Abstract

Groundwater recharge and discharge relation along the flow path in the regional catchment of Samail, Oman has been investigated using different isotopes and conventional hydrochemistry. The subsurface geology is complex and variable ranging from karstified carbonate rocks at the elevated areas of North Oman Mountains (NOM) to fractured ophiolitic sequence overlain by porous medium of Quaternary alluvium gravel at the top of the geologic section. The alluvium is thickening from elevated area downstream to exceed 300 m at the lower reaches of the catchment. The boundary between the carbonates and the ophiolites is controlled by a major thrust along which several springs are originating. Groundwater generally flows south-north with a hydraulic gradient decreasing to the south.

Groundwater samples (total 74) from deep and shallow wells as well as springs were analyzed for the isotopes C^{14}, ^{2}H, O^{18} and $^{87}Sr/^{86}Sr$ and major cations and anions. Carbon-14 dating (18.9 ka to modern), wells hydrograph analyses, $^{87}Sr/^{86}Sr$ data (0.70810 – 0.70895) and ^{2}H, O^{18} suggest two main sources of recharge: 1- direct infiltration through stream bed into alluvium and 2- recharge from carbonates lineaments and fissures into the alluvium and ophiolites. The recharge of the alluvium takes place across the entire catchment. The wells hydrograph analyses and $^{87}Sr/^{86}Sr$ data (0.70810 – 0.70895) show that the alluvium and Ophiolite are partly interconnected and recharged by the same water source with a delayed recharge response of 2-3 months. Groundwater in the southern part of the catchment is isotopically depleted water indicating a high altitude recharge source, whereas deviation from meteoric water line in the lower catchment indicates the effect of evaporation.

Spring discharge from the NOM down the gradient indicates local, intermediate and regional flow systems of a groundwater residence time ranging between a few years to a maximum of ca 10K years at the terminal end of flow. The Ca:Mg ratio varies in the different rock types indicating the influence of geology on the hydrochemistry.

Petrographic and geochemical characteristics of the Oman ophiolite lower crust

B. ABILY[1*], G. CEULENEER[1], M. GRÉGOIRE[1], M. PYTHON[2] AND M. BENOIT[1]

[1]CNRS, UMR 5563, Laboratoire Géosciences Environnement Toulouse, Observatoire Midi-Pyrénées, Toulouse, France (*presenting author: benedicte.abily@get.obs-mip.fr; georges.ceuleneer@get.obs-mip.fr; michel.gregoire@get.obs-mip.fr; mathieu.benoit@get.obs-mip.fr)

[2]Hokkaido University, Department of Natural History Science, Division of Earth and Planetary Systems Sciences, Sapporo, Japan (marie@mail.sci.hokudai.ac.jp)

Layered cumulates making up the lower crustal section of the Oman ophiolite are largely considered as the result of the fractional crystallization of normal mid-ocean ridge basaltic (N-MORB) melts at low pressure. A glance to former studies reveals however that layered cumulates have been explored only in some massifs and that no global petrological study of this unit has been performed at the ophiolite scale. Moreover, in the mantle section, melt migration structures are filled with cumulates from two contrasted parental melts: one with a N-MORB tholeiitic affinity and one with a depleted andesitic affinity, this latter being the most widespread [1].

In order to better constrain the origin of layered cumulates in the Oman ophiolite, we have conducted a petrographic and geochemical study (electron microprobe and LA-ICP-MS) on about 700 samples from the lower crustal section of seven major massifs. We discovered that abundant (~15%) primitive cumulates (XMg>80%) are characterized by the early crystallization of orthopyroxene implying parental melts significantly richer in SiO_2 than N-MORB. Moreover, at the same differentiation degree, plagioclases of the layered cumulates are richer in anorthite and clinopyroxenes (cpx) are more depleted in Al_2O_3, TiO_2 and Rare Earth Elements (REE) than N-MORB cumulates. These characteristics are reminiscent of boninitic-andesitic melts although layered cumulates do not present the extreme depletion in High Field Strengh Elements (HFSE) and the REE patterns typical of supra-subduction zone boninites. The simplest way to account for these observations is to invoke mixing between N-MORB melts extracted from an asthenospheric source and silica enriched melts produced by hydrated re-melting of a depleted lithospheric source, both melts migrating in mantle channels before feeding magma chambers.

We used TiO_2 in cpx to semi-quantitatively determine the contribution of both magmatic end-members to parental melts in selected stratigraphic cumulative sections distributed along the ophiolite. This quantification in a key massif displaying a diapiric structure [2] reveals that the relative contribution of both sources evolved during the upwelling of the asthenospheric diapir within the lithosphere, an observation in agreement with melt migration structures distribution in the mantle section of this massif.

