daughter elements is needed but also the ratios of parent to daughter elements. In terms of Sm-Nd isotopic system, the precise and accurate determination of $^{147}Sm/^{144}Nd$ and $^{143}Nd/^{144}Nd$ isotope ratios in rocks and minerals is essential in applications of geochemical tracer and geochronology in the geological and planetary sciences. Generally, $^{147}Sm/^{144}Nd$ ratio can be determined by isotope dilution (ID) analysis, which is, without doubt, a well-known technique for its excellent precision and accuracy when properly used. This technique requires the use of artificial and costly enriched spikes (*e.g.,* commonly-used ^{149}Sm and ^{150}Nd spike). This is usually done in two steps: (1) the determination of total concentration of Sm and Nd by ID method; and (2) calculation of the concentration of isotope to evaluate $^{147}Sm/^{144}Nd$ ratios from their isotopic abundances. As for $^{143}Nd/^{144}Nd$ ratio measurements, owing to its inherent high precision, classic TIMS is still regarded as the benchmark technique for Nd isotope analysis. Recently, MC-ICP-MS has become a competitive technique for $^{143}Nd/^{144}Nd$ ratio measurements with high sample throughput and comparable precision to classic TIMS since its commercial advent in the mid 1990s.

MC-ICP-MS has the potential for directly measuring isotope ratios of different elements contained in single solution. The main objective of our work is attempted to study the performance of MC-ICP-MS for simultaneous measurement $^{147}Sm/^{144}Nd$ and $^{143}Nd/^{144}Nd$ ratios after one-step chemical purification. Up to now, this is the first report of simultaneous measurement $^{147}Sm/^{144}Nd$ and $^{143}Nd/^{144}Nd$ ratios of real geological sample without used costly spikes. Then we carried out present protocol on several international standard solution and certified reference materials encompassing a wide range of silicate rock type. The results are compared well with those obtained by the conventional approach involving ID methods. Therefore, the Nd and Sm separation and costly spike is unnecessary, allowing for a simple and rapid sample preparation and the high analytical throughput inherent to the MC-ICP-MS can be fully exploited for classic Sm-Nd isotope analyses.

Magma mixing as trigger for sulfide saturation in the UG2 chromitite (Bushveld, South Africa): Evidence from recrystallized silicate and sulfide melt inclusions in chromite

MEIJUAN YAO[1, 2] AND PEDRO J. JUGO[1]*

[1]Laurentian University, Sudbury, Canada,
[2]China University of Geosciences, Beijing, China,
yaomeijuan@cugb.edu.cn, yaomeijuan1016@126.com

Abstract

Mineral assemblages enclosed in chromite grains from the UG2 chromitite reef (Bushveld Igneous Complex, South Africa) were analyzed to understand the genesis of sulfides in this reef and in chromitite seams elsewhere. Two distinct types of assemblages were found. The first type consists of assemblages containing only sulfides. These range from complex assemblages containing pyrrhotite, chalcopyrite, pentlandite, and pyrite (up to ~60 micrometers in diameter and with roughly circular sections) to chalcopyrite-pentlandite pairs to small and isolated crystals of chalcopyrite or pentlandite (of less than 5 micrometers diameter). The more complex assemblages were likely trapped as an immiscible sulfide melt that produced the sulfide assemblages on cooling. The origin of the isolated sulfides grains in chromite is less certain. They could be the only exposed phase of multi-phase assemblages (with other phases hidden within the grain or removed during polishing) but could be interpreted also as crystalline sulfides that co-precipitated with chromite. The second type consists of assemblages containing quartz, Na-rich plagioclase (An_8 to An_{21}), pyroxene, biotite, zircon, rutile, chalcopyrite, and pentlandite. These silicate-oxide-sulfide assemblages are also interpreted as the result of slow cooling of immiscible melts trapped during chromite growth. However, the proportion of sulfide to non-sulfide phases observed in section is variable and the apparent volume of sulfides to silicates is too large to be explained solely by sulfide saturation from a S-bearing silicate melt. Thus, these assemblages likely represent simultaneous trapping of two immiscible liquids (a sulfide melt and a silicate melt) in variable proportions. The chromitites also contain interstitial (intercumulus) pyroxene, Ca-rich plagioclase (An_{61} to An_{76}), and minor sulfides (mostly chalcopyrite, pentlandite, and pyrite; but no pyrrhotite). The presence of quartz and zircon in the enclosed assemblages and the sharp contrast in composition between interstitial plagioclase (An_{61} to An_{76}) end enclosed plagioclase (An_8 to An_{21}) is consistent with the existence of a felsic silicate melt during chromite crystallization and, therefore, consistent with models proposing felsic-mafic magma mixing as the trigger for chromite and sulfide saturation. Similar features have been documented in the Merensky reef of the Bushveld Igneous Complex[1]. Thus, felsic-mafic magma mixing events could have been a recurrent feature during the crystallization of the Bushveld Igneous Complex.

Segregation Processes in Metamorphism: the Role of Nucleation

B. W. D. YARDLEY[1]* G. SCHETTLER[2] AND W. HEINRICH[2]

[1]University of Leeds, Leeds, U K, b.w.d.yardley@leeds.ac.uk (*presenting author)

[2] GFZ, Potsdam, Germany, georg.schettler@gfz-potsdam.de whsati@gfz-potsdam.de

The composition of veins is often assumed to reflect the composition of the fluids from which they form, but where veins form by segregation from the surrounding rocks, it may be that the nature of the minerals that nucleate in the vein actually determines the composition, and hence dictates what segregates. Pelitic schists in eastern Connemara, Ireland, experienced low-P, high-T regional metamorphism and exhibit a progression from staurolite zone to andalusite-staurolite assemblages. However andalusite appears in schist-hosted veins at slightly lower grades than in the schist itself, often forming veins that are over 75% andalusite, with quartz and minor muscovite. Andalusite veins are only present in staurolite schists but the wall rocks are not immediately depleted in Al-silicate. One interpretation of the veins is that they arise through selective nucleation of andalusite in fracture walls when the staurolite – muscovite breakdown reaction is first overstepped. This nucleation pattern in turn drives progressive concentration of Al-silicate into the fracture to form a vein.

We have carried out hydrothermal experiments which appear to mimic the effect of nucleation-controlled segregation in a closed system. Small cylinders of fine grained honfels, with a central hole drilled out for part of their length, were loaded in gold capsules with water or NaCl solution and run for periods of up to 3 months, generally at 400°C and 3kbar. Two starting rocks were used: a cordierite – K-feldspar hornfels and a two-pyroxene basaltic hornfels.

At the end of the experiments the basaltic hornfels cores were coated with fine-grained, honeycomb-textured saponite, but coarser saponite lined the central cavity, and was particularly well-developed in the experiment with 3M NaCl fluid. Orthopyroxene in the rock core was partially replaced by saponite but also developed secondary porosity. Pelitic hornfels with 3M NaCl developed albite overgrowths on K-feldspar which grew into the central cavity, while an experiment at 500°C with pure water developed euhedral quatz crystals in the central cavity, which was lined with new mica growths.

The experiments all took place in closed systems and resulted in segregation of material into the central cavity provided, and to a lesser extent to space between core and capsule. Analyses of water extracted from runs with basaltic hornfels show that Na, K and Ca concentrations were much greater than those of Mg and Al, whereas the saponite is near to the Mg-end member with several percent Al.

We conclude that the composition of the material that segregated was dictated by the composition of the phases that nucleated, and was not closely related to the composition of the fluid. These results emphasise the difficulty in identifying the role of segregation in forming veins from consideration of mass transfer distances, since the transport step is not initially rate-limiting.

Sulfur and Lead Isotopic compositions of Hetaoping Pb-Zn Deposit, Baoshan, China

LIN YE[1*], YULONG YANG[1,2], TAN BAO[1,2]

[1] State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, China yelin@vip.gyig.ac.cn

[2] Graduate School of Chinese Academy of Sciences, Beijing, China

Located in the northern of Baoshan block, the Hetaoping Pb-Zn deposit is one of the most important types of Pb-Zn deposit at the northern-middle section of Lancangjiang tectonic-metallogenic belt in Western Yunnan Province. Strata exposed in the ore area range from Upper Sinian to Cambrian in age. The deposit consists of five sectors with a total reserve of over 2.0 million tons of Pb+Zn. Its orebody is vein in shape and hosted in skarn and marbleized limestone of the Upper Cambrian Hetaoping Formation, and controlled by Baichonghe anticline and SN-trending compresso-tensional interstratal faults. Skarnized, silicification, marbleization and pyritization is dominant wall-rock alteration.

Systematic studies on the sulfur and lead isotope compositions of sulfide minerals, ore and regional strata shows that: (1) the sulfur isotopic compositions of most sulfide minerals are characterized by relatively lower positive values with a narrow variation range (0.95‰~7.20‰, mean value=4.88‰), which is consistent with that of hydrothermal type deposits related to the intermediate-acid granitic intrusion in Baoshan region, but different from that of sulfate in Cambrian oceans. Moreover, some sulfide minerals interfused by reductive sulfur of strata also show higher sulfur isotopic compositions, relative to that of magmatic sulfur. It is suggested that the sulfur in the ore-forming fluids of the deposit deived mainly from deep magma chamber and partly from the Cambrian submarine sulfates. Normally, the sulfur isotope compositions of different sulfide minerals display the trend of $\delta^{34}S_{sphalerite} > \delta^{34}S_{chalcopyrite} > \delta^{34}S_{galena}$, implying the sulfur in the ore-forming fluids of the ore field had already reached isotopic equilibrium. The results of sulfur isotopic geothermometer show there is a relatively high temperature(415~488°C) mineralizing stage in this deposit; (2) The consistent lead isotopic compositions in galena and sphalerite are characterized by the the feature of the upper crustal lead with high μ value (>9.58) and low radiogenic lead isotopic composition, which are different from that of Cambrian strata, but and similar to that of Yanshanian - Himalayan crust type granites in Baoshan region, indicate that the ore lead of this deposit probably came from the upper crustal rocks with high concentration of U and Th. The concealed intermediate-acid intrusive rocks may be the important source of lead, while the strata (e.g. Hetaoping Formation) also contribute some lead to the deposit.

It is suggested that the Hetaoping deposit belong to middle-high temperature skarn type Pb-Zn deposit related to concealed intermediate-acid crust type intrusive rocks, the magmatic hydrothermal might play an important role during the mineralization process.

The impact of gas on flow of DNAPL in porous media

SHUJUN YE[1*], JING YANG[1] AND JICHUN WU[1]

[1]Department of Hydrosciences, Nanjing University, Nanjing, China, sjye@nju.edu.cn

In order to investigate the multiphase flow and migrate of dense non-aqueous phase liquid (DNAPL) in a gas/water two phase system in porous media, two DNAPL infiltration experiments were conducted in a two-dimensional sand-filled cell (55 cm wide x 45 cm high x 1.28 cm thick). TCE was selected as DNAPL. In the first experiment, TCE was injected to the cell under water saturated condition. About 213ml of TCE was injected. In the second experiment, after 223 ml of air displacing water, TCE was added to the cell under gas/water two phase condition. About 194 ml of TCE was added. Light Transmission Method was applied to monitor the DNAPL flow process [1] and quantify DNAPL saturation. Comparing the results of the two experiments, the gas phase hindered the horizontal movement of TCE, shown as Fig.1 and Fig2. The volume of TCE calculated by its saturation obtained from the light transmission method agreed with that recorded injection volume under water saturated condition and gas/water two phase condition, and the migration process of TCE was clearly demonstrated by dynamic variations of the light intensity.

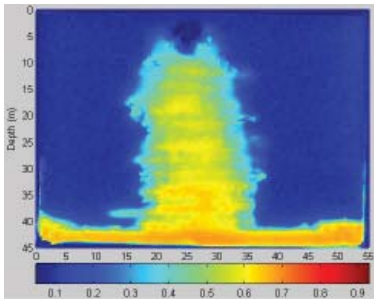

Figure 1: The distribution of TCE saturation in the flow cell in NAPL/water two phase system

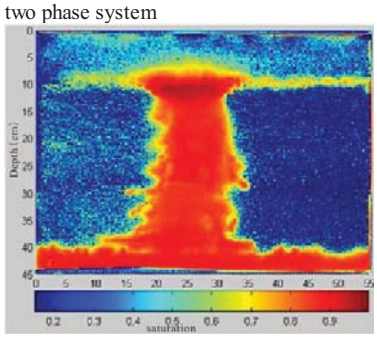

Figure 2: The distribution of TCE saturation in the flow cell in NAPL/water/gas three phase system

Genome-enabled study of alternate respiratory pathways in a novel As(V)-respiring bacterium

INES RAUSCHENBACH[1], ELISABETTA BINI[1], MAX M. HÄGGBLOM[1], NATHAN YEE[1*]

[1]Rutgers University, New Brunswick NJ, USA nyee@envsci.rutgers.edu (* presenting author)

Background

A redox hierarchy based on thermodynamics is frequently invoked to explain the microbial utilization of electron acceptors in which the substrate that provides the most energy for cell growth is preferentially reduced. However, recent experimental and modeling studies have suggested that a thermodynamic ladder of electron accepting processes does not always develop in anaerobic microbial systems. From a physiological perspective, microbes may have evolved growth and respiratory mechanisms that do not follow the electron tower paradigm.

Desulfurispirillum indicum strain S5 is an obligate anaerobic bacterium belonging to the phylum *Chrysiogenetes*. This organism is able to grow by respiring arsenate to arsenite, nitrate to ammonium, as well as selenate and selenite to elemental selenium. From genome analysis, the genes encoding for respiratory arsenate reductase (Arr), periplasmic nitrate reductase (Nap) and the membrane-bound nitrate reductase (Nar) have been identified. Using this genomic information, we carried out gene expression and growth experiments to test the redox hierarchy hypothesis in strain S5.

Materials and Methods

Strain S5was grown anaerobically in a mineral salts medium containing nitrate and/or arsenate as the electron acceptor. Growth was monitored by measuring the optical density and direct cell counts. The loss of arsenate and nitrate from the culture medium was monitored using ion chromatography. Gene expression of *D. indicum* growing under arsenate and nitrate reducing conditions was examined using qRT-PCR. Primer pairs were used for the specific detection of *arrA*, *narG*, and *napA* genes. After RNA extraction and DNAse treatment, qRT-PCR reactions were carried out using the iScript One-Step qRT-PCR with SYBR Green Kit.

Results and Discussion

Consistent with thermodynamic predictions, the experimental results showed that the reduction of nitrate to ammonium yielded higher cell densities than the reduction arsenate to arsenite. However, S5 grew considerably faster by respiration on arsenate compared to nitrate, with doubling times of 4.3 ± 0.2 h and 19.2 ± 2.0 h respectively. S5 growing on both electron acceptors exhibited the preferential utilization of arsenate before nitrate. The expression of the arsenate reductase gene *arrA* was up-regulated approximately 100-fold during arsenate reduction, as determined by qRT-PCR. Conversely, the nitrate reductase genes *narG* and *napA* were constitutively expressed under the conditions tested. The results of this study suggest that physiology, rather than thermodynamics, controls the growth rates and hierarchy of electron acceptor utilization in *D. indicum* strain S5.

$^{18}O^{18}O$ and $^{17}O^{18}O$ in the atmosphere

LAURENCE Y. YEUNG*, EDWARD D. YOUNG, AND EDWIN A. SCHAUBLE

University of California-Los Angeles, Los Angeles, CA, USA
lyyeung@ucla.edu (* presenting author)

The isotopic composition of atmospheric O_2 reflects the balance between photosynthesis, respiration, and the hydrologic cycle over millennial timescales. The Quaternary oxygen-isotope budget in atmospheric O_2, however, is under-constrained, and measurements of the $^{18}O^{18}O$ and $^{17}O^{18}O$ content in the atmosphere will provide additional information.

For instance, the tendency for ^{18}O-^{18}O and ^{17}O-^{18}O bonds to form upon photosynthesis is expected to be insensitive to the isotopic composition of the source water, as C-O bond ordering in carbonates has been shown to be independent of the isotopic composition of carbonate source water [1]; water has no O-O bonds to pass on, so photosynthetic O_2 cannot inherit a bond-ordering signature from its source water.

Oxygen consumption via respiration, in contrast, is expected to alter the bond ordering in O_2. Microbial respiration and photorespiration fractionate oxygen isotopologues in a manner similar to Knudsen diffusion, leaving the residue between +14-30‰ and +7-15‰ enriched in $\delta^{18}O$ and $\delta^{17}O$, respectively [2,3] resulting in the well-known atmospheric Dole effect. If the mass dependence of respiration mimics that of diffusion, then $^{18}O^{18}O$ and $^{17}O^{18}O$ in the fractionated residue should be depleted relative to the stochastic distribution [1]. Thus, the Dole effect may manifest itself as a depletion in $^{18}O^{18}O$ and $^{17}O^{18}O$ relative to the stochastic distribution in atmospheric O_2.

We examined the exceedingly rare $^{18}O^{18}O$ and $^{17}O^{18}O$ isotopic variants of O_2 in tropospheric air. We find that these species are enriched relative to the stochastic distribution of isotopes – opposite in sign from signatures predicted to be imposed by the biosphere. We demonstrate, with laboratory experiments, that bond ordering in atmospheric O_2 is likely governed by autocatalytic $O(^3P)$ + O_2 isotope-exchange reactions that cycle through the atmospheric O_2 reservoir on decadal timescales. Our analysis of the atmospheric budget suggests that trends in O-O bond ordering over geologic time may be sensitive to tropospheric $O(^3P)$ concentrations, tropopause temperature, and stratosphere-troposphere exchange flux, offering constraints on the abundance of short-lived trace gases and the strength of circulation in the ancient atmosphere.

Characterizing the dissolved organic composition of water in the oilsands region via FT-ICR MS

Y. YI[1,2*+], J. HAN[3+], S.J. BIRKS[1], J.J. GIBSON[1,2], C. BORCHERS[3]

[1]Integrated Water Management, Alberta Innovates-Technology Futures
[2]Department of Geography, University of Victoria
[3]University of Victoria - Genome BC, Proteomics Centre
yiyi@uvic.ca (*presenting author, + equal contribution to the research)

Introduction

Ultrahigh-resolution FT-ICR MS (Fourier Transform – Ion Cyclotron Resonance) is an emerging technique to characterize complex compositions of thousands of organic compounds dissolved in water and provide the potential to help identify impacts of oilsands development on aquatic environments. Here, we present a case study demonstrating the distinct compositional differences in the organic profiles of various water types collected in the region, which highlights the potential of FT-ICR MS in characterizing and profiling water for environmental monitoring and water resources management.

Results and Discussion

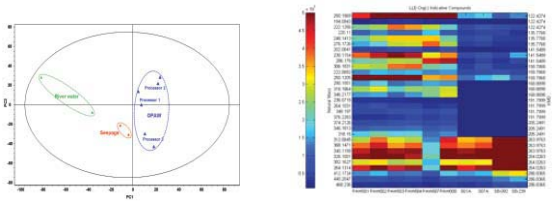

Figure 1: a) the score plot of PCA of FT-ICRMS results acquired in negative mode demonstrating distinctions and differences among various types of water. **b) heatmap** showing proposed key indicative compounds for each water type.

The FT-ICR MS analyses after Liquid-Liquid Extraction of oil sands process affected waters (OPAW) and river water lead to the successful detection of up to 7,300 compounds in water samples. The organic-rich OPAW and seepage samples analyzed in this study showed a wide range of organic compositions. Distinct patterns of mass distribution and elemental composition can be linked to the type of water. Principle Component Analysis (PCA) showed clear separation trends and groupings among various water types (Figure 1a). Further statistical analysis via Partial Least Square Discrimination Analysis (PLS-DA) proposed a series of homologues indicative of each water type (Figure 1b). The distinctive organic profile of industrially processed water as compared to background organics suggests great potential in applying FT-ICR MS in water resources management and aquatic environmental monitoring.

Reactive transport modeling of Sr-90 sorption in reactive sandpacks

Jun Yin[1,*], K. Ulrich Mayer[2], and Sung-Wook Jeen[3]

1. University of British Columbia, Earth and Ocean Sciences, jyin@eos.ubc.ca (* presenting author)
2. University of British Columbia, Earth and Ocean Sciences, umayer@eos.ubc.ca
3. Atomic Energy of Canada Limited, Chalk River Laboratories, jeens@aecl.ca

Granular clinoptilolite was shown to be an effective material to treat groundwater contaminated with the radionuclide Sr-90, as proven in a permeable reactive barrier (PRB) at the Chalk River site, Ontario, Canada [1]. A large number of pore volumes can be treated, because clinoptilolite is characterized by a high sorption potential with effective distribution coefficients (K_d) exceeding 6900 cm^3/g [2]. Recently, an alternative treatment technology has been proposed, using the same reactive material as an in-situ reactive sandpack to reduce contaminant levels in extracted groundwater. Reactive sandpacks can be installed around the well during construction and contaminated water is treated in the direct vicinity of the extraction well [2].

A proof-of-concept study was initiated by conducting a series of in-well column experiments to test adsorption behaviour for Sr-90 and contaminant treatment for flow conditions representative to those near a well screen [2]. Fitted distribution coefficients were strongly correlated to flow rates, indicating that Sr-90 adsorption cannot be described by an equilibrium sorption model [2]. In addition, a reduction in flow rates was observed over time, which was attributed to iron oxide precipitation in the treatment material [2], potentially also causing a reduction in clinoptilolite reactivity.

To further interpret the observed data, the reactive transport model MIN3P was used to simulate the experimental results in an attempt to better understand the sorption mechanisms. Transient boundary conditions were accounted for by varying flow rates and aqueous Sr-90 concentrations. Preliminary results confirm that the distribution coefficient (K_d) varies as a function of flow rates and breakthrough occurs earlier than predicted based on the equilibrium model. Therefore, in addition to transient boundary conditions, a kinetically-controlled linear adsorption model is used to reproduce observation data.

In addition, we evaluate whether a cation exchange model coupled with multi-rate mass transfer processes provides a more adequate description of Sr-90 attenuation. Building on the work of Jeen et al. [3], a formulation that simultaneously considers the reduction of hydraulic conductivity and decrease of reactivity as a function of mineral precipitation will be presented. This new formulation will allow to carry out long-term simulations constrained by experimental data, accounting for iron oxide precipitation as observed in the sectioned solid samples.