Geochemistry of upper mantle xenoliths and host basalts from NE Bavaria

LUKÁŠ ACKERMAN[1*], PETR ŠPAČEK[2], JAROMÍR ULRYCH[1]

[1]Institute of Geology v.v.i., Academy of Sciences of the Czech Republic, Rozvojová 269, 165 00, Praha 6, Czech Republic, ackerman@gli.cas.cz (* presenting author)

[2]Institute of Geophysics v.v.i., Academy of Sciences of the Czech Republic, Boční II, 141 34, Praha 4, Czech Republic

Introduction

The European Cenozoic Rift System (ECRIS) volcanics contain abundant upper mantle xenoliths. Their composition ranges from lherzolite to dunite with subordinate pyroxenite and they record complex histories including different partial melting degrees and basaltic/carbonatitic melt metasomatism [1,2,3]. We studied mantle xenoliths and their host lavas from Zinst, Hirschentanz and Teichelberg (NE Bavaria, Germany).

Host basalts

The host lavas have composition of basanites (based on TAS classification), have typical LREE-enriched patterns (La_N/Yb_N = 17-24) and show enrichment in trace elements (e.g., LILE, Nb), but depletion in K and Pb. Their Sr-Nd isotopic composition calculated at 30 Ma is similar ($^{87}Sr/^{86}Sr_{30Ma}$ = 0.7033-0.7035, ε_{Nd30Ma} = +4.0-4.6). However, Teichelberg basanite has more radiogenic $^{143}Nd/^{144}Nd$ (ε_{Nd} of +4.6), but less radiogenic $^{87}Sr/^{86}Sr$ (0.7033). Nevertheless, this Sr-Nd composition is similar to those of the European Astenospheric Reservoir. All these signatures suggest basanite derivation from garnet- and phlogopite/amphibole-bearing subcontinental lithospheric mantle.

Mantle xenoliths

The abundant xenoliths at Zinst, Hirschentanz and Teichelberg are mostly of spinel lherzolite composition with rare occurence of harzburgite. Coarse-granular types with strain-free grains predominate, however the textures are mostly non-equilibrated with olivine typically displaying non-unimodal grain-size and grain-shape distributions. Rare transitions to high-stress porphyroclastic textures suggest weak, late deformation. Spinel occurs as individual, mostly rounded grains or form sympletitic intergrowths with pyroxenes. In some xenoliths, symplectites recording complex multiphase garnet decomposition in presence of melts/fluids were identified. Spinel lherzolites with predominance of orthopyroxene over clinopyroxene were selected for analyses. They have fairly homogeneous equilibrium temperatures for the entire suite from 940 to 1040 °C. Variable Al_2O_3 contents and negative correlation between MgO and other major oxides likely suggest different partial melting degrees. On the other hand, the entire xenolith suite is significantly, but variably enriched in LREE (La_N/Yb_N = 3.5-23) and other trace elements (e.g., Rb, U, Sr, Pb), but depleted in Th and HFSE (Zr, Hf, Nb). This suggests cryptic metasomatic overprint by melt and/or fluid. Extremely variable CaO/Al_2O_3 ratios ranging from 0.5 to 1.6, the presence of common melt pockets containing carbonate and the negative HFSE anomalies may suggest metasomatism by alkaline and/or carbonatitic melts.

Experimental investigation of Ti in garnet at eclogite facies conditions

MICHAEL R. ACKERSON[1*], E. BRUCE WATSON[1], FRANK S. SPEAR[1]

[1]Department of Earth and Environmental Sciences, Rensselaer Polytechnic Institute, Troy, NY 12180, USA *ackerm3@rpi.edu (presenting author)

Garnet is a common mineral in metamorphic systems over a wide range of temperatures and pressures whose crystal chemistry has allowed for the calibration of several useful garnet-based geothermometers. Designing additional garnet-based thermometers could aid in the interpretation of metamorphic systems and deepen our understanding of the evolution of the crust. Developing such thermometers is dependent on our understanding of the nature of elemental substitutions within garnet. In this study we focused on understanding the nature of Ti incorporation into garnet and the possibility of Ti-based garnet geothermometers.

Garnets were grown in basalt, pelite and amphibolite bulk compositions. The bulk starting materials were doped with 5 wt. % TiO_2 to ensure saturation in either rutile or ilmenite. In addition, 1 wt. % ZrO_2 was added to saturate in zircon, and 10 wt. % H_2O to achieve water saturation. In some cases seed garnets were included in the experiments to facilitate new garnet growth. Experiments were conducted at temperatures ranging from 800-900ºC, pressures between 1.5-2.5 GPa, and they were buffered at QFM. The runs were preformed in silver capsules on a piston-cylinder apparatus. The compositions of minerals and the melt were analyzed by electron microprobe and LA-ICPMS. Accurate microprobe measurement of Ti content in garnets was complicated by secondary fluorescence from ilmenite and rutile crystals that occurred as inclusions in most garnets.

Typical phase assemblages from these experiments include garnet, clinopyroxene, ilmenite and melt ± rutile. Measured Ti concentrations in garnet range from ppm up to 2.5 wt % and these preliminary results show that the Ti concentration does not depend solely on temperature. Rather, a negative correlation between Ti and Al may indicate that the main mechanism for entry of Ti into the garnet lattice is a coupled substitution on the octahedral site ($Ti^{4+} + M^{2+} \leftrightarrow 2Al^{3+}$, where $M^{2+}=Mg^{2+}$, Fe^{2+}, or Mn^{2+}). If this mechanism is valid, then equilibria controlling the Ti concentration must include phase components other than those in garnet that will define the tschermak activity and application of Ti-based garnet geothermometers will require accurate activity models these components in the system.

Instantaneously developed crustal geochemical signatures in anatectic melts, and melt interconnection in the protolith

ANTONIO ACOSTA-VIGIL[1*], JÖRG HERMANN[2], DAVID LONDON[3] AND GEORGE B. MORGAN VI[3]

[1] CSIC-Universidad de Granada, IACT, aacosta@ugr.es (* presenting author)
[2]The Australian National University, RSES, joerg.hermann@anu.edu.au
[3]The University of Oklahoma, SGG, dlondon@ou.edu, gmorgan@ou.edu

One important issue to investigate in Earth Sciences is the rate of natural processes. Crustal anatexis and granite formation is key for understanding the generation and differentiation of the continental crust.

We have conducted an experimental program on the melting of solid rock cylinders of pelitic composition, 3-6 mm in diameter and 5-20 mm in length, at 690-800ºC, 200 and 700 MPa, under dry and wet conditions and for durations ranging from 1 hr to 60 days. The starting material is a schist with a mineral assemblage made of Ms+Bt+Crd+Pl+St+And, trace Kfs and accessories Gr+Ilm+Zrn+Mnz+Xen. All experiments produced variable proportions of melt that quenched to glass, and that was analyzed by electron microprobe and laser ablation ICP-MS.

Results show that granite melts can be generated, and likely interconnected throughout the entire protolith, in just hours to a few days, during anatexis at H_2O-saturated ($a_{H2O}\approx1$) but also H_2O-undersaturated ($a_{H2O}<<1$) conditions. Melting starts simultaneously along Qtz-Pl and Qtz-Ms interfaces and Qtz-Pl-Ms junctions distributed throughout the entire core, resulting in rapid melt interconnection. Microstructural observations indicate that residual Pl and Crd recrystallize even at low degrees of overstepping in temperature. Typically crustal geochemical signatures in the melt are developed extremely rapid in terms of both major and trace element compositions. For instance, melts from H_2O-undersaturated experiments at 730ºC and 700 MPa show, after 7 days, mean concentrations of ≈170 (s.d.=45) ppm Rb, ≈150 (65) ppm Sr, ≈6 (1) ppm Sc, ≈12 (9) ppm Zr and ≈25 (10) ppm ∑REE. Likewise, melts generated during H_2O-saturated anatexis at 730ºC and 700 MPa show, after only 4 days, mean concentrations of ≈110 (30) ppm Rb, ≈170 (60) ppm Sr, ≈5 (2) ppm Sc, ≈22 (8) ppm Zr and ≈60 (28) ppm ∑REE. Although heterogeneous, the compositions of these melts are similar to S-type leucogranites and glasses in anatectic metasedimentary enclaves.

This data implies that granitic melts loaded with trace elements can potentially be generated and extracted rapidly from the source. The results have implications for the transport mechanisms of certain trace elements (e.g. Zr, LREE) thoroughout granite melts, as well as for the calculation of melt residence times by using the measured concentrations of these trace elements in granites. However, the effect of the rate of heat supply (infinite, in these experiments) on the rate of melting and the composition of melt might represent a limitation for the general applicability of these results.