Multi-episodic modification of the lower crust beneath the North China block: responses to the Phanerozoic decratonization

JI-FENG YING*, HONG-FU ZHANG, YAN-JIE TANG, BEN-XUN SU, XIN-HUA ZHOU

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China, jfying@mail.iggcas.ac.cn (* presenting author)

It has been generally accepted that the North China craton has considerably lost its continental lithospheric root in the Phanerozoic on the basis of multidisciplinary studies on the lithosphric evolution over the past decade. The formerly existed thick, cold Archean lithospheric mantle has been severely thinned, destructed and replaced by relatively hot and young mantle with oceanic affinity. It is worth noting, however, that the previous investigations regarding to the lithospheric evolution were mainly focued on the mantle lithosphere, how does the lower crust, namely, the other part of the lithosphere respond to such tremendous change in lithospheric structure is another important issue to be addressed.

With the outcrops of crustal materials as old as 3.8 Ga, the North China craton is one of the oldest cratons in the world. The widely distributed 2.5 Ga basement, on the one hand confirmed the existence of ancient lower crust, and on the other hand suggested that the North China was cratonized at that time. Our latest geochronological and geochemical studies on a suite of lower crustal granulite xenoliths entrapped in the Mesozoic volcanic rocks, along with the results of granulite and pyroxenite xeoliths from the other localities on the craton have shed light on the evolution of the lower crust. Zircon U-Pb age analyses revealed that, besides the ubiquitous Archean age population (predominantly 2.5 Ga), there are also Phanerozoic age populations ranging from Permian to Paleogene, varying from different localities. The Archean age population implies the existence of the ancient lower crust throughout the North China craton, while the Phanerozoic age populations imply that the ancient lower crust has been modified, most possibly through multi-episodic magmatic underplating. Zircons of different age populations also show varied Hf isotopic compositions, suggesting that the underplating magmas were from different sources. In addition to the compositional modification, the depth that the lower crust extended at different time was also changed remarkably, similar to the thinning mantle lithosphere during the Phanerozoic, the thickness of lower crust has also been thinned since the early Mesozoic.

This study was financially supported by the NSFC grant (40973027) and the Chinese Academy of Sciences (KZCX2-YW-Q08-3-1, KZCX2-EW-QN106) .

Drying behavior of a rock and its implication to weathering

TADASHI YOKOYAMA[1*], NAOKI NISHIYAMA[1]

[1]Department of Earth and Space Science, Osaka University
tadashi@ess.sci.osaka-u.ac.jp (* presenting author),
nnishiyama@ess.sci.osaka-u.ac.jp

Rocks near the ground surface undergo cyclic wetting and drying. Dynamic movement of pore water and significant change of chemical composition are induced by drying. Knowledge on these processes is important for considering weathering of rocks. We studied the way pore water moves and solute concentration changes during drying. A core of porous rhyolite from Kozushima, Japan [1], main pore diameter ranging from 0.1 μm to 260 μm, was used in the experiment. The core was saturated with deionized water, dried at 20°C and weight loss was monitored. Figure 1 shows the change in water-saturation (water volume per total pore volume) with elapsed time of drying. Drying rate was relatively constant for the initial 5 hours (constant-rate stage [2]) and then decreased (falling-rate stage [2]). In order to evaluate the size and chemical composition of pore water under different degrees of drying, we employed centrifugation. It is known that water is progressively extracted from water-bearing rock in order of large to small pores as centrifugal speed increases [3]. Therefore, by extracting pore water with increasing centrifugal speed in incremental steps, we can know the changes in the size of pore water and the solute concentration with progress of drying. The result of the stepwise centrifugation (Figure 2) demonstrates that as drying advances, first larger pores and subsequently smaller pores lose water. Also, solute concentration significantly changed with the progress of drying. Based on the results, we discuss how drying affects dissolution of primary minerals and precipitation of secondary products.

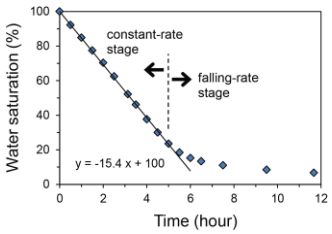

Figure 1: Change in water-saturation with elapsed time of drying

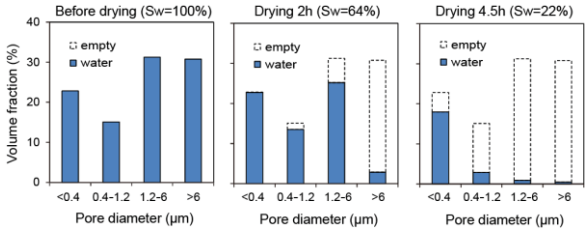

Figure 2: Change in size distribution of pore water with progress of drying (Sw: water saturation)

Sr isotope anomalies in chondritic acid leachates

TETSUYA YOKOYAMA[1*], NOBUAKI ITO[1], YUSUKE FUKAMI[1] AND WATARU OKUI[1]

[1] Deptartment of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan. (*: tetsuya.yoko@geo.titech.ac.jp)

A variety of nucleosynthetic isotope anomalies for heavy elements are documented in bulk chondrites and their components. Such data point to the existence of isotope heterogeneity in the protosolar nebula [1-2], although the mechanism that preserved nebular spatial heterogeneity at the time of planetary formation is not totally understood. In this study, we investigated stable Sr isotopic anomalies in carbonaceous chondrites. Strontium has four isotopes produced by the stellar nucleosynthesis of s-process (^{86}Sr, ^{87}Sr and ^{88}Sr), r-process (^{87}Sr and ^{88}Sr), and p-process (^{84}Sr). Radioactive decay of ^{87}Rb ($T_{1/2}$ = 48.8 Gyr) also contributes to ^{87}Sr. Recently, high precision TIMS analysis revealed both mineral and planetary scale Sr isotope anomalies in various meteorites [3]. Large ^{84}Sr excesses (>100 ppm) were also found in CAIs [3,4].

To better understand the isotopically anomalous carriers for Sr in chondrites, we examined the sequential acid leaching for bulk rocks of two chondrites, Allende (CV3) and Tagish Lake (C2-ung), and analyzed Sr isotopes by TIMS. We followed the leaching procedure of [5], in which powdered chondrites were successively leached from weak to harsh acids in six steps; AcOH (20°C) – HNO_3 (20°C) – HCl (75°C) – HF+HCl (75°C) – HF+HCl (150°C) – HNO_3+HF (120°C). The ^{84}Sr/^{86}Sr ratios are reported in μ^{84}Sr units, which represent 10^6 relative deviations from NIST987 Sr. Most of the Allende leachates have positive μ^{84}Sr that are close to the bulk Allende (+75 ppm). For Tagish Lake, the μ^{84}Sr gradually decrease from leachate #1 (+40 ppm) to #5 (-16 ppm), and an extremely large negative anomaly (-326 ppm) is observed in leachate #6. Bulk Tagish Lake has a marginally positive μ^{84}Sr (+16 ppm) that is apparently lower than that of bulk Allende.

The positive μ^{84}Sr represents the existence of materials enriched in Sr synthesized by the p- and/or r-process, while the enrichment of s-process Sr makes a negative μ^{84}Sr. Most of the presolar phases in Allende has been destroyed via thermal metamorphism on the parent body. Thus, the anomalies in Allende leachates are presumed to be dominated by CAI components. We found no FUN-like CAI signature which has a drastically low μ^{84}Sr (-4200 ppm, [6]). The μ^{84}Sr in Tagish Lake leachates suggest that leachates 1 and 2 contain presolar grains rich in p- and/or r-process Sr, while leachate 6 contains presolar grains rich in s-process Sr. This means that Tagish Lake has at least two different presolar phases produced in different stellar environment. The easily leachable presolar phase(s) in leachates #1 and #2 is not yet identified, but presumably consists of minerals produced by supernovae. The acid resistant phase in leachate #6 is most likely presolar SiC synthesized in AGB stars.

Spectroscopic and Quantum Chemical Investigation of Selective Incorporation of Arsenate and Selenite into Calcite

YUKA YOKOYAMA*, YOSHIO TAKAHASHI, AND MASATO TANAKA

Hiroshima University, Hiroshima, Japan
yoshiyuka@hiroshima-u.ac.jp (* presenting author)

Calcite ($CaCO_3$) is known as a mineral which can play a role as an effective scavenger of toxic elements in the surface environment. This study focused on the interactions of arsenic (As) and selenium (Se) oxyanions with calcite. The contamination of natural water with them is occurring in various areas in the world. Especially, migration of ^{79}Se from nuclear wastes to biosphere will pose a serious problem for the safe geological disposal of nuclear wastes.

Our coprecipitation experiments and XANES measurements revealed that calcite selectively incorporated arsenate rather than arsenite [1], and selenite was selectively incorporated rather than selenate. Although molecular geometries of dissolved selenite and selenate are similar to those of arsenite and arsenate, respectively, there is no relationship between their molecular geometries and incorporation behavior into calcite. EXAFS analyses using FEFF shows that these oxyanions are incorporated into calcite through substitution with carbonate ion, which indicated that these impurities are combined with Ca^{2+} ion when they deposit on the calcite surface. In order to determine the factor controlling the preferences of arsenate and selinite for the incorporation of As and Se, respectively, into calcite, their affinities to Ca^{2+} ion, which reflect their reactivities with calcite at the calcite-water interface, were evaluated based on the quantum chemical calculation (QCC).

Estimation of intermolecular binding energies between each oxyanion and Ca^{2+} ion by QCC shows that the affinity orders for Ca^{2+} ion are arsenite > arsenate and selenite > selenate. The preference of selenite for incorporation into calcite is related to its higher affinity to Ca^{2+} ion than selenate. On the other hand, though QCC shows that arsenite has higher affinity for Ca^{2+} ion than arsenate, arsenite is hardly incorporated into calcite as shown experimentally [1]. This preference can be attributed to the difficulty of arsenite deprotonation as shown in its large dissociation constant (p*K*a = 9.3). Other oxyanions (arsenate, selenite, and selenate) dissociate into their anionic forms and can interact with Ca^{2+} ion under pH conditions where calcite can precipitate, whereas neutrally charged arsenite cannot display its high affinity for Ca^{2+} ion except for under high alkaline condition. Hence, the factors controlling their preferences for the incorporation into calcite are different between As and Se; for As, the charge of the aqueous species is important, whereas affinity to Ca^{2+} ion is important for Se. Additional QCC of the interactions between the oxyanions and calcite surface with the cluster models mimicking calcite-water mineral interface is expected to contribute to further investigation at the molecuar-scale. The present findings should provide some insights into natural behavior of As and Se, because their oxidation states are variable in subsurface environment.

Pore-scale evaluation of calcium carbonate precipitation and dissolution kinetics in a microfluidic pore network

HONGKYU YOON[1*], THOMAS DEWERS[1], ALBERT J. VALOCCHI[2], AND CHARLES J. WERTH[2]

[1] Geomechanics, Sandia National Laboratories, Albuquerque, USA, hyoon@sandia.gov (* presenting author), tdewers@sandia.gov
[2] Civil and Environmental Engineering, University of Illinois, Urbana, IL, USA, valocchi@illinois.edu, werth@illinois.edu

Introduction and background

Dissolved CO_2 during geological CO_2 storage may react with minerals in fractured rocks or confined aquifers resulting in mineral precipitation and dissolution. The overall rate of reaction can be affected by coupled processes among hydrodynamics, transport, and reactions at the (sub) pore-scale. Pore-scale models of coupled fluid flow, reactive transport, and heterogeneous reaction at mineral surfaces developed in our previous work [1] are applied to account for transient experimental results of calcium carbonate precipitation and dissolution in a microfluidic pore network [2]. In the micromodel, precipitation is induced by transverse mixing along the centerline in pore bodies. Pore-scale modeling is used as a basis for understanding the significance of pore-scale processes that may accoutn for large-scale phenomena involving geochemical reactions.

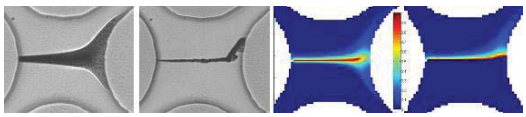

Figure 1: Experimental images (left) and simulated results (right) of $CaCO_3$ precipitates at 13 min and 118 min in the micromodel

The model is used to test the influence of different reaction rate laws on spatial and temporal reaction patterns. These include elementary reaction-based, affinity-based, and nano-scale in-situ measurement-based rate laws in the literature. The sensitivity of diffusion coefficient, reactive surface area, and rate constant on precipitate morphology, reaction rate, and amount of precipitates are evaluated in order to evaluate the governing physics of sub-micron scale reactions. Implications for evaluating mineral precipitation patterns observed in natural analogues for CO_2 storage and leakage are discussed to link pore-scale models to domains of relevance for geological CO_2 storage.

Carbon sequestration using asbestos-containing slate waste: detoxification of asbestos and carbonate mineralization

SUNGJUN YOON* AND YUL ROH-
Chonnam National University, Gwangju, Korea, rohy@jnu.ac.kr

Introduction

One of the representative asbestos-containing waste materials is a slate used as a roofing material. Asbestos-containing slate waste consists of chrysotile asbestos (10~20%) and cement (80~90%). As time goes by, calcium hydroxide which forms a constituent part of cement dissolves in water and chrysotile asbestos harmfully remain in the environment. Generally, asbestos-containing slate waste is dumped in controlled waste sites in Korea. However, this cannot be regarded as an ultimate solution because dispersion of asbestos fibers in the air is an intrinsic risk during dumping operations and in the long term management. An alternative solution is thermal transformation of asbestos-containing material into non-hazardous phase [1, 2]. Also, chrysotile is one of the raw materials to form carbonate mineral for CO_2 sequestration in previous studies [3, 4]. Therefore, the aims of the study were to detoxify chrysotile asbestos in slate waste via heat treatment and to sequester CO_2 using asbestos-containing slate waste via carbonate mineralization.

Materials and Methods

Two steps of experiments were designed: (1) transformation of fibrous asbestos into non-fibrous material through heat treatment after pulvering the slate waste and (2) synthesis of carbonate mineral, calcite ($CaCO_3$), via the physicochemical reactions of heat treated slate waste with CO_2. Chemicophysical properties of slate wastes before and after the treatment were investigated by TG-DTA and XRF analyses. And mineralogical characteristics of the slate waste and byproducts after treatments were examined by PLM, XRD, SEM, TEM and EDS analyses.

Results and Conclusion

Mineral characterization showed minerals such as chrysotile [$Mg_3Si_2O_5(OH)_4$], calcium hydroxide [$Ca(OH)_2$] and calcite ($CaCO_3$) in the slate waste were transformed to magnesite ($MgCO_3$), fosterite (Mg_2SiO_4), and calcium oxide (CaO) by heat treatment. PLM, SEM and TEM analyses showed that chrysotile fibers were transformed into rod-shaped forsterite. Calcite ($CaCO_3$) was formed after reaction of heat treated slate with CO_2. These results indicate that thermal treatment of asbestos-containing slate combined with physicochemical reactions with CO_2 can detoxify chrysotile asbestos in slate waste and sequester CO_2 by forming carbonate mineral.

Geological Environmental assessment of Lakes Shinji-ko and Nakaumi by stream sediment, Shimane Prefecture, Japan.

KEISUKE YOSHIDA[1*] AND ICHIRO MATSUMOTO[1]

[1] Department of Education, Shimane University, Matsue, Japan,
keisuke0406@gmail.com (* presenting author)
chromim@edu.shimane-u.ac.jp (second author)

Lakes Shinji-ko and Nakaumi

Lakes Shinji-ko and Nakaumi are the continuous brackish water lakes representing Japan, located Japan seacoast side over Shimane and Tottori prefectures. These lakes had many brackish resources and sightseeing, and many researches have mainly been done water quality or an ecosystem. It is because declining of water quality and the influence on brackish products are becoming serious by human life in recent years [1]. In this research, we investigated the sediment from the river, which flows into lakes. It is because sediment is an basically very important for the ecosystem of the bottom of a lakes. Moreover, it is expected that the rate of an influence to a lakes will be estimatable.

Results and discussion

In this research, we observed the mineral composition of sediment by using of XRD-method and mode counting of minerals and rock fragments under the microscope. All sediment mainly consists of Quartz, feldspars and rock fragment, and accompany with hornblende, biotite, pyroxene, olivine and magnetite. There are no difference between Lakes Shinji-ko and Nakaumi. However, rivers which flow in from south of lakes show high ratio in “granite origin-mineral and fragment”. This result is concordant with geological feather surrounding the lakes. That is Thertiary sandstone and mudstone is mainly consisting of Shimane peninsula, which closes the north of a lakes. The granite is widely distributed to the south of lakes. That is, it became clear that the chemical influence according to the geology of the basin is brought to a lake through each river. Importance of this is that the rate of the chemical influence in natural became calculable with the basin area of each river.

It makes clear that Hii river has most affected the lakes Shinji-ko and Nakaumi, as a preliminary report. And Iinashi river has also large affected the lake Nakaumi as well as Hii river. Matsumoto (2009) has reported the same result using a heavy metal element concentration [2, 3, 4]. Our preliminary report is concordant with the result and idea of Matsumoto (2009). In addition, Matsumoto (2009) show only Hii and Iinashi rivers, however we can show the almost all river surrounding the lakes. We are going to study these results in details further and to perform the environmental impact assessment to the lakes Shinji-ko and Nakaumi from viewpoints of a nature and a human life.

Sr isotopic composition of pore water of shelf cores from IODP Expedition 317: Canterbury Basin, New Zealand

TOSHIHIRO YOSHIMURA[1]*, HODAKA KAWAHATA[1], MASAHARU TANIMIZU[2], SIMON C. GEORGE[3], JULIUS S. LIPP[4], AND GEORGE E. CLAYPOOL[5]

[1] Atmosphere and Ocean Research Insttitute, The University of Tokyo, yoshimura@aori.u-tokyo.ac.jp (* presenting author)

We used Sr isotope ratios to investigate diagenetic and sedimentary controls on the chemical composition of pore water in shelf sediments of deep-penetration (>300 m) cores recovered by Integrated Ocean Drilling Program Expedition 317 at three sites on a landward-to-basinward transect in the Canterbury Basin off New Zealand (sites U1353, U1354, and U1351, Fig. 1).

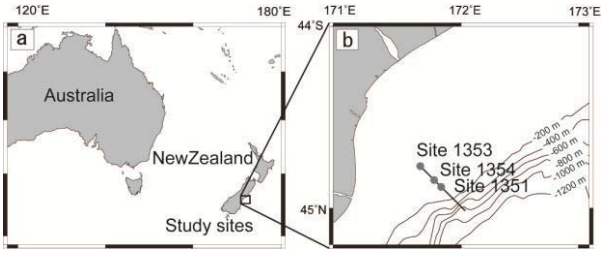

Figure 1: Map showing the locations of drilling sites of IODP Expedition 317: Canterbury Basin, New Zealand.

In general, the pore-water Sr concentration increased as $^{87}Sr/^{86}Sr$ values decreased in the shelf environment. Such Sr enrichment accompanied by rapid decreases of $^{87}Sr/^{86}Sr$ reflect the diagenetic release of Sr from reactive minerals such as biogenic carbonate and silicate minerals (e.g., plagioclase, mica). The degree of Sr enrichment was less and $^{87}Sr/^{86}Sr$ was higher in the pore water of the core from the most nearshore site (U1353) compared with the other two cores. Moreover, molar ratios of major cations remained constant throughout most of the U1353 core. These results suggest that the site U1353 sediments underwent less diagenesis. In addition, a less saline lens was observed in the uppermost 150 m only at site U1353. $^{87}Sr/^{86}Sr$ values in the less saline lens were uniform, and the plot of $^{87}Sr/^{86}Sr$ versus 1/Sr showed no significant mixing trend related to salinity changes. The $^{87}Sr/^{86}Sr$ data suggest that the less saline lens can be explained by the introduction of freshwater in the past in association with sea-level fluctuations. The repeated freshwater intrusion during periods of emergence followed by seawater replenishment after submergence that probably accompanied Pleistocene to Holocene sea-level changes would have homogenized $^{87}Sr/^{86}Sr$ values and caused some pore water to be discharged into the ocean. Moreover, no hydrocarbons were detected at site U1353 and sulfate concentrations were close to the seawater value. We propose that during sea-level lowstands, climate-driven flushing of pore water was accompanied by the inhibition of methane generation in the fine-grained sediments.

Fate of nitrogen during oxic submarine groundwater discharge into Stony Brook Harbor, New York

CAITLIN YOUNG[1*], GILBERT N HANSON[2]

[1]Stony Brook University, Stony Brook,NY,11794, USA, (correspondence: cryoung@ic.sunysb.edu)
[2]Stony Brook University, Stony Brook,NY,11794, USA, (ghanson@notes.cc.sunysb.edu)

A combination of electrical resistivity surveys, porewater sampling and ultrasonic seepage meter measurements were used to investigate nitrogen attenuation in a subterranean estuary STE in Stony Brook Harbour, an embayment with direct connection to Long Island Sound. Nitrogen loading calculations for Long Island Sound assume conservative transport of nitrogen during submarine groundwater discharge through the subterranean estuary (STE) [1]. However, the STE is increasingly recognized as a potential nitrogen sink due to rapidly changing redox conditions at the freshwater/saltwater interface. To minimize cesspool and lawn fertilizer derived nitrogen inputs to coastal waters, municipal land planners require better estimates of nitrogen attenuation in the STE.

Coupled land-sea electrical resistivity profiles show distinct shallow saline tidal recirculation cells overlying a 9m thick freshwater zone in the coastal aquifer. STE porewater was sampled in two perpendicular to shore piezometer transects 75m apart. Each transect consisted of 5 piezometer wells, sampled at intervals of 0.5m to a maximum depth of 7.6m. Ultrasonic seepage meters were placed offshore to record discharge during STE porewater sampling. A combination of N_2/Ar and $\delta^{15}N\text{-}NO_3^-$ are used to determine extent of denitrification in the shallow saline transition zone. This approach is used in traditional groundwater denitrification studies[2] but this study is the first to employ this method in a STE.

The shallow saline transition zone, where salt water from tidal oscillations penetrates into discharging fresh water, is the most geochemically active portion of this STE. Dissolved oxygen concentrations were above 70% saturation throughout the freshwater portion of the STE. Where dissolved oxygen concentrations were less than 2mg L^{-1}, nitrate concentrations were less than 50μM L^{-1} and salinity was 20ppt or greater, but no NH_4^+ is present. Along one transect, NO_3^- concentrations decreased seaward to 5 mg L^{-1} over a distance of 26 meters. Anammox, coupled nitrification-denitrification or dilution of nitrate in the shallow saline zone may account for this removal of nitrogen.

In STEs where groundwater is oxic, nitrate concentrations remain high but may be diluted during transport, as evidenced by silica and sulfate porewater distributions. Nitrogen attenuation occurs in the shallow saline transition zone, where saltwater derived dissolved organic carbon drives microbial reactions. Combined N_2/Ar and $^{15}N\text{-}NO_3^-$ elucidate attenuation mechanisms in the shallow saline transition zone.

Chondrite Chronology, Planetesimal Accretion, and Implications for Water Delivery to Earth

EDWARD D. YOUNG[1*], HILKE E. SCHLICHTING[1,2]

[1]Department of Earth and Space Sciences, UCLA 595 Charles E. Young Drive East, Los Angeles, CA, eyoung@ess.ucla.edu (* presenting author)

[2]Hubble Fellow, hilke.schlichting@gmail.com

Two advances in the fields of cosmochemistry and solar system dynamics are raising new questions about the materials from which Earth and the other terrestrial planets were made. One is a change in our understanding of the relative antiquity of differentiated and undifferentiated planetesimals in the early solar system and the other is the recognition that planetesimals were widely scattered as a consequence of giant planet migration. We address the potential implications of these advances here.

High-precision chronometers based on short-lived radionuclides and their decay products (e.g., ^{182}Hf/^{182}W, ^{26}Al/^{26}Mg) reveal that bodies that differentiated into a rocky mantle and metallic core formed very rapidly, often with metal-silicate separation ages nearly indistinguishable from calcium-aluminum-rich inclusion (CAI) formation. Similarly, it is now well known that chondrules comprising chondrites formed several million years after CAIs. For example, new Mg isotope data from this lab for CV and LL3 chondrites show a single initial ^{26}Al/^{27}Al of 1.25x10^{-5}, corresponding to a crystallization age of 1.5 Myr after closure of the solar system based on $\Delta t = -1 / \lambda \ln\left(\left(^{26}\mathrm{Al}/^{27}\mathrm{Al}\right) / \left(^{26}\mathrm{Al}/^{27}\mathrm{Al}\right)_{\odot}\right)$. These data and other published data analogous to these in turn are suggesting that chondrites themselves accreted as late as ~ 3 and possibly even 4 Myr post CAI. Ordinary chondrites, representing the inner asteroid belt (S-type asteroids), and carbonaceous chondrites, representative of the central asteroid belt (C-type asteroids), both exhibit late chondrule formation (> 1 Myr). Therefore, the idea that heliocentric gradations in the distribution of asteroid types is the consequence of a sharp gradient in accretion time seems less likely now.

A simple order-of-magnitude calculation suggests that the growth timescale for a planetesimal of radius R, in the absence of gravitational focusing, is given by $\tau \sim \rho R / (\sigma\Omega)$ where ρ is the density of the coagulating planetesimals, σ is the mass surface density of solids and Ω is the Keplerian angular frequency around the sun. This implies a growth timescale for a 10km sized planetesimal at 3 AU of $\tau \sim 1.3\ (a / 3\mathrm{AU})^{3}$ Myr where we used $\rho \sim 3\mathrm{g/cm}^3$ and assumed a minimum mass solar nebular with a surface density profile $\sigma \propto r^{-1.5}$ (r = heliocentric distance). The scaling with semi-major axis, a, suggests a delayed growth of ~3Mys, as indicated by chondrule chronology data, can be achieved by forming planetesimals at 4AU (i.e., beyond the asteroid belt). Formation *in situ* in the asteroid belt would suggest accretion within ~ 0.4 to 1.5 Myr.

Recent models for giant planet migration allow for populating the asteroid belt and the terrestrial planet region with small bodies from distal regions of the early solar system. We suggest that combining the detailed chronology of chondrites with a better understanding of planetesimal growth timescales can be used to test these models.

Responses of deep-sea carbonate system to carbon reorganization and sea level changes

[4]*Department of Earth Sciences, University of Bristol, Bristol, UK*

It is widely accepted that lower atmospheric CO_2 during glacials is caused by a greater sequestration of carbon in deep oceans. However, specific mechanisms causing such changes remain elusive despite intensive studies in the past decades. Transferring carbon into and out of the deep ocean would inevitably affect deep ocean carbonate chemistry such as deep water carbonate ion concentration and carbon isotopes (*1*). The associated deep ocean carbonate compensation and ocean alkalinity changes serve as important feedbacks to further affect atmospheric CO_2. As a step forward to understand the deep ocean carbonate system, we quantify deep-sea carbonate ion concentration using benthic foraminiferal B/Ca (*2*) and δ^{11}B (*3*) ratios for a few cores from the equatorial Pacific Ocean at various water depths over the last glacial-interglacial cycle. Combined with carbon isotopes, these results provide insights into the carbon cycle in the atmosphere-ocean-terrestrial biosphere system in the past. We explore responses of deep-sea carbonate chemistry to ocean circulation changes, the carbon reorganization within the ocean, and the shelf-basin carbonate fractionation associated with sea level changes. Our data allow us to evaluate past ocean alkalinity changes and their impacts on atmospheric CO_2. The reconstructed deep-sea carbonate ion also places constraints on what controlled the deep ocean carbonate preservation in the past (*4*).

Transformation and interaction of trace elements in soil-plant system under waterlogged and dry cultivation, southeastern China

XUYIN YUAN[1,2]*, TIANYUAN LI[2], AND JIZHOU LI[1,2]

[1]Key Laboratory of Integrated Regulation and Resource Development on Shallow Lakes, MOE, Nanjing, China, *yxy_hjy@hhu.edu.cn (* presenting author)
[2] Hohai University, College of Environment, Nanjing, China

Introduction

The yellow brown soil is a primary soil in the southeast China, which is cultivated for crop planting. The cultivation in waterlogged and dry fields is common manner in the study area. Trace elements of corps (rice and rape) and soils in two cultivated conditions were investigated to expound their transformation and interaction in soil-plant system. It is beneficial for risk assessment of trace metals in different land uses.

Results

The ratio of trace element concentration in crop shoot to that in soil is defined as an translocation coefficient (T), and the ratio of trace element concentration in grain to that in shoot as a allocation coefficient (A). These coefficients were researched in two soil-crop systems (rice-waterlogged field and rape-dry field). The results displayed T >1 for Cd and Mo, 0.44 < T < 0.86 for As, Hg, Se, Zn and Cu, T < 1 for Pb and Cr in soil- rice system. But the allocation coefficients for all trace elements in rice were less than 1. It showed A> 0.5 for Mo, 0.1< A < 0.5 for Hg, Se, Cu, Zn, Cd and Cr, A <0.1 for As and Pb. In the dry field, it showed that the translocation coefficients of rape were larger than 1 for Cd, 0.14< T<0.55 for Zn, Cu, Mo, Se and Hg, T< 0.1 for Pb and As. Meanwhile, the allocation coefficients of Zn and Mo were larger than 1, and those of other elements were between 0.01 and 0.57.

Based on correlation analyses, the significant affecting factors for metal translocation of rice were sulphur and pH value, and $CaCO_3$ showed a weak effect. Sulphur was also in the primary factor influencing the elemental allocation from shoot to grain, P and B were the secondary factors. Fe oxides took a important role in promoting translocation of trace elements, TOC and $CaCO_3$ also showed obviously effects on metal translocation of rape. The allocation coefficients of rape were significantly affected by iron. The other affecting factors included P, S, K and Na. It is indicated the nutrient elements are important for allocation of metals in crop[1].

Conclusions

Overall, the crop under waterlogged field shows high translocation ratios of trace elements, but trace elements under dry field are more easy to transport for shoot to grain. Relatively, the crop translocation and allocation show more affecting factors under dry field, which may due to redox and elemental characteristicss of soils[2].

[4]fagervold@obs-banyuls.fr, [5]lebris@obs-banyuls.fr

Seafloor wood-falls were recently found to support chemosynthetic communities, pointing to the development of reducing conditions and redox interfaces in these organic falls over time. This discovery was in contrast with the presumed sluggish degradation of woody substrates containing such recalcitrant organic polymers. Two major questions arise in this context: How and when wood-falls transform into anoxic-sulfidic environments and what biotic and abiotic processes regulate the concentrations of redox sensitive degradation products, particularly reduced sulfur, on wood-falls? In this communication we describe a 200-day chemical dynamics of redox species on the surface and the interior of a simulated marine wood-fall using continuous multi-analyte voltammetry with Au/Hg microelectrodes, and discuss the combined microbial and abiotic kinetics of possible sulfur transformations during marine wood-fall degradation. Our voltammetry results showed that after a 5-week suboxic period, the wood interior became sulfidic, and after 8 weeks, sulfide was detected at the surface for the first time. Steady-state sulfidic conditions in the wood interior were observed after about 13 weeks, following an unsteady period where sulfide concentration fluctuated between 1 mM and several µM. Sulfide oxidation seems to play an important part in the wood-fall sulfur cycle as evidenced by the surface biofilm bacterial composition and the relatively lower concentrations of sulfide on the wood surface. The succession of transient dynamic states, in otherwise physically and chemically stable experimental conditions, suggests a complex dynamic system linking microbial communities producing and consuming sulfide with the reactivity of wood components towards sulfide. These findings shed light on the dynamics of the transformation of wood-falls into anoxic-sulfidic environments and have implications for the fate of land-derived coarse woody debris in the marine environment.

[3]Institute for Environmental Research, Australian Nuclear Science and Technology Organisation, Lucas Heights, Australia, fink@ansto.gov.au; richard.collins@unsw.edu.au

The conversion of coastal lowland sulfidic sediments for agricultural activities has been a common practice and has caused substantial acidification and degradation of adjacent estuarine water quality and ecosystems in Eastern Australia, and other areas worldwide [1].

The geochemistry of Al in acid sulfate soils (ASS) has rarely been the focus of research that has been published to date despite the abundance of this metal in released waters. Reactive, or, exchangeable Al can easily be sorbed/desorbed from soil mineral surfaces. Hence, the study of this pool of Al represents an opportunity to identify some release mechanisms and a more appropriate method to estimate Al likely to be released from ASS.

Extractants were chosen to isolate the exchangeable pool of Al in 30 soil samples from the Tweed Shire in north-eastern NSW, Australia: 1M KCl ($Al_{KCl\ ext}$), 0.2 M $CuCl_2$ ($Al_{CuCl2\ ext}$) and isotope exchange using ^{26}Al as a tracer (Al_{exch}) with analysis via Accelerator Mass Spectrometry (AMS). 1M KCl extraction is a standard method to determine the 'exchangeable' pool of Al and other metals [2 - 6] and is currently the recommended method for ASS. $CuCl_2$ was used for its high affinity for organic ligands [2, 3, 7] while ^{26}Al isotope exchange is a novel method than can be used to study the complex processes of aluminum storage and release [7, 8].

The results showed that the pool of Al extracted by 1M KCl was significantly lower than the isotopically exchangeable Al, especially in NOM-rich soils. Al_{CuCl2} was higher than $Al_{KCl\ ext}$ in all soils and was up to 8-fold higher in high NOM content soils, suggesting significant complexation of Al by NOM.

Therefore, the data obtained from current methods of estimation of exchangeable Al in ASS containing large amounts of NOM should be used cautiously as they will not be representative of the reactive Al likely to be released into solution and to contribute to acid generation.

Glacial-interglacial paleotemeperatures and paleohydrology in the Jourdan River Valley from clumped isotopes in fresh water snails.

SHIKMA ZAARUR[1*], MORDECHAI STEIN[2], HAGIT AFFEK[1]

[1]Yale University, Geology and Geophysics , New Haven, USA shikma.zaarur@yale.edu (* presenting author), hagit.affek@yale.edu

[2]Geological Survey of Israel, Jerusalem, Israel, motistein@gsi.gov.il

Oxygen isotope composition of carbonate minerals is the most popular proxy in paleo-climate research and is especially common in the marine environment; however, since implementation of $\delta^{18}O$ records for reconstruction of environmental temperatures requires an independent estimate of paleo-water composition, it is difficult to interpret this proxy in terrestrial records. Carbonate clumped isotopes thermometry is based on the relationship of ^{13}C-^{18}O bond abundance in the carbonate lattice (measured as Δ_{47}) with the carbonate formation temperature. Most marine biogenic carbonates are consistent with the laboratory precipitation experiments that are used as calibration for the clumped isotopes thermometer.

We examine Δ_{47} in fresh water snails, focusing on *Melanopsis* snails that were collected in various water-bodies along the Jordan Rift Valley (Israel). The modern samples cover a range of ~10°C. As in marine biogenic carbonates, the temperatures derived from clumped isotopes in these modern shells are consistent with the water temperatures. Measured oxygen isotopic compositions of sampled water-bodies broadly agrees with $\delta^{18}O_{water}$ values calculated from clumped isotope temperatures and living-shell $\delta^{18}O$. This suggests that clumped isotopes in *Melanopsis* shells, as in marine organisms, reflect isotopic equilibrium and agree with the same clumped isotopes thermometer calibration.

We further analysed fossil *Melanopsis* snails collected in the Northern Jordan Valley and at sites near the modern-day northern and the southern banks of the Sea of Galilee. Our samples ages range from MIS 3 to Late-Holocene. We find fairly constant temperatures during the glacial period with low temperatures and $\delta^{18}O_{water}$. Post-glacial temperature increase to a peak in Mid-Holocene, followed by a decrease to intermediate modern values. River and lake water temperatures are generally warmer than estimated Mediterranean Sea surface temperatures [1]. Mid-Holocene Jordan River and northern Sea of Galilee water are ^{18}O-enriched by ~2‰ relative to both the LGM and modern values, and southern Sea of Galilee waters are highly enriched.

This enrichment is opposite to the depletion glacial-interglacial trend observed in other regional records such as Dead Sea sediments, Soreq cave speleothems, and Mediterranean Sea foraminifera. It is likely to reflect a change in the hydrological balance, mainly in the contribution of snow-melt to the Jordan River. The difference between the northern and southern Sea of Galilee sites are likely to reflect a change in lake evaporation following the partitioning of the glacial Lake Lisan into 2 basins with the difference observed between Southern Sea of Galilee and Northern Jordan River Valley reflecting the hydrological evolution of the northern basin through the Holocene.

Silica-stabilized actinide(IV) colloids at near-neutral pH

H. ZÄNKER[1*], S. WEISS[1], C. HENNIG[1], I. DREISSIG[1]

[1]Helmholtz-Zentrum Dressden-Rossendorf, Institute of Resource Ecology, P.O. Box 51 01 19, D-1314 Dresden, Germany (*presenting author, h.zaenker@hzdr.de)

Due to their low solubility, tetravalent actinides, An(IV), are usually assumed to be immobile in natural waters. However, it is also well known that insoluble precipitation products can be mobile if they occur as colloids. For An(IV) oxyhydroxides this phenomenon has thoroughly been studied [1]. Here we describe the formation of a new type of An(IV) colloids [2].

Evidence is provided that uranium(IV) and Th(IV) can form silicate-containing colloids in near-neutral solutions containing background chemicals of geogenic nature (carbonate, silicate, sodium ions). These particles remain stable in aqueous suspension over years. A concentration of up to 10^{-3} M of colloid-borne An(IV) was observed which is a concentration significantly higher than the concentrations of truly dissolved or colloidally suspended waterborne An(IV) species hitherto reported for the near-neutral pH range. The prevailing size of the particles is below 20 nm. The higher the silicate concentration and the pH, the smaller (and obviously the more stable) are the particles that are formed (however, silicate at the concentrations tested does not form particles in the absence of the actinides). Electrostatic repulsion due to a negative zeta potential caused by the silicate stabilizes the nanoparticles. The isoelectric point of the nanoparticles is shifted toward lower pH values by the silicate. The mechanism of colloidal stabilization can be regarded as "sequestration" by silicate, a phenomenon well known from trivalent heavy metal ions such as iron(III) [3] or curium(III) [4], but never reported for tetravalent actinides so far. U-O-Si bonds, which increasingly replace the U-O-U bonds of the amorphous uranium(IV) oxyhydroxide with increasing silicate concentrations, make up the internal structure of the colloids. The next-neighbor coordination of U(IV) in the U(IV)-silica colloids is comparable with that of coffinite, $USiO_4$.

The assessment of actinide behavior in the aquatic environment should take the possible existence of An(IV)-silica colloids into consideration. Their occurrence might influence actinide migration in anoxic waters.

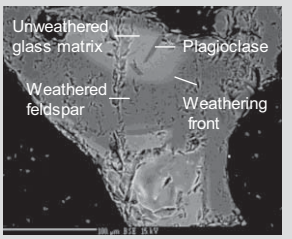
[2] University of Arizona, Soil Water and Environmental Science chorover@cals.arizona.edu, perdrial@email.arizona.edu, jnperdri@email.arizona.edu, rmaier@ag.arizona.edu

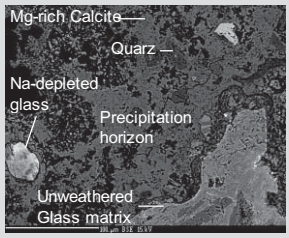
Weathering of rock primary minerals is among the first biogeochemical events that dictates the availability of major and micro elements for wider ecosystem and ultimately shapes landscape structure and its evolution [1]. This is also the focus of two multi-annual, different scale experiments initiated at Biosphere-2, University of Arizona, i.e. 'Bio-weathering experiment' and 'Landscape Evolution Observatory'. Basalt, one of the major crustal renewal rocks on Earth, has been chosen as test rock in both studies.

In order to predict incipient mineralogical changes and element cycling during the experiments, and hence provide a link to natural setting, we examined basalt weathering progression at microscale from a total of 20 surface and subsurface samples collected on the external slopes of Merriam volcano at Flagstaff, N. Arizona. Samples representing both, unweathered and weathered granular basalt were subjected to electron microprobe and synchrotron-based XRD.

The analyses discriminated two major mineral transformation events. The presence of a weathering front inside grain structure



A



B

Figure 1: Microprobe results showing (A) weathering front and (B) surface grain precipitation in Flagstaff basalt

(Fig. 1A) is indicative of preferential weathering and shows loss of primary ions of Ca, Na, Mg and P from both, amorphous glass matrix and embeded crystaline minerals.

Secondly, there is evidence of low-temperature secondary phase precipitation onto primary mineral surfaces with major elements incorporating into various hydrous minerals including Mg-Al silicates, Mg and Mg-P rich calcites, Si-P calcite and quartz (Fig. 1B). The results and field assessment are consistent with large scale dissolution of glass and feldspars starting at crater top, followed by reprecipitation as Ca and Si-rich phases (often evaporites) in areas where subsurface flow at mountain base is shallow.

The effects of magma composition on the genesis of magmatic-hydrothermal ore deposits

ZOLTAN ZAJACZ[1*], PHILIP CANDELA[2], PHILIP PICCOLI[2] AND CARMEN-SANCHEZ VALLE[1]

[1]ETH Zürich, Zürich, Switzerland, zoltan.zajacz@erdw.ethz.ch (* presenting author)

[2]University of Maryland, College Park, USA, candela@umd.edu

The composition of magmas significantly affects the likelyhood of the formation of various magmatic-hydrothermal ore deposits. Understanding the distribution of economically important metals and their key ligands (S and Cl) between the liquid, solid and volatile phases in the system is of prime importance for the prediction of the efficiency of their sequestration from evolving magmas.

We conducted experiments to investigate the solubilities and partitioning of Au, Cu, Mo, S and Cl as a function of silicate melt composition, oxygen fugacity and temperature. Gold shows the lowest affinity to dissolve in oxide matrices and its solubility is primarily controlled by reduced S-species both in magmatic volatiles and silicate melts. The efficiency of the complexation of Au by S in the latter phases is furhter increased by increasing alkali metal and chloride activities. Estimated volatile/melt partition coefficients of Au suggest that it can be extracted efficiently by magmatic volatiles from mafic to intermediate magmas in early stages of magmatic evolution.

Copper shows a much lower affinity to complex with sulfur both in the volatile phase and the silicate melt. In most magmatic volatiles, Cu-chloride complexes are predicted to be dominant, with the exception of sulfur-rich alkaline magmas. In silicate melts, Cu dissolves into the oxide matrix and its solubility is only moderately increased by the presence of S and Cl in concentrations typical of natural systems. Both increasing degree of polymerization, and decreasing temperature reduce Cu solubilities in silicate melts; however, the effect of temperature is greater. As temperature shows the opposite effect on Cu solubility in magmatic volatiles and pyrrhotite relative to the melt, it is likely that the Cu budget of evolving magmas shifts in favour of these phases. The extraction of Cu by magmatic volatiles may be prevented if the magma evolves in the sulfide stability field ($\log f O_2 < NNO+0.5$) and the sulfides get entrapped in crystallizing minerals, or are otherwise left at deeper levels, preventing their later resorption due to S loss from the system during degassing. As opposed to Au, the extraction of Cu by exsolving volatiles will only be efficient from evolved magmas. Thus, input of volatiles originating from mafic magmas into the hydrothermal fluids will only promote porphyry Cu deposit formation through addition of S. Such volatiles will increase the Au/Cu ratio of the forming ore deposit in relatively reduced systems ($\log f O_2 < NNO+0.5$).

Molybdenum dissolves as an oxide species, and partitions in favor of andesite melts independent of S and Cl concentrations in the volatile phase within the compositional range realistic for natural systems. It is likely that higher volatile/melt partition coefficents of Mo previously observed in felsic systems is due to the reduced solubility of Mo in polymerized melts. Therefore, efficient Mo extraction is most likely from highly evolved felsic magmas.