Five years of Keck OSIRIS observations of Titan: quantifying the transport of aerosol haze

MÁTÉ ÁDÁMKOVICS[1*] AND IMKE DE PATER[1]

[1]Astronomy Department, University of California, Berkeley, CA USA mate@berkeley.edu (* presenting author)

Abstract

We present spatially-resolved observations of Titan in the near-infrared obtained with the field integral spectrograph, OSIRIS, at the W. M. Keck Observatory. Datacubes were acquired in H (1.5 μm) and K (2 μm) bands from April 2006 to January 2012. Broadband spectra reveal the aerosol vertical structure from the surface through the stratosphere. We describe the temporal and spatial variation in aerosol distribution as constrained by our radiative transfer models, which include updates to methane opacity and aerosol scattering.

Observations

The OSIRIS imaging spectrograph is behind the adaptive optics system on the Keck II telescope. The instrument uses a 2048 × 2048 pixel Rockwell Hawaii-2 detector, which in our observing mode corresponds to at a spatial plate-scale of 0.020" and a spectral resolution (λ/δλ) of ~4000. We observe in both H- and K-bands when possible, covering 1.473–1.803 and 1.965–2.381 μm, respectively. The field of view is 0.32" × 1.28", such that four ~5min exposures are required to cover the entire ~1" diameter disk of Titan. We obtain datacubes on an approximately yearly basis between Apr 2006 and Jan 2012. Data are reduced using the OSIRIS data reduction pipeline, which includes flat-fielding, sky-subtraction, cosmic-ray rejection, wavelength calibration, spectral extraction and datacube assembly. Mosaicking of individual exposures is not performed with the pipeline due to spurious data near the edges of the field of view, likely caused by faulty lenslet masking. While individual exposures are nearly diffraction-limited in spatial resolution, assembling datacubes into mosaics is often limited by systematic offsets of up to a few pixels between exposures.

Aerosol Opacity Retrieval

Our models incorporate well-established numerical solutions to the radiative transfer equation and successfully simulate observations [1,2,3]. A discrete ordinates method is used with 16 pseudo-plane-parallel layers from 0 – 200 km altitude. The atmospheric vertical structure and aersol scattering measured by the Huygens probe is used as the default in the model. We explore several methods of scaling and varying the aersol structure for geographic locations and times when the Huygens probe measurements no longer apply.

Results

We describe an algorithm for navigating and reconstructing datacubes while selecting against lenslet masking artifacts. Mosaicked datacubes are used to retrieve the spatially-resolved atmospheric aerosol distribution on Titan with our radiative transfer model. We describe how the slow seasonal variation in the latitudinal haze gradient is punctuated by episodes of increased scattering.

Applications of Raman XYZ mapping in the Earth sciences

FRAN ADAR[1], DAVID TUSCHEL[1] , AND ROBERT BODNAR[2,*]

[1]HORIBA Scientific, Edison, NJ, U.S.A., fran.adar@horiba.com; David.tuschel@horiba.com

[2]Virginia Tech, Blacksburg, VA, U.S.A., rjb@vt.edu

Introduction

Raman spectroscopy is a powerful tool that has been applied widely in the earth sciences to characterize a variety of fluid and solid materials. While microspot Raman analyses have been used with great success to identify and characterize materials, it has previously been less useful for characterizing minor components in samples and for characterizing sample heterogeneities. The recent development of high-speed, high resolution mapping capabilities using the SWIFT™ (Scanning With Incredibly Fast Times)[1] apparatus now makes it possible to obtain high spectral, high spatial resolution Raman maps quickly and easily.

Applications

One of the most successful applications of Raman spectroscopy in the earth sciences has been to analyze fluid (FI) and melt inclusions (MI). Many fluid phases that are common in FI, including H_2O, CO_2, CH_4, H_2S. etc., are easily recognized and in some cases quantified using their Raman band intensities and/or positions. Recently, there has been much interest in searching for small amounts of H_2O in FI that previously had been thought to contain only CO_2. Confirming the presence of even small amounts of water in FI is important in understanding some upper mantle processes in which, as a result of exposure to high temperatures and pressures, hydrated minerals lose water that may then occupy FI. At room temperature the liquid H_2O phase occurs as a thin, sub-microscopic rim on the walls of the inclusion, it has therefore been diffficult, if not impossible, to locate the H_2O film using spot analysis. Raman mapping, however, facilitates the search for H_2O in these inclusions and provides a rapid method to survey large numbers of FI to see which, if any contain H_2O.