Methods for quantifying methane fluxes during shale hydraulic fracturing

RASA ZALAKEVICIUTE[1], JED P. SPARKS[1*], ROBERT HOWARTH[1], ANTHONY INGRAFFEA[1], ROXANNE MARINO[1]

[1]Cornell University, Ithaca, NY, U.S.A., jps66@cornel.edu*

The U.S. Department of Energy currently predicts an increase of ~75% by 2035 of the total domestic production of natural gas from unconventional sources [1]. One of the unconventional methods used to an ever-increasing degree is shale gas extraction, using hydraulic fracturing and vertical drilling. However, this process is highly uncertain in terms of the magnitude of methane loss to the atmosphere during well production, storage, and transport. Methane has a significant global warming potential and a need exists to quantify the amount of fugitive gas loss during the lifetime of well operation.

We outline the current measurement techniques that could be employed to assess methane fluxes associated with hydraulic fracturing. These techniques include ground-based eddy covariance (EC) flux systems (e.g., the LI-COR 7700 open-path methane gas analyzer). EC is a continuous, fast in situ measurement technique, providing net flux of an atmospheric component at thirty-minute resolution. It can be used from a variety of platforms including tall towers and tethered balloons offering variable flux footprints depending upon implementation. Other methods include airborne platforms using small to medium size aircraft providing very large footprint and robust flux measurements. Advantages and drawbacks exist for each method depending upon the scale of measurement. Identification of methane sources is usually not possible from most flux measurements unless isotopic measurements are made in parallel. Advances in cavity ring-down spectroscopy have made isotopic measurements fast and reliable and reasonably deployable on multiple platforms including aircraft. Here we present recommendations for future measurement and assessment of fugitive methane associated with hydraulic fracturing of shale.

Non-traditional isotope variations at Cedar Butte volcano; insight into magmatic differentiation

T. ZAMBARDI[1*], X.-X. LI[1], C.C. LUNDSTROM[1]

C. HOLMDEN[2] AND M. MCCURRY[3]

[1]Dpt. of Geology, Univ. of Illinois Urbana-Champaign, IL, USA.
[2]Dpt. of Geological Sciences, Univ. of Saskatchewan, Canada.
[3]Dpt. Of Geology, Univ. of Idaho, ID, USA.

Cedar Butte (ID, USA) is a silicic volcano in the mainly basaltic Eastern Snake River Plain that produced a compositionally zoned rhyolite to basaltic andesite eruption sequence at ~400 ka. This study aims to investigate the stable isotopic compositions of Ca and Fe for selected samples from the Cedar Butte magmatic suite. Previous work shows the suite follows expectations of fractional crystallization. Despite the limited isotopic fractionations expected from non-traditional stable isotope systems in high-temperature contexts, current mass-spectrometry methods allows us to resolve significant, albeit small, isotopic variations. These tools should help us to both track and better understand differentiation mechanisms related to rock petrogenesis.

Fe isotope ratios were measured using a Nu plasma HR MC-ICP-MS (Nu Instrument, Inc.) in dry plasma mode using the sample-standard bracketing method. Results are expressed as permil δ^{57}Fe values relative to the IRMM-14 isotopic reference material. Ca isotope ratios were measured using a double spike method on a TIMS (Finnigan Triton). Calcium data are expressed as δ^{44}Ca relative to SRM915a reference material. Long-term external reproducibilities are 0.1‰ and 0.07‰ (2SD) for δ^{57}Fe and δ^{44}Ca, respectively.

Total δ^{57}Fe variations in this study range from 0.10‰ to 0.62‰, and correlate with SiO_2 content as observed previously [e.g., 1, 2, 3]. Samples from basaltic to andesitic compositions do not exhibit significant δ^{57}Fe variations (from 0.10‰ to 0.19‰), whereas samples from andesitic to rhyolitic compositions show a positive correlation leading to a 0.5‰ increase of δ^{57}Fe in the most differentiated materials. Ca isotopes do not display as clear a correlation as Fe, although the most differentiated samples also tend to enrich in heavy isotopes. Total δ^{44}Ca variations range from -1.41‰ to -0.86‰, with the exception of one Ca-rich rhyolite that displays an extremely negative – and reproducible – δ^{44}Ca = -2.5‰. This sample however did not yield a comparably shifted δ^{57}Fe value. These results thus underline the ability of multiple stable isotope data to identify multiple sources and selective processes affecting the overall differentiation process. Additional information may be provided by measurements of other stable isotopes systems such as Si and Mg.

We assess 4 possible processes for explaining the isotope-differentiation relationship: 1) fractional crystallization [2]; 2) thermal migration [4]; fluid/rock interactions [1, 3], and/or partial melting/assimilation of preexisting crustal materials.

[3]University of Illinois at Chicago, Chicago USA.

Introduction

Subcontinuum approaches based on first-principles theory have been successfully applied to a variety of condensed matter problems in the past, including reactivity of glass and mineral surfaces with water, to develop understanding of reaction mechanisms at the atomic scale and provide estimates of reaction rates. To develop atomistic-informed constitutive models for the dissolution rate, we chose to study a well-characterized crystalline aluminosilicate – orthoclase - as initial model system. Time resolved X-ray reflectivity was previously used to obtain the face-specific dissolution rates of orthoclase (001) surfaces under a wide range of pH and temperature conditions.[1] By studying elementary reactions of water and ions on orthoclase using first-principles methods, and combining these studies with Kinetic Monte Carlo (KMC) simulations, our goal is to develop fundamental models to understand the observed experimental dependence of dissolution rates on pH and temperature.

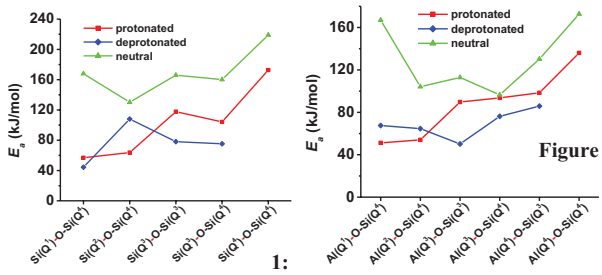

Figure 1: Calculated activation energies for different sites on the orthoclase (001) surface.

Results and Conclusion

We have performed first-principles-based modelling of surface site distribution as a function of pH and temperature on orthoclase surfaces of two different orientations (001) and (010). Differences in the surface species distribution are found for the two surfaces, suggesting different initial dissolution behavior. To evaluate reaction pathways, we have performed first-principles calculations of reaction barriers for water reactions with neutral, protonated and deprotonated sites of constituting network formers Si and Al (Fig. 1). The calculated reaction barriers together with the surface site distribution model are used to estimate the overall dissolution rates and compare with experimental values.[1] Kinetic Monte Carlo studies were used to validate a phenomenological constitutive model. This work is aimed at better understanding of the dissolution behavior and development of predictive models for dissolution rates.

In situ monitoring of lepidocrocite bio-reduction and magnetite formation by backscattering Mössbauer spectroscopy

ZEGEYE ASFAW*, ABDELMOULA MUSTAPHA, AND RUBY CHRISTIAN.

University of Lorraine LCPME UMR 7564 CNRS –, Jean Barriol Institute, 405 rue de Vandoeuvre, 54600 Villers-lès-Nancy, France (*correspondence: asfaw.zegeye@lcpme.cnrs-nancy.fr)

Magnetite, a mixed valence Fe(II-III) oxide ($Fe_{3-\delta}O_4$), is a commonly occurring mineral on Earth usually found in soils and sediments. Depending on the geochemical environments in which Fe(III) bio-reduction takes place, dissimilatory iron reducing bacteria (DIRB) activity can lead to diverse biogenic minerals such as magnetite. Consequently, the discovery of magnetite at depth of 6.7 km in subsurface has been used as a marker of DIRB activity [1-2]. Moreover, the quantity of extracellular magnetite induced by DIRB could be several thousand times more than magnetotactic bacteria do per unit of biomass [3-4]. Whereas, many reports have focused on magnetite precipitated by magnetotactic bacteria, very few studies have been able to demonstrate the unequivocal existence of extracellularly precipitated magnetite. This discrepancy could be explained by the higher reactivity of magnetite formed by DIRB [5]. Indeed, the reactivity and stability of magnetite is dictated partly by its stoichiometry. It was shown that stoichiometric magnetite had the lowest reduction potential in comparison with a non-stoichiometric magnetite, consistent with higher reactivity toward pollutants such as nitrobenzene compounds [6].

The miniaturized Mössbauer spectrometer (MIMOS II) was used to monitor *in situ* the mineralogical transformation of lepidocrocite (γ-FeOOH) in *Shewanella putrefaciens* CIP 8040 culture under anaerobic condition using methanoate as the electron source. Magnetite ($Fe_{3-\delta}O_4$) was the only biogenic mineral formed during the course of the incubation. The analysis of the biogenic mineral by transmission electron microscopy (TEM) revealed cube-shaped crystals with a relatively homogeneous grain size of about 50 nm. After one day of incubation, the departure from stoichiometry δ of the biogenerated magnetite was very low (δ ~ 0.025) and rapidly reached values close to zero indicating the precipitation of a stoichiometric magnetite. The experimental setup used in this study could be replicated in field experiments when assessing the formation of magnetite in modern geological settings when its formation is suspected to be caused by a strong bacterial activity.

rstern@ualberta.ca

In this study we present new results of detailed investigation on zircon populations from several granitoids of Swaziland, which comprises the oldest crust of the Kaapvaal Craton with intrusion ages between 3.66 and 2.70 Ga. Zircons from all granitoids show significant internal variations with respect to their U-Pb ages, REE patterns, and $\delta^{18}O$ (VSMOW) – far beyond analytical uncertainties, but show within error identical initial $^{176}Hf/^{177}Hf$ isotope compositions. These patterns are most pronounced for the oldest granitoids from Swaziland, comprising the 3.66 Ga TTG gneisses from Piggs peak. CL/BSE images reveal clear core-rim relationships for most zircons, but also zircons with complex zoning related to several stages of alteration. Pb-Pb ages of the "magmatic" zircon cores scatter between 3.65 to 3.26 Ga, Th/U = 0.32 to 1.12, $\delta^{18}O$ = 5.4 to 3.4‰. Furthermore, they show steep to moderate chondrite normalized LREE-patterns with a positive slope (La/Sm_N=0.002 to 0.09). In contrast, the "metamorphic" rims commonly show diffuse zoning patterns in CL, and lower Pb-Pb ages (3.28 to 3.20 Ga), Th/U (0.01 to 0.3) and $\delta^{18}O$ (1.3 to 1.7‰), and a negative slopes in LREE patterns (La/Sm_N = 2.8-3.5). Despite these differences, the analyses of all domains yielded identical initial $^{176}Hf/^{177}Hf$ of 0.28040 ± 0.00004 (2 SD). This indicates that all zircon domains (core, rims, alteration zones) were initially formed during magma crystallisation at ca. 3.66 Ga, and that the different domains were differently affected by subsequent alteration processes, causing a reset of the U-Th-Pb system, and dramatic changes of the REE patterns and $\delta^{18}O$, but left the hafnium isotope system unaffected. The low $\delta^{18}O$ of the zircon rims + altered domains (1.5‰) indicate that they probably formed by interaction with hot meteoric water. This interpretation is consistent with the strongly elevated LREE contents. These hydrothermal fluids obviously also altered some of the magmatic cores (5.3-4.1‰), even such which still look pristine in CL images and with concordant U-Pb ages! This observation has clear consequences for the interpretation of the Hadean/Early Archean detrital zircons.

The role of water in the petrogenesis of arc magmas from SW Japan

Thermometry and hygrometry in SW Japan arc volcanics

We have studied mafic melts from the volcanic centres of Kirishima, Aso, Kuju, Yufu, and Oninomi in Kyushu, and Abu, Menkame, Daisen and Kannabe in Western Honshu. We present results from pyroxene thermometry, 2-pyroxene thermobarometry, and plagioclase hygrometry, extending our published dataset from this region [1]. We show that initial magma water contents vary coherently along the arc, dropping from about 5wt% in Kyushu to about 2wt% in Western Honshu. Water appears to control (a) the average ponding depth of magmas at a given temperature, (b) the equilibrium phase assembleage during lower crustal differentiation and therefore the geochemical evolution of mafic melts towards intermediate (andesitic and adakitic) compositions [1].

SIMS determination of hydrogen in volcanic olivines

To determine H_2O variations directly, we have attempted to measure hydrogen in olivine by SIMS, because melt inclusions in magnesian olivines from this area are generally too small for analysis. Hydrogen concentrations are ubiquitously low (typically < 20 ppm), and in contrast to plagioclase hygrometry data do not vary coherently along the SW Japan arc (Fig. 1). Crystallization modeling suggests that olivine only becomes stable at upper crustal pressures (< 5 kbar) in these magmas, which at that stage all may already have experienced some degassing. We conclude that plagioclase is more suitable than olivine in determining the H_2O content of parental arc magmas, even if olivine melt inclusions are available.

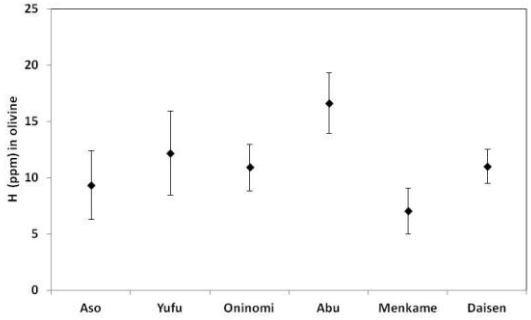

Figure 1: Summary of hydrogen concentrations in volcanic olivines from SW Japan, n ~ 10 for each center.

[3]Development & Comprehensive Utilization of Marine Sedimentary Brine Sichuan Provincial Key Laboratory, Chengdu, 611530, P. R. China
(* correspondence: zengyster@gmail.com)

Besides salt lake brine, underground brine is another kind of important liquid mineral resource. Pingluoba underground brine, located in the west of Sichuan basin, is famous for its high concentration of sodium, potassium, lithium, borate, and rubidium. The potassium reserves of Pingluoba underground brine is about 4.55 million ton. The exploitation of this brine can reduce the burden of potassium requirement in China.

The Pingluoba underground brine belongs to a marine sedimentary deep brine, with distinguishing features of deep buried depth (over 4500 m), high pressure (about 97 MPa), high temperature (about 393 K), and high salinity (over 420 g/L). [1] The hydrochemistry of Pingluoba underground brine is a chloride type and the main component of the brine can be simplified as the complex system $Li^+ + K^+ + Rb^+ + Mg^{2+} + Cl^- +$ borate $+ H_2O$. In this six-component system, magnesium chloride can form various hydrate salts and a solid solution can be easily formed between potassium and rubidium in chloride solution.

To exploit brine resources, the studies on the phase equilibria about the water-salt system at multi-temperature are necessary. Up to now, a series of researches about the metastable phase equilibria of the salt – water system enriched with potassium focused on Pingluoba underground brine have been done at 298 K, 323 K, 348 K by our research group.[2-6] These research results give us good information about the crystalloid forms, crystallization zones, and crystallization order of different salts, which are useful for the exploiting of brine. Neverless, most of the exiting research focused on the ternary and quaternary subsystems, the results are not enough for the comprehensive utilization of the brine, the investigation about the more complex system are necessary.

Saline springs in the Canadian high Arctic where water flows perennially at constant temperatures, despite the presence of deep (>400 m) permafrost, are being studied as possible environments for the development of bacterial life as an analogue for similar situations in other planets. Most documented spring activity occurs marginal to large evaporite diapirs (e.g. salt domes), and have been interpreted to represent recent phenomena related to deglaciation [1].

A relict of an ancient precursor of the active springs was found in 2005 on a steep west flank eroded by White Glacier (WG) at Expedition Fiord, Axel Heiberg Island (79.44˚N; 90.70˚W; 350 m.a.s.l.). A network of veins, mineralized fractures, layered masses and breccias is exposed across an area of ca. 350 x 50 m, where the host rock is brecciated dolomitic limestone and sandstone, anhydrite-gypsum, and intrusive igneous rocks (altered basalt). Mineralization consists of calcite in acicular, radial aggregates lining fractures and cavities, with textures wholly reminiscent of brownish calcite in active springs at Colour Peak, only 13.7 km southwest of this site. Iceland spar calcite fills the centre of larger cavities. Abundant crystalline Fe sulfides (FeS_2 marcasite, pyrite) occur in the veins and as alteration of basalt. Quartz occurs in some veins, and epidote and chlorite rim some veins where the host rock is igneous.

Fluid inclusions in calcite (5-10 μm) have salinities that fall into two distinct groups: one very low, ca. 1.5 and another ca. 16 NaCl wt% equivalent. Inclusions that occupy growth zones in some of the coarser acicular calcite crystals and deemed primary, have T_h ranging from 100˚C to 300˚C (n = 26, average 207˚C; independent of salinity), hence orders of magnitude higher than the average ca. 6˚C [2] of the brines in the active springs. Despite the similarities of the WG site with perennial springs at nearby Colour Peak [2], these results cannot be explained by models invoking shallow circulation of fluids related to deglaciation [e.g. 1]. We propose a model by which deeply-circulating hot basinal fluids associated with evaporite structures mixed with low-salinity surficial waters, in recurrent pulses. Low-temperature thermochronology (apatite fission tracks) indicates that the rocks now exposed at the surface at WG were at several km depth and temperatures of ca. 100°C until ca. 10 Ma, thus compatible with long-lasting circulation of warm fluids well before the Quaternary and ample opportunity for microbial colonization.

Photochemical models of the evolution of atmospheric redox on the early Earth suggest that a collapse in reductants (e.g., methane) was equally important to (if not required for) the rise in O_2 associated with the GOE [e.g., 1]. We present geochemical records directly linking changes in atmospheric chemistry with periodic increases in methane concentrations in the Neoarchean atmosphere. We have generated a multi-proxy dataset of ocean and atmospheric redox from sediments deposited on the Campbellrand-Malmani platform of South Africa from ~2.65-2.5 Ga, on the run-up to the GOE. Trends in Fe speciation and major sulfur isotope ratios ($\delta^{34}S_{pyrite}$) provide evidence for oxygen production in microbial mats and localized oxygenation of surface waters. At the same time, minor sulfur isotope values ($\Delta^{33}S$ and $\Delta^{36}S$) preserve mass-independent fractionations (S-MIF) indicative of a reducing atmosphere. Most significantly, changes in the character of S-MIF signals occur in several distinct sedimentary intervals correlated with areas of highly ^{13}C-depleted organic matter. These correlations extend to other datasets, implying a global trend between methane in the biosphere and variations in atmospheric S-MIF signals. We hypothesize that these signals record the periodic formation of a hydrocarbon haze at high CH_4:CO_2 ratios [e.g., 2], which could have altered S-MIF signals, either through shielding or by changing the redox chemistry of S species in the atmosphere. These results suggest that carbon-bearing compounds played an important role in regulating the redox state of the Neoarchean atmosphere, and support arguments that the GOE would have required (and/or could have been caused by) a concommital decrease in the biological flux of methane.

Volumetric properties of KCl-NaCl and $CaCl_2$-NaCl binary aqueous solutions at elevated temperatures and pressures

D. ZEZIN*, T. DRIESNER, AND C. SANCHEZ-VALLE

Institute of Geochemistry and Petrology, ETH Zurich, Clausiusstrasse 25, 8092 Zurich, Switzerland denis.zezin@erdw.ethz.ch (*presenting author), thomas.driesner@erdw.ethz.ch, carmen.sanchez@erdw.ethz.ch

Modeling and understanding of geochemical processes involving aqueous fluids requires knowledge of thermodynamic properties of such solutions. Aqueous solutions in the upper crust are typically mixtures of electrolytes, thus the properties of an aqueous fluid cannot be approximated by a single-electrolyte model (e.g., NaCl-H_2O) accurately. The properties of multi-electrolyte mixtures are largely unstudied at elevated temperatures, and at pressures above the vapour pressure saturation curve. Namely, data on volumetric properties that would characterize the pressure-dependencies are essentially inexistent. These data are of particular importance in hydrothermal and geothermal fluid-related modeling, petroleum and geothermal reservoir engineering, processing and utilization of industrial brines and CO_2. We have undertaken a detailed study of the volumetric properties of multicomponent electrolyte solutions over a wide range of temperatures, pressures, and compositions.

This experimental study provides the volumetric properties of KCl-NaCl and $CaCl_2$-NaCl aqueous electrolyte solutions at temperatures up to 300 °C and pressures up to 400 bar for ionic strengths up5.8 and 12 m, respectively. A vibrating-tube densimeter was used to measure the relative density of aqueous solutions containing mixtures of alkali and alkali earth chlorides. Pressure, temperature and composition dependence of the density of binary mixtures were constrained. Mean apparent molar volume of the electrolyte solutions were calculated from the experimental data. A model based on a Pitzer-type equation was used to approximate the apparent molar volume of solutions and evaluate the partial molar volumes of dissolved components. The latter were compared to other mixing models predicting the properties of mixture of electrolytes from the properties of pure end-member electrolyte solutions.

The pressure- and concentration- dependence of the apparent molar volume may also provide important information about the structure of a solution and ionic interactions occurring in aqueous liquids. The pressure dependence of activity coefficients of dissolved components can be revealed from the variable pressure series of density measurements. Ultimately, the results of this study will permit a quantitative modeling of the properties of complex aqueous solutions and simulation of fluid-rock interaction processes occurring in geochemically relevant systems.

Kinetics of phosphate adsorption on goethite in seawater

JIA-ZHONG ZHANG *, AND CHARLES FISCHER

Ocean Chemistry Division, Atlantic Oceanographic and Meteorological Laboratory, National Oceanic and Atmospheric Administration, Miami, Florida 33149, USA
jia-zhong.zhang@noaa.gov (* presenting author)

The adsorption kinetics of phosphate on goethite was studied at low concentrations of both adsorbent and adsorbate to adequately measure the initial rate of decreasing phosphate concentration in solution. Phosphate sortion desplayed a two-step process. A rapid decrease in phosphate concentration was observed during the first few minutes, which was followed by a slow decrease over hours and days. Batch experimental data were fitted with a model of film-diffusion at particle-water interface for the fast process and a intra-particle/pore diffusion model for the slow process.

Batch adsorption experiments were performed at different concentrations of goethite and phosphate, as well as a range of temperatures and salinities in pH 7.9 seawater. The rate of adsorption increased with increasing concentrations of either goethite or initial phosphate concentration. At a given goethite and phosphate concentrations, the rate of adsorption increased linearly with increasing temperature from 5 to 45°C. The rate of adsorption also increased with decreasing salinity from 36 to 18 A more rapid increase was observed at salinities below 18.

Phosphate adsorption rates were similar both in seawater and artificial seawater. Comparison of rates in different seasalt solutions was used to reveal the effect of individual ions on the adsorption rate. The rate decreased exponentially with an increasing bicarbonate concentration at a constant pH 7.9. At seawater pH and total dissolved inorganic carbon concentration (2mM), the rates were constant in NaCl solution with concentrations ranging from 0.1-0.7M. This suggests that the initial rate is independent of ionic strength. The addition of SO_4^{2-} to the NaCl solution decreased the rate. In contrast, the rate was increased with the addition of Ca^{2+} or Mg^{2+} to the NaCl solution. Adding Ca^{2+}, Mg^{2+} and SO_4^{2-} together at the seawater ratio diminished the acceleration effects of Ca^{2+} or Mg^{2+}. This is likely due to the formation of ion pairs of $CaSO_4$ and $MgSO_4$ which reduced the free ion concentrations. For anions in seawater, the capacity for rate reduction was in an order of $HCO_3^- > SO_4^{2-} > Cl^-$. For cations, the order for capacity of rate acceleration was $Ca^{2+} > Mg^{2+} > Na^+$.

In-situ determination of crystal structure of $(Mg,Fe)SiO_3$

LI ZHANG[1*], WENGE YANG[2], YUE MENG[3], LIN WANG[2], QIAO-SHI ZENG[4], WENDY L. MAO[4,5] AND HO-KWANG MAO[1]

[5]Photon Science and Stanford Institute for Materials and Energy Sciences, SLAC National Accelerator Laboratory, Menlo Park, USA

$(Mg,Fe)SiO_3$ silicate is believed to be the principal mineral in Earth's lower mantle. Precise measurements of structural transitions and associated changes in composition of $(Mg,Fe)SiO_3$ at the high pressure (P) and temperature (T) conditions within Earth's lower mantle are required to interpret the seismic observations.

The $(Mg_{1-x},Fe_x)SiO_3$ (x=0.15 and 0.4) orthopyroxene starting materials were compressed to 60-130 GPa in separate symmetric diamond anvil cells and heated by the double-sided YLF laser system at the beamline 16 ID-B of the Advanced Photon Source (APS), Argonne National Laboratory (ANL). The crystal structure of the $(Mg_{1-x},Fe_x)SiO_3$ phase was studied as a function of pressure and temperature, in comparison with the known *Pbnm* orthorhombic structure. The structural details of the micron-size $(Mg,Fe)SiO_3$ crystals at high pressure were determined by the combined *in-situ* powder X-ray diffraction (XRD) and single-crystal XRD techniques. The unit-cell parameters were obtained from powder XRD measurements. The orientation matrix of individual micron-size crystal was determined in a polycrystalline sample with a focused 5×10 μm monochromatic X-ray beam. All possible reflections were then predicted with tuning diffraction angle and intensity of each reflection was measured for structure solution.

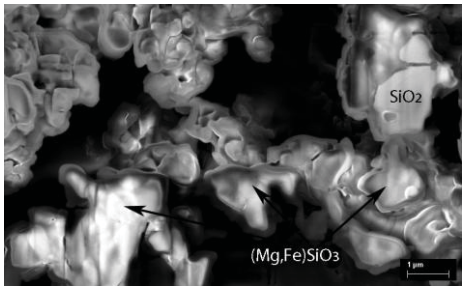

Figure 1: Cross-section of recovered $(Mg,Fe)SiO_3$ and SiO_2 in $(Mg_{0.6},Fe_{0.4})SiO_3$ from 85 GPa and 2500 K in Neon media.

The recovered samples were prepared by FIB (focused ion beam) for chemical analysis. $(Mg,Fe)SiO_3$, (Mg,Fe)O, SiO_2 and metallic Fe were selectively present in the recovered product, depending on temperature profile and starting composition.

The structural information of $(Mg,Fe)SiO_3$ silicate and associated changes in chemical composition at high *P-T* conditions is used to build a reliable mineralogical model for the lower mantle in consistent with the seismic observations.

Smart surfaces with switchable superoleophilicity and superoleophobicity in aqueous media: toward controllable oil/water separation

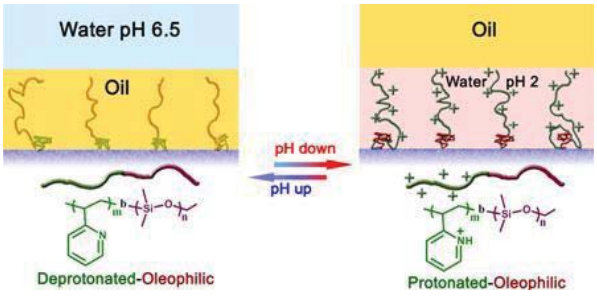
LIANBIN ZHANG[1], ZHONGHAI ZHANG[1], PEN GWANG[1,*]

[1]Chemical and Life Sciences and Engineering Division, Water Desalination and Reuse Center (WDRC), King Abdullah University of Science and Technology (KAUST), Thuwal 23955-6900, Saudi Arabia, lianbin.zhang@kaust.edu.sa, zhonghai.zhang@kaust.edu.sa, peng.wang@kaust.edu.sa (* presenting author)

Abstract

Advanced materials with surfaces that have controllable oil wettability when submerged in aqueous media have great potential for various underwater applications. Here, we have developed smart surfaces on commonly used materials, including non-woven textiles and polyurethane sponges, that are able to switch between superoleophilicity and superoleophobicity in aqueous media. The smart surfaces are obtained by grafting a block copolymer comprising blocks of pH-responsive poly(2-vinylpyridine) and oleophilic/hydrophobic polydimethylsiloxane (i.e., P2VP-*b*-PDMS) on these materials. The P2VP block can alter its wettability and its conformation via protonation and deprotonation in response to the pH of aqueous media, which provides controllable and switchable access of oil by the PDMS block, resulting in the switchable surface oil wettability in aqueous media. On the other hand, the high flexibility of the PDMS block facilitates the reversible switching of the surface oil wettability. As a proof of concept, we also demonstrate that materials functionalized with our smart surfaces can be used for highly controllable oil/water separation processes.

Figure: Graphic abstract



Schematics showing the switchable oil wettability of the P2VP-b-PDMSgrafted surface in aqueous media with different pH.

Formation and evolution of Precambrian crust in South China: insights from the Dongling complex

SHAO-BING ZHANG, QIANG HE, YONG-FEI ZHENG

School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China (sbzhang@ustc.edu.cn)

To understand the early history of Precambrian crust in South China, a combined study of isotope geochronology and geochemistry was carried out for a Precambrian complex at Dongling, which was traditonally viewed as one of the most anicent basements in South China. The Dongling Complex is exposed at Anqing in the interior of South China and mainly composed of schist and gneiss. It is intruded by a Mesozoic granite pluton and covered by Phanerozoic strata. We analyzed whole-rock major and trace elements, zircon U-Pb and Lu-Hf isotopes, and mineral oxygen isotopes in schist and gneiss from the Dongling complex. The results provide not only temporal constraints on the deposition and metamorphism of metasedimentary protolith, but also insights into the formation and evolusuion of Precambrian crust in South China.

The whole-rock REE and trace elements in the Dongling complex show similar patterns in the spidergram to PAAS and upper continental crust. Mineral O isotope analyses obtained that most zircon $\delta^{18}O$ values are higher than 6‰ and most quartze $\delta^{18}O$ values are higher than 10‰, suggesting that their sources experienced low-temperature supracrustal recycling. Zircon U-Pb dating gave three groups of Precambrian ages. The first group of ages are older than 2.4 Ga, as high as 2.8 Ga. Some of them were obtained from inherited zircon cores and others are from the detrital zircon of Archean age. The second group is about 2.0 Ga, mainly obtained from zircon without oscillatory zone. The third group is about 800 Ma and can be categorized into two subgroups at 730-780 Ma and 800-830 Ma. This group of zircon have typical oscillatory zones of magmatic origin. Zircon grains with different U-Pb ages have similar REE partition patterns but variable total REE concentrations, indicating diversity of their sources. Zircon Lu-Hf isotope compositions vary significantly for three groups of zircons. The first group has variably negative $\varepsilon_{Hf}(t)$ values. The ~2.0 Ga zircon grains have variable $\varepsilon_{Hf}(t)$ values from -19.8 to -5.6 and two-stage Hf model ages (T_{DM2}) from 2.99 to 3.81 Ga, suggesting reworking of Archaen rocks in the middle Palaeproterozoic. The ~800 Ma zircon grains have variable $\varepsilon_{Hf}(t)$ values from -24.8 to 4.9 and T_{DM2} from 1.39 to 3.18 Ga, suggesting reworking of both ancient and juvenile crustal rocks in the middle Neoproterozoic. There is a lack of positive $\varepsilon_{Hf}(t)$ values close to the depleted mantle value, suggesting that the growth of juvenile crust is not recorded in these zircon grains.

In conclusion, premetamorphic protolith of the Dongling complex was probably deposited at middle Neoproterozoic. It contains crustal relicts of Late Archean, Paleoproterozoic and Neoproterozoic, suggests crustal reworking at these times in South China.

Chlorite Dissolution Rates in scCO$_2$-Saturated Saline Water at 100°C and 100 bar

SHUO ZHANG[1,2*], LI YANG[2], DONALD J. DEPAOLO[2], AND CARL STEEFEL[2]

[1]University of California Berkeley, Earth and Planetary Science, shuozhang@berkeley.edu (* presenting author)
[2]Lawrence Berkeley National Laboratory, Earth Sciences, lyang@lbl.gov , djdepaolo@lbl.gov , cisteefel@lbl.gov

Mineralogical trapping is one of several trapping mechanisms of CO_2 for geological carbon sequestration, and presents the most secure form of CO_2 storage over millenia. Mineralization of CO_2 requires release of cations from dissolution of divalent cation-bearing silicate minerals, so the extent and timing of CO_2 mineralization depends on the mineralogy and dissolution kinetics of the sandstone reservoir rocks. There are currently few experiments that measure the coupled dissolution and precipitation rates of reactions of multi-mineral systems under the conditions of sequestration. We have experimentally measured the rate of chlorite dissolution in saline water saturated with supercritical CO_2 (pCO_2 = 100 bar) at 100ºC using a mixed flow reactor. This experiment simulates the reactive front of supercritical CO_2 and aquifer water.

Chlorite is mechanically broken to pieces in the cm-range and then ground to millimetre size. Particles from 100 to 150 micron are sieved (surface area = 4.872 m^2 g^{-1}) and washed. 1 gram of chlorite particles is used for the experiment. The reactor is filled with saline water (0.01 mol/L NaCl), and brought to experimental run temperature. Supercritical CO_2 is pumped into the reactor to 100 bar and then equilibrated with saline water at this temperature and pressure. Saline water fills 260 ml of the 300 ml reactor and forms a 40 ml CO_2 cushion above the water surface to ensure that brine is always saturated with CO_2. The reactor containing chlorite is stirred as saline water is continually pumped through.

The measured release rate of Fe and Mg is 1-2 picomole/m^2/sec, which is not far from typical silicate dissolution rates under standard laboratory conditions. Nevertheless, this rate, especially when considered in the light of relatively high surface area for chlorite, is sufficient to allow substantial CO_2 mineralization in chlorite-bearing sands on a timescale of 1000 years.

Lattice Boltzmann modelling of Stellate Plagioclase, central layered series of Isle of Rum, Scotland

Abstract

We propose a model for the formation of branching plagioclase textures visible at both macroscopic (~cm to m) and microscopic scale within melagabbro, Isle of Rum Scotland. The plagioclase crystals are typically linked as twins and form meshes of planar stellate structures (m-scale) with a large range in geometrical organization from patchy to radiating. Evidence of macroscopic crystal aggregation and alignment is attributed to interfacial free energy minimization at the microscopic scale during growth. Accordingly, a binary immiscible Lattice Boltzmann model was developed to simulate diffusion of simplified plagioclase in the melt phase. Isothermal phase transitions modelled via first order chemical reactions are subsequently coupled with stochastic dynamics at the crystal growth front to simulate energy minimization processes including twinning during crystallization in an igneous environment. A flexible coupling of the solid phase with respect to the melt phase sets the overall ratio between the rate of diffusion and chemical enrichment in the liquid state and the rate of crystallization. Results are in reasonable agreement with observations. Aspects of the model and current progress will be presented.

New Understanding of Changxing Formation reefs in Permian in eastern Sichuan area, China

Liu Zhicheng[1], Zhang Tingshan[1]*, Yang Wei[1], Ming Huajun[1], Dang Lurui[2], Zheng Chao[2],Yang Yang[3]

[1]State Key Lab. of Oil & Gas Reservoir Geology and Exploitation Engineering, Chengdu, China, zts_3@126.com (* presenting author)

[2]Chongqing Gas District of SW Oil & Gas Co., Ltd., CNPC, Chongqing, China, zhengchao@petrochina.com.cn

[3] Shunan Gas District of SW Oil & Gas Co., Ltd., CNPC, Luzhou, China, jerp@qq.com

Reefs have been reported in Changxing formation within the eastern Sichuan area, are important gas reservoirs.[1] They have been characterized by coralline sponges, including the sphinctozoans and inozoans as their framebuilder.[2] These reefs are mainly divided into platform marginal reef and patch reef in platform, with obvious different characteristics. The platform marginal reef is characterized by large scale, integrate facies belt of reef combination, strong water energy, controlled by paleogeographic location and paleogeomorphic environment, and fasciculate distribution mainly on both sides of the oceanic trough. In contrast, the patch reef in platform is characterized by small scale, weak water energy, a few reef -forming organism individual, no deposition of reef front or reef back, more cycles of the reef, development of thrombolite, inexplicit distribution regularity, controlled by paleogeomorphology, and random distribution along local highland in the platform(Figture1). Samples of reefs rock and host rock were examined using thin sections，casting sections and scanning electron microscope experiments. and the application of various analytical techniques including analysis to reservoir properties - pore structure parameters curve and pattern analysis of pore structure, reservoir characteristics of reef have been thoroughly investigated. The results revealed a very close relationship between the reservoir and reefs. The reservoir were be strictly controlled by both sedimentary microfacies and lithology. The favorable facies belt includes framework reef and bonding reef. The rock types of reservoir mainly are dolomite particles, micrite particles and the bioclastic. The reef has complex types of pores, and the reservoir space of reef including intergranular dissolution pore, large dissolution pore, dissolution pore, intragranular dissolved pore and large cavity pore. The formation of the pores are mainly affected by the cementation and dissolution with few primary pores, however, the secondary pores are abundant and form excellent reservoir for gas.

Re-Os isotopes of Chaihe mantle xenoliths constrain the age of the subcontinental lithospheric mantle in Inner Mongolia Province, China

YAN-LONG ZHANG[1,*], WEN-CHUN GE[1], CHUAN-ZHOU LIU[2]

[1] College of Earth Sciences, Jilin university, Changchun, China, zhangyanlong@jlu.edu.cn (* Presenting author)

[2] Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China, chzliu@mail.iggcas.ac.cn

Nearly 30 Cenozoic volcanoes that were erupted during the Pleistocene-Holocene have been discovered in Chaihe area, mid-Great Xing'an Range. The Holocene alkaline basalts contain abundant mantle xenoliths. The 27 samples selected in this study are composed of 11 spinel lherzolites, 8 spinel harzburgites，7 garnet lherzolites and one garnet harzburgite. The garnet is commonly kelyphited. The spinel lherzolites contain 1.36-3.52 wt.% Al_2O_3 and 1.55-3.84 wt.% CaO, whereas the harzburgites have lower contents of both Al_2O_3 and CaO, i.e. ~0.46-1.69 wt.% and ~0.36-1.32 wt.%, respectively. Clinopyroxene in the harzburgites is enriched in LREE, and displays negative Ba, Nb, Zr, Hf and Ti anomalies. Clinopyroxene in the lherzolites show variable REE patterns, such as LREE-enriched, LREE-depleted and MREE-enriched patterns. The Chaihe xenoliths have $^{187}Os/^{188}Os$ ratios ranging from 0.1106 to 0.1276. The most refractory spinel harzburgite (03Ch-10), with an olivine Fo value of 92.1, has the lowest $^{187}Os/^{188}Os$ ratios of 0.1106, which gives a rehenium depletion age (T_{RD}) of 2.6 Ga relative to the primitive upper mantle (PUM). Sr-Nd-Hf isotopes ($^{87}Sr/^{86}Sr$= 0.70665, $^{143}Nd/^{144}Nd$=0.51289, $^{176}Hf/^{177}Hf$=0.282805) of clinopyroxene in this sample is slightly more enriched than that in other samples ($^{87}Sr/^{86}Sr$= 0.70252-0.70504, $^{143}Nd/^{144}Nd$=0.51289-0.51366, $^{176}Hf/^{177}Hf$=0.283125-0.284552). This indicates the existence of ancient lithospheric mantle relics in the Chaihe region. On the other hand, the $^{187}Os/^{188}Os$ ratios are 0.12066-0.12755 in spinel lherzolites, 0.12278-0.12716 in garnet lherzolites, 0.11214-0.12359 in spinel harzburgites (except 03Ch-10), and 0.11453 in garnet harzburgite. Most of xenoliths have $^{187}Os/^{188}Os$ ratios indistinguishable from the modern convecting upper mantle [1], and their clinopyroxenes also have depleted Sr-Nd-Hf isotope compositions. Therefore, lithospheric mantle in the Chaihe region is mainly composed of juvenile mantle accreted from the asthenosphere, but with minor ancient mantle relics.

Ring Index: Towards quality-controls for the TEX_{86} paleothermometer

YI GE ZHANG* AND MARK PAGANI

Department of Geology and Geophysics, Yale University, New Haven, CT 06511, yige.zhang@yale.edu (*presenting author)

The ocean temperature proxy TEX_{86} is founded on the distribution of cyclopentane rings associated with the archaeal membrane lipids, glycerol dialkyl glycerol tetraethers (GDGTs). Because GDGTs are ubiquitous in marine sediments, TEX_{86} temperatures have been increasingly applied to a variety of marine settings from the Cretaceous through the Cenozoic. However, some TEX_{86}-derived paleotemperatures are known to substantially deviate from other proxy-based temeprature records, and appear to challenge our physical understanding of the climate system. These issues could be due, in part, to incomplete knowledge of GDGT production, transportation and preservation, or evolutionary effects that cause the TEX_{86} temperature calibration to deviate from modern relationships. Presently, there is no established criteria to determine the quality or veracity of TEX_{86} paleotemperatures.

Here we report a potential method to assess the veracity of TEX_{86} temperatures using the close relationship between Ring Index (RI, weighted average number of cyclopentane rings in GDGTs) and TEX_{86} in the modern ocean, computed from surface sediment dataset published by Kim et al., (2010) and Ho et al., (2011) [1, 2]. Correlation between RI and TEX_{86} is no surprise because TEX_{86} is based on the observation that the average number of cyclopentane rings in the GDGT pool increases with growth temperature [3]. In other words, RI and TEX_{86} will always closely correlate if the GDGT distribution is temperature dependent, although RI represents the total weighted ring average while TEX_{86} represents a subset of GDGTs using four compounds. When RI and TEX_{86} values are decoupled, it suggests that environmental signals other than temperature influence the relative adundance of GDGTs. Indeed, the modern ocean RI-TEX_{86} correlation disappears from samples associated with gas hydrates where GDGTs are derived from methanotrophic archaea [4]. Alternatively, when RI and TEX_{86} are related but their relationship deviates from the correlation expressed by modern ocean GDGT distribution, it likely implies that TEX_{86} is still reflecting temperature, but application of the modern calibration is no longer warranted and the precision of the TEX_{86} temperature is compromised.

We evaluated the RI-TEX_{86} relationship using published and unpublished data from the Cretaceous to Cenozoic and demonstrate that in sample sets where the RI-TEX_{86} relationship resembles the modern calibration, TEX_{86} appears to produce temperature estimates that are more consistent, and in better agreements with other temperature proxies. In constrast, TEX_{86}-derived temperatures often lack consistency and are less comparable to other available temperature proxies (e.g. $U^{k'}_{37}$, Mg/Ca) when the modern RI-TEX_{86} correlation fails.

Light Elements in the Core and Equilibration Degree with Silicate Mantle: Perspective from First-Principles Molecular Dynamics

YIGANG ZHANG[1], QING-ZHU YIN[2*]

[1]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, 100029, China, zhangyg@mail.iggcas.ac.cn

[2]Department of Geology, University of California, Davis, One Shields Avenue, Davis, CA 95616, USA (*presenting author) qyin@ucdavis.edu

The degree of chemical equilibration (hereafter as *Ke*), defined as the cumulative mass fraction of the metalic core in equilibrium with the silicate mantle during the Earth accretion processes, greatly influences determination of the timing of the Earth core formation [1]. If *Ke* is larger than ~0.4, Hf-W chronology implies a fast accretion in less than 30 Myr for the Earth. Otherwise, Hf-W data can only be used to constrain the *Ke* instead of timing [1]. Here we use the two-phase first-principles molecular dynamics (FPMD) [2] to constrain the solubility of light elements in liquid iron in equilibration with silicate melt at temperatures from 2500 to 4200 K, pressures from 20 to 120 GPa, and two compositions simplified from the "O-bearing" and "Si-bearing" bulk Earth model compositions of McDonough [3]. The solubility data are then used in the simulations of the many possible accretion scenarios of the Earth as outlined in [4], considering magma ocean depth, homogeneous vs heterogeneous accretion etc. For each accretion route, we calculate the effective core-mantle equilibration degree (*Ke*),

$$K_e = \sum_{i}^{N} Ke_i \times W_i$$

where Ke_i *and* W_i are the core-mantle equilibration degree and the accreted mass fraction of the i^{th} step, respectively. The successful *Ke* are selected based on the criterion that the resulting Earth's core must meet the required density deficit [5]. The *Ke* in those successful simulations are all found to be larger than 0.57, implying that the core-mantle differentiation has to occur early [1], within 30 millions years from the beginning of the solar system as originally stated [6].