Key to implementation of this method is the rapid mapping of many inclusions. This is achieved with SWIFT™ in which the sample is translated continuously and the detector readout is synchronized with that motion. Multivariate analysis methods are used to construct the Raman maps and indicate the presence, in this case, of the water. The same mapping technique has been used to examine the distribution of water in silicate melt inclusions, and to compare cathodoluminescence zones in zircon with the degree of metamictization of the sample based on Raman peak positions.

The Ediacarian Nitrogen Isotope Conundrum

MAGALI ADER[1*], PIERRE SANSJOFRE[1], GALEN P. HALVERSON[2], RICARDO TRINDADE[3]

[1]IPGP, Paris, France, ader@ipgp.fr (* presenting author), sansjofre@ipgp.fr

[3]AIG-USP, Sao Paulo, Brazil, rtrindad@iag.usp.br

Nitrate cycling and isotope composition ($\delta^{15}N$) in the oceans are strongly linked to the water column redox structure via its control on nitrogen speciation. The present-day nitrate $\delta^{15}N$ in the oceans results from the balance beween molecular nitrogen fixation, which yields nitrate close to 0‰, and water column denitrification which increases residual nitrate $\delta^{15}N$ [1]. In upwelling zones, where disoxic conditions result in partial denitrification, residual nitrate $\delta^{15}N$ are usually higher than +5‰. Since surface sediments most often record the $\delta^{15}N$ of the nitrogen source used by primary producers and changes minimally during diagenesis, sediment $\delta^{15}N$ can be used as a proxy for water column redox structure and nutrient influx [2]. During the Phanerozoic, sedimentary $\delta^{15}N$ values typically cluster close to 5‰, except during ocean anoxic events (OAEs), when values are close to 0‰ [3]. These low $\delta^{15}N$ values are attributed to a complete removal of fixed nitrogen species at the chemocline, which leaves nitrogen fixation as the dominant pathway of N assimilation.

The Ediacarian Period is expected to have seen a long-lived ocean redox stratification and the onset of deep ocean oxygenation. Hence significant variations in sedimentary $\delta^{15}N$ values are to be expected in Ediacarian succesions. Yet, hardly any $\delta^{15}N$ data have been published so far for this period. We present preliminary $\delta^{15}N$ data for 5 different Ediacarian platforms (South China, Svalbard, Canada, Brasil). Most of these platforms preserve separate evidence for redox stratification, but most of the data range between 3 and 6‰, with a few outliers reaching 1 or 9‰. These data suggest either a dominantly oxic Ediacaran ocean at odds with other proxies (geochemistry, sulfur isotopes and iron speciation), or an Ediacarian marine nitrogen cycle that operated very differently from Phanerozoic OAEs.

Biomineralization in Corals and the The Hunt for New Tracers of the Past Ocean

JESS F. ADKINS[1]* AND ALEX GAGNON[2]

[1]Dept. of Geology and Planetary Sciences, Caltech, Pasadena, CA, USA, jess@gps.caltech.edu

[2]Earth Science Division, LBNL, Berkeley, CA, USA, acgagnon@lbnl.net

Geochemical records from biogenic carbonates are a mainstay of our understanding of past climates. Isotopic and elemental abundances are often correlated with aspects of the modern water column to 'calibrate' a tracer. Even in light of large offsets from chemical equilibrium, this approach has served the field very well. Emiliani demonstrated that there were donzens (not four) major glaciations in the past few million years. Yet the $\delta^{18}O$ tracer he used is still debated today for what part of its signal is climate and what part is 'vital effect'. In light of both these sucesses and challenges, it is our hope to show how the study of disequilibrium effects can lead to better paleo tracers.

We have been using deep-sea corals as a natural laboratory for studying these vital effects because they grow in modern seawater with relatively constant conditions. Our approach has been to first demonstrate that corals use seawater as the basis for their calcifying fluid which is then modified by specific biological processes before deposition in the skeleton. This direction was first outlined by McConnaughey over 20 years ago and while the details of his models have been challenged his basic approach is still important today. We will review work on the stable isotopes of carbon and oxygen, Mg/Ca, Sr/Ca, U/Ca, and several other tracers in an attempt to build a better understanding of how corals calcify and how this affects the record of past climate. Using a Rayleigh model of Me/Ca uptake into the skeletons we propose a new thermometer based on the trend of data from a single individual in Mg/Ca versus Sr/Ca space. In general, the use of simple models, while ignoring important concepts like organic membrane mediation of tracer incorporation, can both guide the development of new tracers and inform the variance already found for more established proxies.