Additional simulations (all at 3200 K and 40 GPa) are also made to calculate the partition coefficients of several other light elements. Combined with the bulk Earth compositions of these elements [3], it is found Si, O, and S are the major light elements in the core while C, P, Mg, H, N, and He are the minor elements in the core. We show [7] that FPMD calculations lend strong support to the classical geochemical mass balance approach in accessing light elements in the core [3]. The impact of lower carbon content to the siderophile and chalcophile element distribution in the Earth's core and mantle (e.g. core pumping of Pb) will need to be critically evaluated. And the helium partition coefficient of $\sim 10^{-2}$ makes the core a plausible source of primordial helium alternative to the undifferentiated lower mantle [8].

On diffusion in heterogeneous media

YOUXUE ZHANG[1]*, LIPING LIU[2]

[1]Dept of Earth and Environ. Sciences, Univ of Michigan, Ann Arbor, MI 48109, USA, youxue@umich.edu (* presenting author)

[2]Dept. of Mechanical & Aerospace Engineering, Dept. of Mathematics, Rutgers Univ, Piscataway, NJ 08554, USA, liu.liping@rutgers.edu

Diffusion in heterogeneous media has been investigated for over forty years. However, the derived equations for bulk (effective) diffusivity in multi-phase systems were mostly incorrect because of the use of an inappropriate similarity between diffusion and other physical properties such as thermal conductivity. The mistake has permeated through the literature and textbooks. Specifically, the role of concentration partitioning between different phases in diffusion was not considered in such similarity relations. In this work, we present the correct method to derive such relations in heterogeneous media.

Barrer [1] used the similarity between diffusivity and thermal conductivity to derive the relation between the bulk (effective) diffusivity and the individual-phase diffusivities. The approach was followed by many others [2-4]. Unfortunately the similarity approach by Barrer [1] is incorrect because there is also dissimilarity. The key difference is that, even though heat conduction and mass diffusion are characterized by a similar flux equation ($\mathbf{J}_{\text{heat}} = -k\nabla T$ for heat conduction and $\mathbf{J}_{\text{mass}} = -D\nabla C$ for diffusion), in heat conduction, T is continuous across phase boundaries, whereas in diffusion, C is usually not continuous across phase boundaries. The concentration in each phase plays a major role in controlling the contribution by the phase to the bulk diffusive flux and hence the bulk diffusivity. For example, if the concentration of a component in a phase is very low, even if the diffusivity in the phase is high, the contribution of diffusion in that phase to the bulk diffusion flux can still be negligible. Hence, previous models for diffusivity in composite materials or multi-mineral rocks, no matter how sophisticated, are fundamentally wrong because the foundation is a mistake.

Correcting the mistake is straightforward. Write the mass flux in terms of chemical potential and mobility [5]:

$$\mathbf{J}_{\text{mass}} = -M\nabla\frac{\mu}{RT},$$

where M is mobility, μ is chemical potential, R is the universal gas constant, and T is absolute temperature. Because $\mu/(RT)$ is continuous across phase boundaries, the relation between bulk mobility and individual-phase mobilities is the same as that between bulk heat conductivity and individual-phase heat conductivities. That is, all previous relations for diffusion cannot be directly applied to diffusivities, but can be applied to mobilities. Then, from the relation between diffusivity and mobility: $D_i = M_i/C_i$ (ignoring nonideality, [5,6]), where C is concentration and subscript i indicates the phase or the bulk system, the correct relations can be obtained, which will be presented.

Probing quartz (101) surface structure in water with X-ray scattering method

Z. ZHANG*[1], P. FENTER[2], AND D. J. WESOLOWSKI[3]

[1] X-ray Science Division, Argonne National Laboratory, Argonne, IL, 60439 (*correspondence: zhanzhang@anl.gov,)

[2] Chemical Sciences and Engineering, Argonne National Laboratory, Argonne, IL 60439 (fenter@anl.gov)

[3] Chemical Science Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831 (wesolowskid@ornl.gov)

Knowledge of the atomic level structures at the quartz water inteface will be a crutial component for understanding the behavior of such surface during the dissolution/precipitation processes. An earlier study probed the interfacial structure of quartz (101) and (100) surface in water along the surface normal direction [1]. Our prevoius work revealed the 3D interfacial structures at the single crystal quartz (101)–deionized water interface, including the relaxations of the atoms in the near surface region and the distribution of the interfacial water molecules [2]. In this study, a different interfacial structure was observed at the quartz (101)-water interface with high resolution surface X-ray scattering method (i.e., crystal truncation rod). This might indicate a different terminations of the surface when in contact with water. The detail structure information of quartz surface in water would be an important first step in revealing the reaction paths of the dissolution/precipitation processes when exposed to aqueous solutions at various conditions.

Mapping target area of magnetite deposits by integrating aeromagnetic data and Fe_2O_3 geochemical data

JIE ZHAO[1*], WENLEI WANG[1], QIUMING CHENG[1,2,3] AND JIANGTAO LIU[1,3]

[1]Department of Earth and Space Science and Engineering, York University, Toronto, Canada, zhaojie@yorku.ca (*presenting author)

[2]Department of Geography, York University, Toronto, Canada

[3]State Key Laboratory of Geological Processes and Mineral Resource, China University of Geosciences, Wuhan and Beijing, China

Magnetite deposit is one of the most productive iron mineralization types in Eastern Tianshan mining zone, China. Previous work on exploring magnetite deposits were mainly consulting with the aeromagnetic survey data and Fe_2O_3 concentration in stream sediment geochemical data. The former is a direct physical indicator of magnetite as well as geologic bodies with extraordinary magnetism. The later is corresponding with existence of assorted iron enrichment (e.g. hematite, magnetite, iron-polymetallic mineralization, etc.). However it is difficult to identify magnetite mineralization when relying on only one of these two datasets because none of the anomalies of these two datasets can be interpreted as unique geological event. The objective of this research is to map the potential area of magnetite deposits by integrating the aeromagnetic survey data and Fe_2O_3 geochemical data with the method of Geographically Weighted Regression (GWR).

Compared to linear regression models, GWR is more realistic to explore the non-stationarity of the coefficients across an area by assigning the independent parameters for each location in space different weights [1]. In this research the singularity [2] of aeromagnetic data and singularity of Fe_2O_3 concentration are assigned as the dependent variable and independent variable, respectively, because the lower values ($\alpha < 2$) in singularity map of Fe_2O_3 and aeromagnetic data can delineate corresponding local accumulation of iron oxide and positive aeromagnetic anomalies.

The regression result of GWR is much more convincing than of the Ordinary Least Square (OLS) by examining the R-squared values. All 3 magnetite deposits in the study area are situated within high value range of coefficient map, which is consistent with the reality that both variables present lower singularity value on the areas of magnetite deposits. However, 14 out of 15 other types of iron deposits are located in the middle and lower coefficient value ranges, which is also proved by the fact that the aeromagnetic data does not present positive anomalies of magnetism around other types of iron deposits. In conclusion, the geographically non-stationary coefficient map produced by GWR can not only differentiate magnetite deposits from other types of iron mineralization, but also delineate target areas with higher potential of magnetite mineralization.

Thermodynamic and Kinetic Effect of Organic Solvent on the Nucleation of Nesquehonite

LIANG ZHAO[1*], CHEN ZHU[1], JUNFENG JI[1], JUN CHEN[1], H. HENRY TENG[1,2]

[1]School of Earth Sciences and Engineering, Nanjing University, Nanjing, PRC, zhaoliang@nju.edu.cn (* presenting author)

[2]Department of Chemistry, the George Washington University, Washington, USA

Introduction

Magnesium carbonate has a number of naturally occurring forms. Of the half dozen phases, nesquehonite is the most commonly observed near ambient conditions while various basic species appear more often at elevated (> ~ 40 ^{o}C) temperature with low pCO_2. Despite its frequent occurrence in nature, nequehonite has not attracted significant attention from scientific communities until recently due to the potential of magnesium in sequestering anthropogenic CO_2. The working principle in the approach of magnesium carbonation can be described in theory by the following reaction:

$$MgO + CO_2 = MgCO_3 \qquad (1)$$

This is a thermodynamically favored reaction not only because it is exothermic (ΔG = -48.31 kJ/mol, 25 ^{o}C) but because the product is also the most stable magnesium carbonate mineral form of all. In reality, however, the formation of anhydrous $MgCO_3$ through this route proves virtually impossible at ambient environments; instead, the tri-hydrate (i.e. nesquehonite) often turns out to be the most common product. Therefore, we should study the crystallization process of nesquehonite to avoid the limit to our understanding of magnesium carbonation reaction and its application to carbon sequestration.

Results and Conclusion

Nesquehonite crystallization experiments were conducted in H_2O and water/dimethylformamide (DMF) mixture to examine solvent effect on the nucleation kinetics. Results show a reduction of nucleation induction time in the presence of DMF and a positive correlation between nucleation rate and DMF concentration. Analysis in the context of the classic nucleation theory reveals an unexpected increase in the surface energy of nesquehonite upon the solvent change, implying that kinetic factors, rather than surface energetics, is the driving force behind the resultant enhancement in nucleation rate. Further analyses suggest that kinetic acceleration under higher surface energy conditions is possible if nucleation proceeds through a cluster aggregation mechanism instead of critical nucleus formation. Fitting the Smoluchowski's coagulation theory to the experimental data seems to provide support to the operation of the non-classic nucleation mechanism as it shows that the cluster association rate is independent of the sizes of the precursors but positively correlated to the DMF concentration, consistent with the scenario of growing population of sub-critical nuclei and ensuing higher probability of cluster collision/aggregation leading to an accelerated nucleation.

Origin of the ~1.74 Ga, Anorthosite-hosted Damiao Fe-Ti-P Ore Deposit, North China

TAI-PING ZHAO[1*], WEI TERRY CHEN[2] AND MEI-FU ZHOU[2]

[1]Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, China, tpzhao@gig.ac.cn

[2]Department of Earth Sciences, University of Hong Kong, Pokfulam Road, Hong Kong, China, chenweifly1@163.com (W.T.Chen), meifuzhou@hotmail (M.F.Zhou)

The Damiao deposit is hosted in the ~1.74 Ga Damiao anorthosite complex, the only known massif-type anorthosite in China. It has been mined for several decades at an annual production of 2 million tons ore, and has long been an important source of Fe, Ti, P and V in China.[1] The deposit contains hundreds of ore bodies occurring as irregular lenses, veins or pods intruding hosting anorthosite. These discordant oxide ores contain abundant but variable apatite, and are classfied into Fe-Ti ore, nelsonitic ore and oxide-apatite gabbronorite on the basis of apatite contents and ore structures.

Combined with detailed field investigations, bulk ore major and mineral EPMA major and LA-ICPMS trace elemental analyses were conducted to understand the origin of the Damiao deposit. Intrusive feature of nelsonitic ores and contrast densities between Fe-Ti oxides and apatite suggest that the nelsonitic ores have crystallized from an immiscible nelsonitic melt. Fe-Ti ores displaying similar compositional range of Fe-Ti oxides and silicate minerals are interpreted to have also crystallized from the immiscible nelsonitic melt, which is further supported by the spatially close association of Fe-Ti and nelsonitic ore bodies and their comparable mineral assemblages of plagioclase, pyroxene, Fe-Ti oxides and apatite. This interpretation that fractional crystallization of the immiscible nelsonitic melt forming both Fe-Ti and nelsonitic ores is well consistent with linear variations of Sr, Y, Th, U and REE contents of apatite and the parallel chondrite-normalized REE patterns.

Oxide-apatite gabbronorite display relatively larger variable but more evolved compositions of silicate minerals than nelsonitic ores (and Fe-Ti ores), pointing to a separate origin in each case. Apatite of oxide-apatite gabbronorite contains lower Sr and MgO but higher REE contents and Y than those of nelsonitic ores, further indicating that nelsonitic ores are relatively more primitive [2], excluding the possibility that they have formed by immiscible segaration from oxide-apatite gabbronorite, as previously proposed. Based on their dissminated texture and continuous chemical variation, we considered that oxide-apatite gabbronorite may have formed by normal fraction crystallization process through a trend of iron enrichment in residual liquids, different from the immiscible origin for nelsonitic ores. Oxygen fagacity (fO_2) might be one of the important factors resulting in different forming processes for nelsonitic ores and oxide-apatite gabbronorite, because liquid immiscibility field expands generally with increasing fO_2. Higher fO_2 for nelsonitic ores is well indicated by their smaller negative Eu anomalies of apatite, because apatite readily accepts the Eu^{3+} into its structure but excludes the larger Eu^{2+}.

Geochemistry and tectonic settings of Carboniferous volcanic rocks in the Junggar basin of China

ZHAO XIA[1]*, WEI YANZHAO[1], YANG JUN[2],LIU JIANGLIN[3], ZHANG JIANBIN[3]

[1]Research Institute of Petroleum Exploration & Development, Petrochina, Beijing, China.
(*correspondence: zhaox601@petrochina.com.cn)

[2]Chang'an University, Xi'an, China.

[3]Fengcheng Oil Feild, Xinjiang Oilfield Company, Petrochina, Xinjiang, China.

Intruduction

The Junggar basin, an important part of central Asia orogenic belt, is a Mesozoic and Cenozoic sedimentary basin developing upon Precambrian crystalline basement and Palaeozoic fold basement. The basement of the Junggar basin is a part of Kazakhstan plate, and interspersed in the Tarim plate and the Siberia plate. The Carboniferous volcanic rocks in the Junggar basin consisting of volcanic lava and volcaniclastic rock are most widely developed. Furthermore, oil and gas reservoirs have found in it. The geochemistry and tectonic settings of Carboniferous volcanic rocks in the Junggar basin are studied in this article. And the research about the tectonic setting of volcanic rocks of the basin has important significance on volcanic rock oil and gas exploration[1].

Method and Resolut

The volcanic lava in this area has characteristics of low K_2O, high Na_2O, high TiO_2 and high ΣREE. The REE distribution plots show the volcanic rocks are enriched in LREE and LILE, and depleted in Nb and Ta. In addition, the plots also reveal the characteristic of LREE and HREE differentiation. The ratios of Th/Nb and Nb/Zr as well as the tectonic setting discrimination diagrams show that the volcanic rock main body is characterized by intraplata volcanic rock, and formed under the tectonic setting of intraplata extension. The lava of this area with low Th/Nb, low La/Nb, slightly elevated LREE, as well as Nb/La-Th/Nb and La/Ba-La/Nb discrimination diagrams, show that depleting of Nb and Ta relative to Th is the result of subtractive component adding to volcanic source[2].

Conclusion

According to geochemical analyses, the lava with charcaterisctics is similar with "post collision arc volcanic rock"[3]. It is generated in an extensional setting of the late stage of orogenesis, and the magma source may be influenced by earlier oceanic plate subduction. Combining with the regional geologic characteristic, Carboniferous volcanic rocks in the Junggar basin were formed in an extensional rifting setting of the late stage of orogenesis, which is consistent with the region rifting function of large scale. The conclusions of this research make a significant improvement for the study of volcanic reservior distribution.

Syn-exhumation magmatism during continental collision: Evidence from alkaline intrusives of Triassic age in the Sulu orogen

ZI-FU ZHAO*, AND YONG-FEI ZHENG

CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China, zfzhao@ustc.edu.cn

While oceanic subduction zones are characterized by syn-subduction arc magmatism, continental subduction zones are characterized by syn-exhumation alkaline magmatism. The latter is illustrated by alkaline intrusive rocks (including gabbro, syenite and granite) in the Sulu orogen, eastern China. In order to decipher the crust-mantle interaction in the continental subduction zone and subsequent decompression melting of ultrahigh-pressure (UHP) metamorphic rocks, we carried out a combined study of zircon U-Pb ages and Lu-Hf isotopes, mineral O isotopes, whole-rock major-trace elements and Sr-Nd isotopes. SIMS and LA-ICPMS zircon U-Pb dating yields Late Triassic ages of 201±2 to 212±1 Ma for their crystallization. These ages are younger than Middle Triassic ages for UHP metamorphism of country rocks, corresponding to the syn-exhumation magmatism during continental collision. The alkaline rocks are characterized by the arc-like patterns of trace element distribution, with relative enrichment of LILE and LREE but relative depletion of HFSE. They have high initial $^{87}Sr/^{86}Sr$ ratios of 0.7064 to 0.7114 and highly negative $\varepsilon_{Nd}(t)$ values of -16.4 to -13.8 with two-stage Nd model ages of 2.11 to 2.33 Ga for whole-rock. Zircon Lu-Hf isotope analyses also show highly negative $\varepsilon_{Hf}(t)$ values of -20.9±0.5 to -14.1±0.9, with two-stage Hf model ages of 2.10±0.06 to 2.56±0.03 Ga. The zircon exhibits relatively consistent $\delta^{18}O$ values of 5.6 to 6.2‰, slightly higher than normal mantle values. The enrichment of radiogenic Sr-Nd-Hf isotopes in the gabbro indicates its origination from an isotopically enriched mantle source, whereas the arc-like pattern of trace element distribution for it suggests a fertile mantle source with enrichment of LILE and LREE. Thus, it is part of the orogenic lithospheric mantle that would be generated by underplate reaction of the subcontinental lithospheric mantle-wedge peridotite with hydrous felsic melts derived from the subducted continental crust during the Triassic continental collision. On the other hand, there are general similarities in trace element and radiogenic isotope characteristics between the syenite-granite and UHP metaigneous rocks in the Dabie-Sulu orogenic belt, suggesting its genetic link to the subducted continental crust itself. Therefore, the alkaline intrusives are derived from partial melting of the orogenic lithospheric mantle and the subducted continental crust in the stage of exhumation. They provide a petrological record of recycling the subducted continental crust into mantle depths with the crust–mantle interaction in the continental subduction channel.

Hydrocarbon generation kinetics of oil cracking in different reaction system

ZHENG HONGJU[1*], WANG ZECHENG[1], AND WANG TONGSHAN[1]

[1] Research Institute of Petroleum Exploration & Development, PetroChina

hjzheng@petrochina.com.cn (*presenting author)

Pyrolysis experiment of crude oil with 3 reaction systems ($MgSO_4+H_2O$+crude oil, $CaSO_4+H_2O$+crude oil, crude oil) are carried out to simulate the gas generation characteristic when H_2O and ions such as SO_4^{2+}, Mg^{2+}, Ca^{2+} participate in the oil cracking, and discuss the generating mechanism of natural gas containing H_2S, and quantitatively calculate the deplete of hydrocarbons and their carbon isotope by TSR.

.The experiment results show that the TSR reaction did not occur under the system of "$CaSO_4+H_2O$+crude oil", oppositely, TSR obviously occurred under the system of "$MgSO_4+H_2O$+crude oil" and the yield rate of H_2S reach up to 60~80ml/g. Hydrocarbon yield rates under the reaction system with TSR occurred are significantly lower than that in the reaction system without TSR occurred (Fig 1), indicating the deplete of gaseous hydrocarbons by TSR [1]. In addition, TSR also had a significant effect on the carbon isotope fractionation of hydrocarbons, so that methane, ethane, propane carbon isotope weight gain with a range of 3~6‰ (Table 1).The activation energy distribution show that, the activation energy of gas generation under the system of "$MgSO_4+H_2O$+crude oil" lower than that in the system of "$CaSO_4+H_2O$+crude oil", the former is 48~60KJ/mol, while the latter is 62~74KJ/mol. It could indicate that participation of Mg^{2+} make a low activation energy of hydrocarbon generation and oil cracking reaction easier.

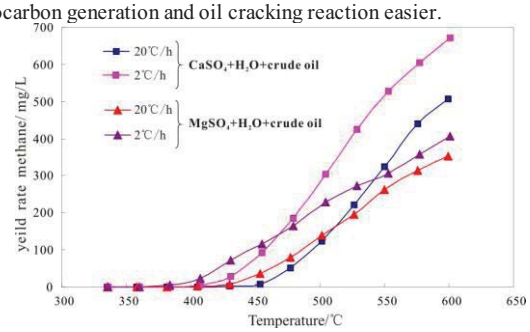

Figure 1: Yield rate of the methane generated in different system

Recent research show that adding buffer such as NaCl into the system of "$CaSO_4+H_2O$+crude oil" could help to TSR, indicating that only SO_4^{2+}-hydrocarbon molecules is not enough in TSR, and the catalyst of metal ions (e.g. Mg^{2+}, Na^{+}) is very important.

Temperature /℃	$MgSO_4+H_2O$+crude oil		$CaSO_4+H_2O$+crude oil	
	Methane	Ethane	Methane	Ethane
453.7	-45.19	-41.73	-54.08	-43.09
501.8	-45.79	-36.74	-49.35	-37.55
550.0	-39.90	-24.66	-43.89	-31.04

Tracing metal inputs and cycles in the South Atlantic with rare earth elements

XIN-YUAN ZHENG[1*], ABIGAIL NOBLE[2], MAK SAITO[2], MATTHEW POINTING[1], PHILIP HOLDSHIP[1], AND GIDEON HENDERSON[1]

[1]University of Oxford, Department of Earth Sciences, Oxford, UK OX1 3AN, xinyuan.zheng@earth.ox.ac.uk (* presenting author)
[2]Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543, UAS

Rare earth element (REE) concentrations in seawater are not only controlled by external inputs such as dusts and rivers, but also fractionated by oceanic processes including scavenging and redox [1]. The characteristic REE patterns imposed by different inputs and processes may provide powerful tools with which to improve understanding of the sources and cycles of biolimiting trace metals such as Fe and Zn. REEs and their isotopes, especially Nd isotopes, are also commonly employed as paleoceanographic tracers to infer the status of the ocean in the past, but there is some controversy about the processes controlling their oceanic distribution.

Despite their potential utility, and their relative ease of measurements, high-quality seawater REE data are usually limited to a few single stations, and remain sparse for much of the modern ocean. This limits our ability to fully understand the cycling of REEs in seawater, or their use to trace micronutrient cycles.

In this study, we use isotope-dilution MC-ICP-MS analysis on ~100ml, and a relatively high sample throughput, to report the first full-depth zonal sections of REE-concentrations in South Atlantic along ~11^{o}S collected by the CoFeMUG cruise, and along 40^{o}S in the Cape Basin collected by UK-GEOTRACES GA10 cruise.