Reduced Mixing Between Two Deep Ocean Cells During the LGM and a Theory for the Cold Phase of Glacials Cycles

JESS F. ADKINS[1]*

[1]Dept. of Geology and Planetary Sciences, Caltech, Pasadena, CA, USA, jess@gps.caltech.edu

In the mid-80s the three so called 'Harvarton Bears' box models emphasized the role of the Southern Ocean in setting past pCO_2 values. This seminal work has sparked a large data collection effort, many related theories of glacial CO_2 cycles, and intense debate. The core message is that a combination of lower Southern Ocean overturning and increased biological nutrient utilization efficiency (phrased at the time as increased biological production) in the polar Antarctic can lower pCO_2 to the LGM value. It is widely accepted that neither process on its own can give rise to the full glacial to interglacial change, and that carbonate compensation also plays an important role in any scenario of pCO_2 lowering. In this work I would like to explore the role of deep ocean mixing as another important process in setting the LGM pCO_2.

There is evidence from casting d18O as a conservative tracer that the ratio of transport to mixing in the deep Southern Ocean was much larger during the LGM. I interpret this measurement as indicating vertical mixing was lower during the glacial and explore two possible ways this could have come about. Both shoaling of the interface between northern and southern sourced deep waters to lie above the rough topography of the mid-ocean ridges, and the filling of the ocean with cold-salty bottom water can lead to much lower values of deep ocean mixing. With a simple box model I will explore the effects of reduced mixing on pCO_2 in the atmosphere and the carbonate ion content of the deep-sea. Finally, I will propose a hypothesis for how a deep ocean teleconnection around Antarctica, that mechanistically links the density contrast between the northern and southern deep ocean cells, can follow a northern high latitute summer time pace maker and lead from interglacials to glacials. The new theory, however, does not explicitly give rise to terminations.

Stability of garnets to chemical weathering: An experimental study

VALENTIN P. AFANASYEV*[1], OLEG V. SNEGIREV[1], NIKOLAY S. TYCHKOV[1] AND NIKOLAY P. POKHILENKO[1]

[1] V.S.Sobolev Institute of geology and mineralogy SB RAS, Novosibirsk, Russia,
avp-diamond@mail.ru (*presenting author)

Iintroduction

Garnets from kimberlites, mainly pyropes, are unstable to lateritic weathering and dissolve to produce distinct surface patterns [1]. Low-Cr orange garnets are less stable than Cr-rich violet varieties, this being a control for trends in placer pyrope assemblages changing away from the primary deposit. The naturally occurring patterns were reproduced in earlier HF etching experiments on pyropes with monitored weight loss. However, those experiments did not include analysis of composition changes in etched pyropes.

Methods and samples

The chemical stability of garnets from kimberlite has been studied in new experiments in which etching in HF was a good model of natural lateritic weathering. We used 226 pyrope grains of main kimberlite-hosted pyrope varieties. The work included weight loss monitoring and analysis of chemistry and parageneses of the output grains.

Results and Conclusion

The etching experiments demonstrated different degrees of chemical stability in garnets of different parageneses, as a function of Cr contents (Fig. 1).

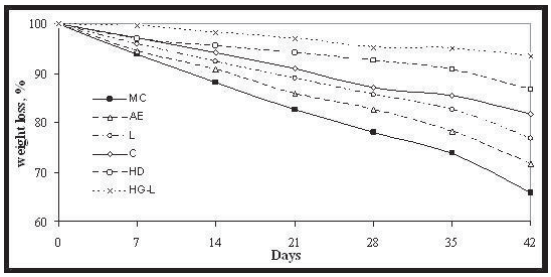

Fig. 1. Stability (weight loss) of garnets to etching in HF. The curves are coded according to assemblages of garnets: MC – megacrysts, AE – wehrlite, L – high-temperature depleted lherzolite, C – normal depleted lherzolite, HD – harzburgite-dunite, HG-L – TiO_2-rich harzburgite-dunite.

The experimental results are well consistent with data from natural pyrope assemblages, specifically, from unweathered pyropes of the Mir kimberlite compared to the weathered ones in the Vodorazdelnye Galechniki (Watershed pebble) placer derived from the same pipe.

Clumped isotopes role in a multi-proxy paleoclimate reconstruction

AFFEK HP[1*], ZAARUR S[1], KLUGE T[1], DUBLYANSKY Y[2], SPÖTL C[2], DOUGLAS P[1], IVANY LC[3], SAENGER C[1], ZHANG YG[1]

[1]Yale University, New Haven, CT, USA, hagit.affek@yale.edu
[2]Universität Innsbruck, Innsbruck, Austria
[3]Syracuse University, Syracuse, NY, USA.

Carbonate clumped isotopes (Δ_{47}) is a temperature proxy that is based on the temperature-dependent preference of ^{13}C and ^{18}O to bind with each other. Δ_{47} of biogenic calcite and aragonite in aquatic organisms (with the exception of fast growing, shallow-water corals) is consistent with a calibration based on laboratory precipitation. Being a thermodynamically controlled proxy that does not depend, at equilibrium, on the composition of the solution in which the carbonate forms, Δ_{47}-based temperatures are better constrained than those from inorganic proxies such as $\delta^{18}O$ and Mg/Ca. It is also better understood than organic proxies such as TEX_{86} that rely on uncertain biological assumptions and unclear calibration. The main disadvantage is the large sample size required, preventing in most cases high-resolution Δ_{47} records. In a multi-proxy approach, clumped isotopes could play a role in high-resolution records, by providing absolute temperatures (and hence water compostions) that are required to constrain the assumptions in other proxies.

We applied clumped isotopes in bivalve shells in concert with the organic temperature proxy TEX_{86} during the Eocene in the Gulf of Mexico and in Seymour Island (Antarctica). Clumped isotope temperatures are consistent with TEX_{86} estimates, although the TEX_{86} calibration that provides the best fit with clumped isotope results varies between high and low latitude environments.

Being independent of the composition of water, Δ_{47} based temperatues can be used to reconstruct water $\delta^{18}O$, often using laboratory precipitation experiments for calibration [1]. However, such laboratory measurements involve relatively fast mineral growth, leading to potential disequilibrium. Calcite growing at an extremely slow rate in Devils Hole (Nevada) is likely to reflect formation under isotopic equilibrium, thus providing a test for the laboratory-based calibrations. Δ_{47} results from Devils Hole calcite yield a constant paleo-water temperature, during both glacial and interglacial periods over the last 180 Ky; it agrees with the modern-day groundwater temperature and confirms that the calcite precipitated at isotopic equilibrium. However, $\delta^{18}O$ is significantly enriched in Holocene calcite as compared to laboratory precipitation calibration [2]. We attribute this difference to the preferential incorporation of light oxygen isotopes during fast mineral growth in laboratory experiments (but not in slow growing Devils Hole calcite), without affecting the ^{13}C-^{18}O distribution that is reflected in Δ_{47}.

LCA of Nanodrugs: Adding Constraints

B. AFFELTRANGER[1*]

[1]National Institute for Industrial Envionment and Risks (INERIS), Chronic Risks Division, BP2 Parc ALATA, 60550 Verneuil-en-Halatte, France, bastien.affeltranger@ineris.fr

Context

It is estimated that inflammatory diseases have now affected more than 80 million people worldwide, and counting. Studies have shown that disorder like rheumatoid arthritis (RA) shortens life span about 10 years. The treatment RA remains a challenge for the medical and scientific community. Vectorisation of active pharmaceutical ingredient(s) (API) is a promising option.

Project aim

NANOFOL proposes to develop a new diagnostic/therapy approach using folate based nanobiodevices (FBN) able to provide a new type of cost efficient treatment for chronic inflammatory diseases such as RA. The FBN is expected to generate low(er) side effects, possibly constituting a solution more advantageous than current therapies.

The concept

NANOFOL undertakes design, development and production of nanobiodevices (FBN) targeting directly effector cells.

Drug assessment issues

Establishing a proof of concept for one or several FBN, and testing it (pre-clinical) is a central aim of the project. However, other aspects of this new therapy shall be assessed – basically consisting in: occupational safety assessment; LCA; socio-economic analysis (SEA). Undertaking these combine difficulties typical of both pharmaceuticals and objects with nanometric caracteristics.

Work presented

This communication presents the key questions raised prior to developing the methodology for LCA and SEA , and how these have been answered. Available knowledge in LCA of nanos could be applied to some extent, as well as guidelines of REACH Regulation (EC). Working out the right hypotheses – a challenge in anticipation of clinical phase trials – did involve experts from the chemical, medical, engineering, social and economic sciences. Therapeutical strategies are introduced as scenarios for running LCA and SEA.