Secondary maxima in REE concentrations at ~1000m observed in these sections are consistent with the presence of UCDW at the same depth, and higher REE concentrations at bottom waters in the western basin than those at Angola Basin conforms to the absence of AABW in Angola Basin which is blocked by Walvis Ridge in the South. Both evidence suggests ocean circulation controlled REE-distribution at ~11^{o}S.

Ce anomalies are used to trace redox-related addition/removal of REEs. Two prominent plumes with elevated Ce-anomaly values and Ce concetrations occur nearshore in Angola Basin in the CoFeMUG section at ~500m and ~1500m respectively, indicating the addition of REEs possibly from reducing shelf sediments. An additional source of REEs is supported by more negative seawater ε_{Nd} than typical for the Angola Basin [2]. Inter-element comparison with Fe and Mn demonstrates elevated Ce anomalies associated with Fe on the east of the basin, but this is not accompanied by increased Mn concentrations, indicating unusual decoupled cycling of Ce and Mn.

The preliminary study on prospecting uranium mine in radioactively physical geography using factor analysis method

Y. ZHENG, XIN-MIN WU*, Y. ZHANG, AND Y.X. YANG

Engineering Research Center of Nuclear Technology Application, East China Institute of Technology, Ministry of Education, Nanchang , Jiangxi Province, China, 330013, ymzheng@ecit.cn (* presenting author)

In natural radioactive energy spectrum measurement, to explain radioactive anomalies an distinguish the type of some soil and rock on the basis of three combination factors of uranium, thorium and potassium were more reasonable and accurate than a single radioactive element [1]. So the original data, based on the collection original data of reconnaissance ground energy spectrum measurement of uranium district in Yanzhuang, Wengyuan County, Guangdong Province, were processed by the method of R type factor analysis. The KMO test value of the Yanzhuang mining area was 0.68 by the calculation, greater than 0.6,and Bartlett's significant parameter was less than 0.05,which reached a significant level, showing that the variables were suitable for principal components analysis .Then the model of factor analysis was established, seen the formula (1), (2).

The first principal component is:

$$y1 = 0.71std.U - 0.03std.Th + 0.70std.K \quad (1)$$

The second principal component is:

$$y2 = -0.19std.U + 0.96std.Th + 0.22std.K \quad (2)$$

Collect original data into the model to calculate the abnormal lower limit for mining area: y1 = 1.793935, y2 = 1.537696. The y1, y2 anomalies delineated figure made by MAPGIS showed that the delimitation from the working drawing of abnormal and practical exploration was unified, which indicated that factor analysis could be a good combination of several factors to form a single measurement for radioactive exploration data interpretation.

This study was granted by open education fund (HJSJYB2010-14) of Engineering Research Center of Nuclear Technology Application, East China Institute of Technology, Ministry of Education, China.

[3] Hefei National Laboratory for Physical Sciences at Microscale, University of Science and Technology of China, Hefei 230026, P. R. China

Biosilica displays many kinds of intricate patterns that are constructed on a nanometer-to-micrometer scale. At the nanoscale, for example, it involves the polymerization products of silica apparently mediated by the interactions between different biomolecules with special functional groups. An emerging consensus is that organic amines (e.g., long chain polyamines), proteins, and polysaccharides are general organic components in diatom's cell walls, and are responsible for the formation of hierarchical silicious structures. Another basic fact in biosilicification is that the silica formation occurs within a specialized compartment known as the silica deposition vesicle (SDV), whose membrane, called the silicalemma, consists of a typical lipid bilayer. Several researches have revealed that the membrane-bound SDV could provide not only spatial constraints but also possibly distinct chemical influences for the polymerization and morphogenesis of the silica. Nevertheless, there are few publications illuminating the interactions between amines and lipids in biosilicification. Herein, dodecylamine (DA) and phospholipid (PL) were selected as model organic additives to influence the precipitation of silica in biomimetic silicification. The results show that increasing PL concentrations leads to the formation of siliceous elongated structures, and the localized enlargement is also clearly observed during the further growth of the elongated structures, displaying some features of silica biomineralization at the earliest recognizable stage of biosilica development in diatom. Moreover, a series of NH_3-PL experiments reveal that no elongated structures can be obtained in the presence of PL, suggesting that the cooperative interactions between PL and DA molecules cause the silica structures to be elongated. Based on the special importance of both organic amines and phospholipid membranes (e.g., silicalemma) for biosilicification, our results may provide a novel pathway towards a deeper insight into the biosilicification mechanism.

Source characteristics of a high-K to ultrapotassic volcanic rock zone in NE China:A typical EMI signature from an orogenic belt

XIN-HUA ZHOU[1] *, JI-AN SHAO[2], JI-FENG YING[1], BEN-XUN SU[1]

[1] State Key Lab of Lithosphere Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China, xhzhou@mail.iggcas.ac.cn, (* presenting author)

[2] College of Earth & Space Sciences, Peking University, wangcc@mail.tsinghua.edu.cn

As a common sense by previous global study, the enriched mantle end-member, i.e. EMI in continental region has been always attributed to craton-related subcontinental lithosphere (eg. Zindler and Hart, 1982, Hofmann, 2003). Based on updated isotopic geochemical survey, we report a case study on high-potassic to ultra-potassic volcanic rock zone in NE China, which shows a typical EMI source geochemical characteristics and located near the east end of East-Central Asian orogenic belt.

The systematic Sr-Nd-Pb-Hf isotopic composition, along with REE and spider diagram patterns of ultra-potassic volcanic rocks, mostly are leucitite, do show a typical EMI end-member signature, not only for entire Phanerozoic mantle-derived rocks in eastern China, but also on global scale, such as compare with those from Lucite Hill and Smoky Butte, North America, and lamproites in Aldan Shield, Far East Russia (eg. Davies et al., 2006). In addition, a sires of metasomatic minerals, such as phlogopite, apatite and so on have been recognized from mantle-derived xenoliths of these host rocks. Detailed mineralogical and geochemical studies have demonstrated the multiple and distinct mantle metasomatism, occurred in different geological time, from ancient one (Archearn) to recent one. Furthmore, the regular geological occurance, NW trending, of these potassic volcanic rocks, accompanied with tectonic rifting, seismic activities and geothermal anomaly would provide severe and further geological and geophysical constraints on the origin of such enriched mantle source beneath an orogenic belt.

A microscopic view of nucleation in the anatase-to-rutile transformation

YA ZHOU [1*] AND KRISTEN A. FICHTHORN [2]

[1]Department of Chemical Engineering,The Pennsylvania State University, University Park, USA zhou@engr.psu.edu (* presenting author)

[2] Department of Chemical Engineering and Department of Physics, The Pennsylvania State University, University Park, USA fichthorn@psu.edu

We use molecular simulation techniques to investigate the anatase-to-rutile transformation in Titania nanocrystals. A thermodynamic analysis indicates that edge and corner atoms significantly influence the critical size at which rutile nanocrystals become energetically preferred over anatase. Using molecular dynamics simulations, we probe kinetics of the transformation in individual anatase nanocrystals and in nanocrystal aggregates. We follow structural evolution using simulated X-ray diffraction. Additionally, we develop a local order parameter to distinguish individual Ti ions as anatase, rutile, or anatase {112} twin-like. We apply our local order parameter to track the formation and growth of rutile nuclei. Anatase {112} twins form easily at surfaces and interfaces of nanocrystal aggregates and rutile nucleates among the twins. Stable rutile nuclei maintain {101} facets during growth, as a result of nucleation from layers of alternating anatase {112} twins. Our results are in agreement with experiment and indicate the central role of {112} twin-like anatase in the transformation.

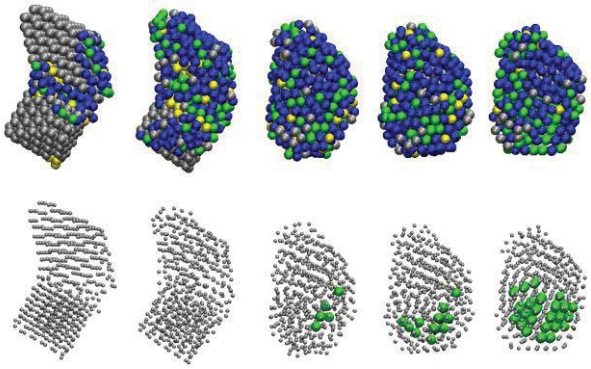

Figure 1: Structural evolution of an aggregate during transformation at 1473 K. Upper row: only Ti ions in the aggregate are shown, with anatase ions in silver, anatase {112} twins in blue, rutile in green, and undefined ions in yellow. Lower row: Ti ions in the stable rutile nuclei are in green and magnified, all other Ti ions are shown in silver.

Temporal changes in magma geochemistry in the northern Lhasa Terrane, Tibet: Response to the Lhasa–Qiangtang collision

DI-CHENG ZHU[1],*, ZHI-DAN ZHAO[1], YAOLING NIU[2,3], YILDIRIM DILEK[1,4], QING WANG[1], XUAN-XUE MO[1]

[1]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing 100083, China, (dchengzhu@163.com); [2]School of Earth Sciences, Lanzhou University, Lanzhou 730000, China (niu.yaoling@yahoo.co.uk); [3]Department of Earth Sciences, Durham University, Durham DH1 3LE, UK (niu.yaoling@yahoo.co.uk); [4]Department of Geology, Miami University, Oxford, OH 45056, USA (dileky@muohio.edu)

Magma generation and evolution is a natural consequence of mantle dynamics and crust-mantle interaction. As a result, magma compositional variation in time and space can be used, in turn, to infer these deep processes. Indeed, the Baingoin Batholith, the largest batholith in the northern Lhasa Terrane, manifests this efficacy. This batholith was emplaced in response to the Lhasa–Qiangtang continental collision (ca. 140–110 Ma). Our data indicate that it was emplaced in three distinct pulses (i.e., 132 ± 2, 121 ± 3, and 113 ± 3 Ma) rather than in a single phase (ca. 121 Ma), as previously thought, and that its magma chemistry changed through time (Figure 1). The 132 ± 2 Ma samples are silica-rich and have small whole-rock ε_{Nd} (t) (–2.7 to –2.4), positive zircon ε_{Hf}(t) (+2.3 to +11.0), low zircon $\delta^{18}O$ (5.81–7.16 ‰) values, and low Ti-in-zircon temperatures (T_{Ti}^{zir} = 630–660°C). The 121 ± 3 Ma samples are compositionally diverse and show varying ε_{Nd}(t) (–10.0 to –4.8), decreased zircon ε_{Hf}(t) [–8.5 to +5.9], increased zircon $\delta^{18}O$ (7.42–9.52 ‰), and increased T_{Ti}^{zir} (ca. 650–750°C) relative to the 132 ± 2 Ma rocks. The 113 ± 3 Ma samples have similar ε_{Nd}(t) (–9.5 to –4.8) and T_{Ti}^{zir} (ca. 680–750°C) but slightly increased zircon ε_{Hf}(t) (–7.1 to +6.4) with varying zircon $\delta^{18}O$ (6.25–11.12 ‰) relative to the 121 ± 3 Ma rocks. Similar changes of magma geochemistry are also present in the coeval magmatic rocks from Yanhu (Figure 1). It is evident that the parental magmas of the 132 ± 2 Ma rocks originated from hydrous partial melting of juvenile crust. Progressive incorporation of ancient crustal material into the source region of the 121 ± 3 Ma rocks coincided with the involvement of the subducting Qiangtang continental crust or the contamination of the Lhasa basement-derived melts during the Lhasa–Qiangtang collision. The significant input of mantle-derived component in the 113 ± 3 Ma rocks may have resulted from slab breakoff-induced magmatism and related mantle melting events, following the final Qiangtang–Lhasa amalgamation.

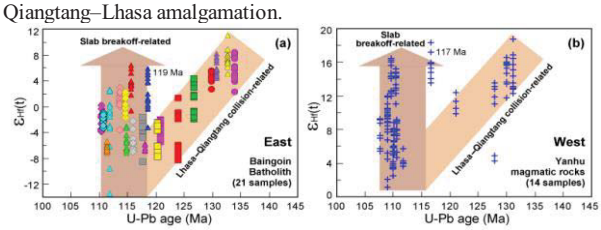

Figure 1: Space-time variations of zircon ε_{Hf}(t) of Early Cretaceous magmatic rocks from the northern Lhasa Terrane, central Tibet

Isotopic fractionation of selenium in higher plants

JIAN-MING ZHU[1,2*], THOMAS M. JOHNSON[2*], HAI-BO QIN[1], XIANG-LI WANG[2] AND YONG-QIANG YUAN[1]

[1]State Key Lab. of Environmental Geochemistry, Inst. of Geochemistry, CAS, Guiyang, 550002, China. zhujianming@vip.gyig.ac.cn (*present author)

[2]Department of Geology, University of Illinois at Urbana-Champaign, Urbana, 61801, USA. tmjohnsn@illinois.edu

The extent of isotopic fractionation of selenium in plants is poorly understood, but potentially is important to understand and quantify the fractionation processes involved in Se biogeochemical cycling in surface environments[1]. Here, by ^{74}Se-^{77}Se double spike technique with high presion developed on HG (hydride generator)-MC-ICP-MS[2], we determined Se isotopic compostion of different plant components including roots, stems, leaves and seeds of rice (*oryza sativa L.*) and corn (*zea mays L.*), and the Se accumulaing herb booor's mustard (*thlaspi arvense L.*). The $\delta^{82/76}$Se values ranged from -1.41‰ to -0.24‰ in rice, from -3.56‰ to -1.80 ‰ in corn, and from -0.62 ‰ to 2.21‰ in mustard herb. The overall range of $\delta^{82/76}$Se was 5.77‰, indicating Se isotopic variation can occur in plants to a small extent.

For all three species, roots are shifted isotopically relative to total Se in the soils they grew in, but not in any systematic way. This probably reflects Se isotopic fractionation among the various Se species in the soils, which is expected to result from redox cycling. Since Se is taken up mainly as selenate, selenite and certain organic compounds, the roots' isotopic composition may differ from the total soil, and is expected to depend on several variables[3].

A slight systematic enrichment in heavy Se isotopes in shoots (above ground) relative to roots occurred in corn and mustard herb with up to 0.22 ‰ in $\Delta\delta^{82/76}Se_{shoot\text{-}root}$, but not in rice. This shows the transport of Se in plants from root to shoot does not induce obvious fractionation. In contrast, $\Delta\delta^{82/76}Se_{leave\text{-}root}$ and $\Delta\delta^{82/76}Se_{leave\text{-}shoot}$ in all three plants show the obvious heavy isotope enrichment in leaves of at least 0.35‰ (the maximum is 1.85‰), indicating there are at least two different types of mechanism to explain Se isotopic variations. One is transport from rhizome to stems which involves no or smaller fractionation; another is from stem to leaves and/or leaves to atmosphere which cause significant fractionation. In the latter case, we envision Se methylation and loss of this volatile species from leaves during growth could induce heavy Se isotope enrichment in leaves, particular in Se accumulated plants such as *thlaspi arvense L.*

Peraluminous rare metal granites in South China

JINCHU ZHU[1]*, RUCHENG WANG[2], JIANJUN LU[3], AND LEI XIE[4]

[1]Nanjing University, Nanjing, China. jczhu@nju.edu.cn (*Presenting author)

[2]Nanjing University, Nanjing, China. rcwang@nju.edu.cn.

[3]Nanjing University, Nanjing, China. lujj@nju.edu.cn.

[4]Nanjing University, Nanjing, China. xielei@nju.edu.cn.

There exist many alumina-saturated Sn-W-Ta-Nb bearing granites in South China, including the Yichun Li-Ta-Nb granite in Jiangxi Province, the Limu Ta-Nb-Sn granite in Guangxi Province, the Xianghualing Ta-Nb-W-Sn granite in Hunan Province, etc. They are usually stocks in occurrence, ultra-acidic in chemistry, rich in Al, Na, Li, Rb, Ta, Nb, Sn, W, F etc. elements, mostly P-rich, but in some cases P-barren.

One of the most fundamental features for these granites is well developed vertical zonation. From the upper contact downwards to the deeper levels the following zones are usually successively observed: the pegmatoid stockscheider (pegmatite, aplite and massive quartz assemblage), the greisen zone, the lepidolite-topaz-albite granite zone, the Li-muscovite granite zone, the two-mica granite zone, and the protolithionite granite zone. Along with the direction from protolithionite granite upwards, Li, Rb, F and rare-metal contents gradually increase, but Zr and REE concentrations gradually decrease. Geological, textural, geochemical evidences and coexisting coeval subvolcanic-volcanic rare metal bearing dykes suggest that this kind of vertical zonation and rare metal mineralization were caused by fractional crystallization and magmatic-hydrothermai differentiation of rare metal-rich parental magmas. This evolutionary process led to gradual depletion of Zr and REE, and gradual enrichment of Li, Rb, Ta, Nb, Sn, W etc. rare metals and F etc. volatiles in the apical parts of the stocks.

The original rocks of the peraluminous rare metal granites in South China are considered to be of S-type derived from the crustal materials, especially for the P-rich ones. However, the aluminous A-type granites are also should be considered, especially for the P-barren ones. For example, the protolithionite granite in the deeper part of the Xianghualing granite has high contents of REE, Y, Zr, Nb, Th, U etc. HFSEs, relatively higher zircon ε_{Hf} values (from -5.9 to -1.9, averaging -4.2) and relatively lower two stage Hf model ages (T_{DM} values from 1.32 Ga to 1.58 Ga, averaging 1.47 Ga), which evidently indicate that this granite belongs to the aluminous A-type and was derived from the crust-mantle mixed sources.

[3]Argonne National Laboratory, Advanced Photon Source, Argonne, IL, USA, ren@aps.anl.gov

Metal and coal mines produce iron-rich sulfuric acid solutions that contain a broad range of toxic elements [1]. These solutions, referred to as acid mine drainage (AMD), adversely affect environmental quality. When AMD mixes with neutral water bodies, such as in rivers or during wetland treatment, interacts with rock surfaces, or reacts with lime during remediation, neutralization occurs. As a result, ferric iron (Fe^{3+}) hydrolyzes and precipitates as Fe oxyhydroxide nanoparticles, such as ferrihydrite and schwertmannite. However, the formation pathways of these nanoparticles are relatively unknown largely due to their rapid formation rates and low abundances of initially-formed species. In this study, we used *in situ* time-resolved synchrotron radiation X-ray diffraction (XRD), quick-scanning extended X-ray absorption fine structure (QEXAFs) and UV-Vis spectroscopic techniques to study the products formed initially ($2 < t < 60$ minutes) when ferric iron sulfate solutions ($[Fe^{3+}] = 0.2$ M) are partially neutralized ($[HCO_3^-]/[Fe^{3+}] < 3$) by addition of $NaHCO_3$.

When $[HCO_3^-]/[Fe^{3+}] = 0.6$ (initial pH ~ 2.2), the only particles formed were ferrihydrite-like clusters that were stable throughout the duration of the experiment. When $[HCO_3^-]/[Fe^{3+}] = 1$ (initial pH ~ 2.5), the ferrihydrite-like molecular clusters formed initially but mostly disappeared and were replaced by schwertmannite. Schwertmannite and larger ferrihydrite particles formed immediately when $[HCO_3^-]/[Fe^{3+}] = 2$ (initial pH ~ 2.7), but the ferrihydrite particles completely disappeared and were replaced by schwertmannite. The schwertmannite particle size increased with reaction time, and extensive particle aggregation occurred.

The ferrihydrite-like cluster is very intriguing and its structure deserves further characterization. The data are consistent with Fe_{13} having Baker-Figgis δ-keggin structure, i.e., the motif in the ferrihydrite structure proposed by Michel et al. [2]. The existence of the cluster may result from sulfate binding on its surface, preventing the cluster from growing into larger ferrihydrite particles.

In conclusion, the results suggest that particular molecular clusters and small nanoparticles may be important, early-formed components of natural acidic solutions.

XPS study of bioleached arsenopyrite by *Acidithiobacillus ferrooxidans*

TINGTING ZHU[1*], XIANCAI LU[1], RUCHENG WANG[1], AND JIANJUN LU[1]

[1]School of Earth Sciences and Engineering, Nanjing University, Nanjing, China, ttzhu.nju@gmail.com (* presenting author)

Arsenopyrite (FeAsS) is a commonly discarded sulfide mineral in mining wastes. The arsenic release from it due to oxidation can cause serious environment contamination in mines. It has been well proved previously that microorganisms can remarkably accelerate the oxidation of arsenopyrite. However, the detailed oxidation mechanism is still unclear. This study on surface chemistry of bioleached arsenopyrite may cast insights into it.

In our experiments, the arsenopyrite obtained from a W-Sn deposit and a strain of *Acidithiobacillus ferrooxidans* isolated from the acid mine drainage in Tongling, eastern China, were used. The sterilized 9K culture with an adjusted Fe^{2+} concentration of 16 mM was poured into 6 flasks and then divided into two groups. Three flasks were inoculated with *Acidithiobacillus ferrooxidans* and the other three were only abiotic. Arsenopyrite particles were dropped into flasks simultaneously, and then extracted after 4 days, 7 days and 10 days, respectively. The reacted samples were freeze-dried in vacuum and ready for SEM observation and XPS analysis.

Several types of secondary mineral, such as elemental sulfur and scorodite, can be observed on the surface of 4 days-biooxidized arsenopyrite. However, native sulfur diminished gradually as bio-oxidation continuing and finally disappeared on the 10 days-biooxidized surface. The XPS depth profiles show that the altered layer of biooxidized arsenopyrite is much thicker than that of abiotic case. In addition, the contents of Fe(III), As(V) and sulfate in surface layer of bio-oxidized arsenopyrite are all higher than those of abiotically oxidized sample. The oxidation progress varies with the elements in both experimental systems. In the biotic system, the oxidized sequence is in the order of As, S, and then Fe, whereas in the abiotic system Fe is preferentially oxidized than As and S. In the depth profile of altered layer of each systems, a transition depth can be identified, where the contents of As, S and Fe change sharply. This depth of bio-oxidized arsenopyrite is about 450 nm, and that of abiotically oxidized one is around 30 nm. The change of Fe speciation in depth profile reveals that *A. ferrooxidans* initially breaks Fe(II)-AsS to form Fe(III)-AsS and a small quantity of Fe(III)-OH, and at a very late stage a trace fraction transform into Fe(III)-SO. For As-oxide, As(III)-O dominates on the bio-oxidized surface while As(I)-O prevails on the abiotically oxidized one. The contents of S^0 and S_n^{2-} of abioticaly oxidized surface keep stable as depth increase, while those of bio-oxidized surface show a significant increase from 500 nm to 1000 nm, which is consistent to the observed emergence and dis-appearance of native sulfur. It is proposed that native sulfur is only an intermediate product during microbial oxidation.

[4] 742911585 @qq.com

Montmorillonite is the most important clay minerals in soils. It has good cation exchange and adsorption capacity. Montmorillonite was a major factor for cadmium retention in soils due to electrostatic attraction, ion exchange, complexation, and precipitation[1]. The sample was collected from Sihui, Guangdong, China. Its physical and chemical properties had been measured, meanwhile, infrared spectroscopy, X-diffraction analysis, and simultaneous thermal analysis had been conducted, then cadmium adsorption behavior on montmorillonite had been studied. The cadmium adsorption on montmorillonite was fit to Langmuir model and Freudlich model, the latter was better. Adsorption of cadmium on montmorillonite was severely affected by ionic strength, the saturated adsorption capacity of cadmium calculated by the Langmuir model had a good negative correlation to ionic strength, the correlation coefficient was 0.9987. The adsorption index (1 / n) concluded by the Freudlich models were smaller, indicating that the montmorillonite was prone to adsorbing Cd^{2+}. The adsorption volume of cadmium on montmorillonite exhibited a process of rise-fall-rise-balance with the time delay at different temperature. The adsorption of cadmium on montmorillonite met the Lagergren second-order kinetic equation well, the correlation coefficients were 0.9999,1,0.9999 at 303, 313, 323 K, respectively. The false thermodynamic parameters were calculated through adsorption kinetics data of cadmium at the different temperature[2], the adsorption enthalpy（ΔH）was 23.31 kJ / mol, it showed that the adsorption process was an endothermic process, and it was the physical adsorption, the free energy of adsorption(ΔG) at different temperature were less than zero, indicating that the adsorption was spontaneous. The absolute value of ΔG increased and the driving force became larger with the temperature increase, the temperature was benefit to the adsorption. The entropy (ΔS) was greater than zero, the degree of disorder increased after Cd adsorbed to the montmorillonite. Cadmium replaced the more lively metal ions (Ca, Na, Mg, etc.) or the hydrogen ion in the interbedded area of montmorillonite, 1mol of cadmium ion could exchange 2mol of hydrogen or sodium ion, which induced the entropy increase more than the entropy decrease caused by ion adsorption [3].The results reported in the present study will benefit environmental contamination applications concerning cadmium mobility, cadmium transformation, and other possible applications in various fields (e.g. soil decontamination, agriculture irrigation and water treatment).

Filamentous microorganisms interacting with sheet silicates

W. ZIDAN[1*], S. NIETZSCHE[2], C. FISCHER[3], E. KOTHE[4], R. GAUPP[1]

[1]Institute of Geosciences, Jena, Germany, wafaa.zidan@uni-jena.de (* presenting author), reinhard.gaupp@uni-jena.de
[2] Center for Electron Microscopy, University Hospital Jena, Germany, sandor.nietzsche@uni-jena.de

[4]Institute of Phytopathology, Jena, Germany, erika.kothe@ uni-jena.de

Aim of the work

The goal of our work is to study the effect of two filamentous microorganisms (the fungus *Schizophyllum commune* and the actinobacterium *Streptomyces acidescabies E13*) on mineral dissolution and surface alteration when incubated with three different sheet silicates; the nontronites (Nau1, Nau2) and ripidolite (clinochlore). Incubation without iron added to the minimal media was performed in order to induce mineral dissolution by microorganisms for nutrient acquisition.

Results and conclusion

While the actinobacterium *S. acidescabies E13* has formed microbial pellets with the three sheet silicates, the fungus *S.* commune hasn't formed any microbial pellets with any of the sheet silicates. The Streptomycete's pellets formed with nontronite were regular, round (Fig. 1A) and there were not too many mineral flakes left as they were dissolved to a large extent, but the hyphae were encrusted. Streptomycete's pellets formed with ripidolite, in contrast to nontronite were irregular (Fig. 1B), many mineral flakes were preserved and the hyphae were smooth. Our interpretation is that the higher Fe concentration of nontronite is responsible for this contrasting behavior in terms of pellet's shape and hyphae's encrustation.

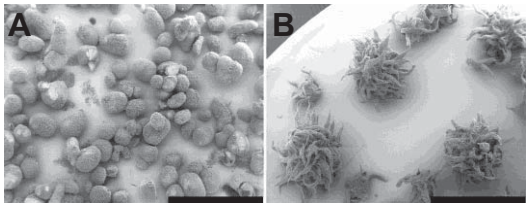

Figure 1: SEM images of Streptomycete's pellets with nontronite (A) and with ripidolite (B). Scale bar: 2 mm.

Furthermore, the *S. acidscabies E13* had decreased the pH from 6 to 4, and once again increased to pH 7 in case of interacting with clinochlore, while with nontronite the pH decreased and stayed constant at pH 4. This suggests that acidification might be a mechanism for mineral dissolution by the actinobacterium. However, this is not the case for the fungus *S. commune,* where the pH stayed neutral. The fungus excreted more protein when interacting with Nau2 as compared to Nau1 and clinochlore. Incubation of *S. commune.* with polished clinochlore samples caused an evolution of deep pits upon interaction as shown by vertical scanning interferometry (VSI). Data were used to analyze reaction kinetics as a function of crystallographic orientation. Our experiments showed different sheet silicate dissolution by filamentous bacterial and fungal microorganisms.

Silicon and oxygen isotopes during diagenesis of the Monterey chert

K. ZIEGLER[1,2,*], J. MARIN-CARBONNE[1,3]

[1]Department of Earth and Space Sciences, University of California, Los Angeles, CA 90095, USA.
[2]current address: Institute of Meteoritics, University of New Mexico, Albuquerque, NM 87131, USA. (kziegler@unm.edu) ([*]presenting author)

An important aspect for the evaluation of the use of (Archean) cherts as proxies for environmental conditions at their formation, is the fidelity of δ^{30}Si and δ^{18}O ratios of cherts during their diagenetic transitions from their precursor material (biogenic opal).

The Miocene Monterey Formation (California) is an exemplary location for the study of chert diagenesis. The Monterey Formation contains a diagenetic silicate sequence from marine biogenic opal-A to opal-CT to cristobalitic chert. This precursor-to-chert transition is due to dissolution-precipitation processes related to interactions of the opal with later diagenetic water [1, 2].

We analyzed δ^{30}Si values by MC-ICPMS (Neptune™), and δ^{18}O values of cherts by ion microprobe (Cameca 1270) at UCLA. Due to ionprobe matrix effects in opal, their δ^{18}O values were taken from literature [1, 3].

The δ^{18}O values of the Monterey opal (37‰) and chert (28-34‰) suggest formation temperatures of 15°C and 48±8°C, respectively [1]. The opal has a δ^{30}Si value of 1.4‰, and the chert has a more negative value of 0.0‰. Diatomaceous opal formed in highly productive oceans is expected to have high δ^{30}Si values, wheras diagenetic fluids expelled from the Monterey Shales during burial are expected to have more negative δ^{30}Si values [4].

The chertification process of the Monterey opal has imprinted δ^{30}Si and δ^{18}O ratios onto Monterey cherts that are different from the initial isotopic values of the biogenic opal. This example illustrates that isotope values of cherts are not necessarily indicative for the environmental conditions that prevailed during intial marine silica deposition.

If the precursor-chert transformation was associated with an external fluid, the isotope ratios of the chert reflect the conditions of this chertification event rather than that of the silica deposition. Such proceses will have to be understood and assessed when using O and Si isotopes of cherts for paleoclimate reconstructions.

We thank Jim Boles (UCSB) for providing the samples.

The distribution of neodymium isotopes and REE patterns in the water column of the tropical Atlantic Ocean

M. ZIERINGER[1], M. FRANK[1]* AND E. HATHORNE[1]

[1]GEOMAR | Helmholtz Centre for Ocean Research, Wischhofstrasse 1-3, 24148 Kiel, Germany (* mfrank@geomar.de)

Neodymium (Nd) isotopes and rare earth element (REE) patterns are used as tracers to fingerprint source provenances of water masses. We present full water column Nd isotopic compositions and dissolved REE distributions in seawater of the tropical Atlantic Ocean. Samples were collected during GEOTRACES expedition A11 (R/V Meteor) from Las Palmas (Canary Islands) to Port of Spain (Trinidad and Tobago).

Highly variable REE concentrations and characteristic REE patterns in surface waters can be grouped into different oceanic provinces and reflect prominent local source provenances, such as volcanic islands and dust particles of continental origin. Generally, concentrations in the eastern basin, especially in the vicinity of the Canary Islands and off the coast of NW Africa, are higher than in the western basin. In the area of the Canary Islands shale-normalized REE patterns are characterized by pronounced heavy REE enrichments originating from weathering of the volcanics while further south REE patterns are almost flat as a consequence of Saharan dust inputs.

Nd concentrations in surface waters range from a minimum of 14 pmol/kg in surface waters with reduced salinities (< 33.6 psu) due to freshwater input by the Amazon river to maxima off NW Africa originating from partial dissolution of Saharan dust and ocean island wheathering. This is also reflected in the surface water Nd isotopic compositions, which range from ε_{Nd} = - 12.7 to - 8.8. The most radiogenic values are measured between Tenerife and Grand Canary while the Nd isotope composition is least radiogenic in the open ocean surface waters.

In addition to the surface waters we present full water column profiles of Nd isotope compositions and REE patterns including samples from all major water masses of the Atlantic Meriodional Overturning Circulation in the western and eastern Atlantic basins.

On the Interpretation of Zircon U-Pb ages from (U)HP Host Gneisses in the Woodlark Rift of Papua New Guinea

Abstract

Conventional analysis of accessory minerals in 'spot-mode' in polished sections samples crystal volumes, that even in high-sensitivity secondary ionization mass spectrometry (SIMS), have diameters of ~10-20 μm. These 'spot mode' analyses can reveal the ages and trace element compositions of crystal domains if the domains are larger than the lateral beam dimensions. They cannot, however, be used to characterize variations that occur over smaller dimension, or that occur at sharp boundaries between discrete domains often observed in cathodoluminescence (CL) images. Because of this spatial limitation, conventional spot analysis cannot be used to investigate processes operative at scales <10 μm, and the relationship between the U-Pb isotopic and trace element records in the same crystal volume.

In this study SIMS depth-profiling was used to characterize zircons from felsic and intermediate gneisses that host the world's youngest (U)HP eclogites in southeastern Papua New Guinea. Many zircon CL images show cores overgrown by dark CL rims. SIMS depth profiling perpendicular to unpolished zircon surfaces, and penetrating to a depth of ~15 μm, effectively measured the U-Pb isotopic and trace element composition at a depth resolution of <1 μm. Crystal domains up-to and across the sharp transition from overgrowth into inherited core were investigated. These depth profiles are augmented by U-Pb data collected in 'spot mode' on 1) polished cross sections, and 2) external (i.e., unpolished) surfaces.

The U-Pb results reveal zircon grew in the Pliocene as individual crystals, and as overgrowths on Late Jurassic to Cretaceous cores. Zircons lacking Cretaceous cores and with uniformly Pliocene ages also displayed complex internal zoning patterns under CL. The Pliocene zircons are within error of $^{40}Ar/^{39}Ar$ mineral ages on the (U)HP host gneisses and indicate zircon crystallization during (U)HP exhumation. The U-Pb zircon systematics in the host gneisses provide information about the protolith age followed by zircon growth at temperatures of ~590 to 690 °C based on Ti-in-zircon thermometry. Small scale geochemical disequilibrium within the host gneisses at the time of zircon crystallization is indicated by contrasting trace element compositions for different zircons that crystallized simultaneously under similar conditions. The fact that zircons of uniform age display complex CL zoning patterns indicates that the zoning observed in CL images is not a function of growth rate, but instead may be related to changes in trace element concentration at the zircon-matrix interface during zircon growth.

Temporal resolution of LA-ICPMS analyses of fish hard parts

Andreas Zitek[*], Johanna Irrgeher[a], Stefanie Kappel, Florian Kendlbacher and Thomas Prohaska

As far as elemental and isotopic distributions vary locally in natural ecosystems, they are also taken up by living organisms and consequently incorporated in time resolved manner in incrementally growing tissues. Increasingly, this phenomenon is also used to answer key questions in fish ecology, such as seasonal habitat use, migration and dispersal.

Unfortunately, basic hydrobiological processes are increasingly disturbed by human activities in river systems all over the world. Understanding the spatio-temporal behaviour of fish and their connectivity needs is crucial for e.g. coordinated river rehabilitation and management.

Beside the local differences in the elemental distributions the naturally varying Sr isotopic composition of river water, derived from geological differences within the river catchment, provides the basic prerequisite for studying these phenomena based on the microchemical analyses of different fish hard parts.

In order for the elemental and isotopic signature of water getting unambigously reflected in hard parts of fish (like otoliths, scales, vertebrae or fin rays), fish have to stay a certain time in an habitat for equilibration and sufficent uptake of the environmental information. However, the time needed for equilibration and for incorporating a unique signal is unknown and differs between species and life stage.

Laser ablation coupled to multi-collector inductively coupled plasma mass spectrometry (LA-(MC)-ICPMS) was used for the determination of elemental concentrations and Sr isotope ratios in fish hard parts for studying the potential reflection of short term migrations and habitat changes. Much effort has been made with respect to the optimization of laser parameters in order to achieve best spatial resolution on different hard parts of fish while keeping uncertainties as low as possible. Fish from different sources (natural, aquaculture) and the related water chemistry were investigated. In addition, a caging experiment was conducted to study the uptake of environmental information into fish hard parts under semi-controlled conditions. European chub, *Squalius cephalus* (L.), for example, were moved between rivers with contrasting water chemistries and exposed in cages for three and six months. The main aim was to determine the required time of residence of a fish in a certain habitat to create a unique signal matchting the river environment when LA-(MC)-ICPMS is used for the determination of both elemental concentrations and Sr isotope ratios. The major focus was set on the analyses of otoliths, vertebrae, scales and fin rays, with the latter two options representing important non-lethal sampling alternatives.

Herein, we present our latest results on on different fish hard parts measurements using LA-ICMPS, including a discussion about the implications of the results for an application of this technology to fish ecological questions.

Thermodynamic properties of antlerite, brochantite, and posnjakite

A. H. ZITTLAU[1*] AND J. MAJZLAN[1]

[1*]Institute of Geosciences, Friedrich-Schiller University, Jena, Germany, (*correspondence: Arne.Zittlau@uni-jena.de)

Weathering of primary copper minerals (e.g., chalcopyrite, bornite) leads to the formation of secondary copper sulfates, phosphates, and arsenates. In this work, we focused on Cu sulfate-hydroxide minerals antlerite ($Cu_3SO_4(OH)_4$), brochantite ($Cu_4SO_4(OH)_6$) and posnjakite ($Cu_4SO_4(OH)_6 \cdot H_2O$). We synthesized these phases in the laboratory and measured their thermodynamic properties.

The synthesis procedure was a titration of a 0.1 M sodium hydroxide solution into a 0.001 M solution of copper sulfate. The temperature of the $CuSO_4$ solution ranged from 25 to 80 °C and the end-point pH was set between 6 and 11. By variations of temperature and the end-point pH, the precipitates contained brochantite, posnjakite, and tenorite (CuO). We were able to determine systematic variations of the nature of the precipitated product with temperature and pH. Antlerite was synthesized as described in [1]. All these samples were characterized by X-ray diffraction (XRD). Subsequently, the best samples were analyzed by scanning electron microscopy (SEM) for phase purity and prepared for calorimetric measurements.

The calorimetric measurements were carried out by an acid-solution calorimeter at T = 298 K in 5 N HCl as the solvent, using CuO, $CuSO_4 \cdot 5H_2O$, and KCl as the reference compounds. For all measurements, appropriate thermochemical cycles were constructed. The formation enthalpies ($\Delta_f H^0$) of antlerite, brochantite and posnjakite are -1734.9±4.0 kJ/mol, -2157.8±7.0 kJ/mol, and -2457.1±7.0 kJ/mol, respectively.

The results presented here will be soon augmented by heat capacity measurements and standard entropy calculations. Once the data are complete, we will calculate phase diagrams and compare them to the synthesis results described above. Our ultimate goal is a comprehensive model of Cu- and sulfate-rich fluids present in oxidation zones of ore deposits and tailings of Cu ores.

19c. Kinetics of interfacial geochemical processes

We investigated the early stage of muscovite alteration combining chemical analysis of the interacting solution with *in situ* Atomic Force Microscopy determinations of the reacting mineral surface. Experiments were carried out using a liquid cell of an Atomic Force Microscopy determining simultaneously the evolution of the reacting fluids and the nanometers size details of the mineral surface. The state of the muscovite monocrystal's pristine (001) surface after cleavage was observed to be perfectly flat, with no apparent evidence of defect points or dislocations. The surface's molecular periodicity resolution showed the hexagonal-like formations typical of the nanoscale occurrence of Si-centered tetrahedral arrangements along muscovite sheets. However, when a solution was introduced in the liquid cell by way of a peristaltic pump, pits appeared rapidly displaying a stair-shape pattern consistent with the mineral structure of a T-O-T periodicity. This early stage evolution is responsible for the stoichiometric Al/Si ratio in solutions. Our nanometer scale determinations allowed us to estimate the anisotropic loss of matter generated by the step movement. We found the directional lateral velocity $\mathbf{V}_{(hk0)}$ to be 3 fold higher than the basal velocity $\mathbf{V}_{(00l)}$, demonstrating the higher reactivity of the lateral compared to basal surfaces during the dissolution process. The directional velocity of dissolution at the lateral face decreased by more then one order of magnitude for a 5-fold increase in pH, while velocity at the basal face did not change significantly as a function of pH. We observed also the formation of new phases of nanometer size that coating the dissolving mineral surface inhibits the step movement with consequence loss in congruency. Coatings that initially form at the lateral higher reactive faces control the overall dissolution process. Coat formation and growth depends on both aqueous solution composition and dissolving mineral structure.

[5]Institute of Marine Sciences, UC Santa Cruz, Santa Cruz, USA, Flegal@ucsc.edu

Background

Seawater was collected from the California Current Upwelling Zone in the northeast Pacific to investigate factors influencing cadmium concentrations and isotopic compositions in that dynamic region. As expected, cadmium and nutrient (phosphate, nitrate) concentrations were highly correlated both (i) in the cores of intense upwelling eddies and (ii) in relaxed and downwelling eddies [1]. Cadmium isotopic composition of those waters and associated plankton were then compared to test the hypothesis that primary productivity accounts for the relative depletion of lighter cadmium isotopes in surface seawater [2]. Cadmium isotopes in seawater were also compared with iron and zinc concentration data to further resolve factors contributing to the cadmium isotope depletion in surface waters.

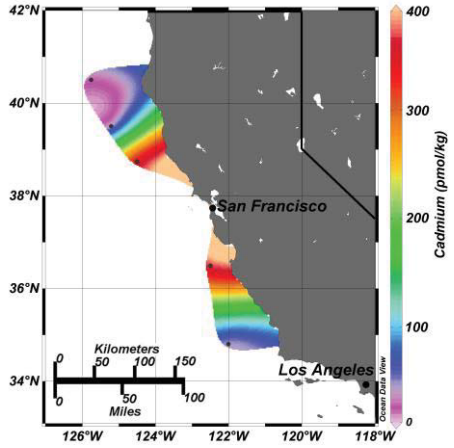

Figure 1: Cadmium concentration (pmol/kg) in the surface waters of the California Current Upwelling Zone.

Preliminary Results

Preliminary results show that freshly upwelled waters have similar cadmium isotopic signatures as deep waters. Nutrient rich waters that had large phytoplankton blooms with subsequent nutrient drawdown showed isotopic fractionation consistent with previous hypotheses [2, 3] and correlate with Fe and Zn data.

Over the last decade constraining the timeframe of brittle faulting has been applied successfully in many case studies. We present fault gouge illite age data from several studies in the European Alps, Finland and Japan. All studies deal with igneous or metamorphic rocks collected from tunnel or drill core samples, which offer a unique advantage as no detrital illite is present in the host rock, thus reducing potential contamination and weathering sources. The age data were obtained using a simplified and standarized method described by Zwingmann et al. (2010). Illite ages range from the Mesoproterozoic (1240±26 Ma) for the Finland samples to the Neogene (6.0±2.1 Ma) for the European Alps study.

For the European Alps study, samples were collected from the AlpTransit tunnel and the K-Ar ages for illite fractions range between 9.5 and 3.9 Ma.

The remarkable dating of Mesoproterozoic and Neoproterozoic ages for the Finnish brittle faults proves the potential of the technique also in the case of extremely old cratonic terranes and their faulting histories. In addition, the preservation of both Meso- and Neoproterozoic isotopic signatures within one single fault core and the geologically meaningful dating of two coexisting but texturally different gouges of different age document a rare case of age determination of a faulting episode and of a subsequent reactivation in the brittle realm.

Within the Japan case study, gouge samples were investigated from a subsurface fault collected within a shaft in the Cretaceous Toki granite. The K-Ar ages of the fractions with no detectable contamination from detrital K-bearing minerals range from 53 to 43 Ma.

In all case studies the illite ages generally decrease with grain size, and they are consistent with the cooling history of the host rocks as bracketed by AFTA and ZFTA ages. The data indicate that that the fault-rock samples formed within the stability field of illite and the main temperature field of brittle deformation (<300°C). The internal consistency of the K-Ar ages of fault gouges from both surface and subsurface samples, as well as their consistency with constraints from field relationships and existing geochronological data demonstrate the potential of this simplified method for providing new data to constraint absolute timing of brittle deformation.