Acknowledgement

The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement NMP4-LA-2009-228827 NANOFOL"

Generating pore fluid isotope and solute profiles in exceptionally low permeability rocks

SARAH AGOSTA*, DALAL HANNA, IVY LIU AND IAN CLARK

Earth Sciences, University of Ottawa, Ottawa, Ontario, Canada, idclark@uottawa.ca, Ratan.Mohapatra@uOttawa.ca

Establishing geochemical and isotopic profiles for aquitard pore fluids is a critical, yet challenging, component of investigations of deep geological settings considered for nuclear waste isolation. A variety of advanced techniques have been developed internationally to extract and analyze pore waters and gases from sediments. However, the exceptionally low-permeability shales and limestones at the Bruce nuclear site, on the eastern margin of the Michigan Basin, demand innovative techniques for the extraction and analysis of pore fluids. Here we describe new methodologies, based on vacuum distillation and diffusive leaching developed to extract water, solutes and gases from rocks with hydraulic conductivities as low as 10^{-15} m s^{-1} and effective diffusion coefficients as low as 10^{-12} m s^{-2}.

Field investigations included the drilling of six cored boreholes to various depths through the ~860 m thick Paleozoic sedimentary sequence at the site. Samples of this high-quality, 76 mm diameter, core were broken to acquire inner material uncontaminated by drilling fluid, and were then crushed to 2-4 mm size to fill four 75 ml Pyrex flasks. Porewater and CO_2 were extracted for content and isotope analysis by heating under vacuum and condensing into 12 ml septum-fitted glass vials. Replicate testing of different rock types found optimum conditions to be 150°C for 6 hours. Solutes were analyzed after leaching with deionized water and normalized to the gravimetrically-measured recovered water content to produce molal concentrations.

The method is well suited to the illite-dominated shales (water contents of 6 to 8%) and for the exceptionally-low water content of the limestones (to less than 1%), as it uses a closed system for water extraction, and reduces error by normalization of solute mass to sample specific water contents. New developments to the method use a closed system ball-mill to crush and then heat smaller chip-samples. This offers greater control for investigating temperatures of release of mineral hydration waters and heterogeneities near permeable features.

Mantle source of back-arc Ecuador volcanoes: insights from B and radiogenic isotopes

SAMUELE AGOSTINI[1*], MATTEO PUERINI[2], ALBERTO RENZULLI[2], AND FILIPPO RIDOLFI[2]

[1]Istituto di Geoscienze e Georisorse, Pisa, Italy, s.agostini@igg.cnr.it (* presenting author)

[2]Dipartimento di Scienze della Terra, della Vita e dell'Ambiente, Urbino, Italy.

The Plio-Quaternary Ecuadorian volcanic arc belonging to the Northern Volcanic Zone (NVZ) of the Andes consists of the Western Cordillera (fore-arc), the Cordillera Real (main-arc) and scattered volcanoes in the rear-arc zone. The largest volcanoes of the rear arc zone are the Sumaco and El Reventador. These volcanoes, despite being located at the same distance from the trench, exhibit erupted magmas of different compositions.

The products of El Reventador are mainly represented by porphyritic lavas, ranging from basalt to rhyolite, with basaltic andesite and andesite being the most abundant. They belong to the medium-K to high-K calc-alkaline series. In contrast, the products of Sumaco are markedly SiO_2-undersaturated and vary from basanite to phonolite. Although both volcanoes show Nb-Ta-Ti negative anomalies typical of subduction-related environments, trace element concentrations are markedly different: modest enrichment in incompatible trace elements is typical of El Reventador lavas, whereas the Sumaco products are strongly enriched in all incompatible elements and show quite low LILE/HFSE ratios (i.e. Ba/Nb 35-105). In addition, El Reventador samples exhibit higher $^{87}Sr/^{86}Sr$ (0.7044-0.7046) and lower $^{143}Nd/^{144}Nd$ (0.51272-0.51280) with respect to Sumaco ($^{87}Sr/^{86}Sr \approx 0.7041$-0.7043, $^{143}Nd/^{144}Nd \approx 0.51284$-0.51297). It is worth noting that the Sr-Nd isotopic fields of the two back-arc volcanoes are well within the Ecuadorian NVZ variation range ($0.7035 < {}^{87}Sr/^{86}Sr < 0.7047$; $0.5126 < {}^{143}Nd/^{144}Nd < 0.5130$) [1]. Nevertheless, El Reventador Sr isotopic ratios are among the highest values of the Ecuadorian volcanic rocks from literature. The two volcanoes show similar and almost constant $^{207}Pb/^{204}Pb$ ratios. The other Sumaco Pb isotope ratios ($18.738 < {}^{206}Pb/^{204}Pb < 18.858$; $38.525 < {}^{208}Pb/^{204}Pb < 38.594$) are comparable with the overall Ecuadorian isotope variations ($18.700 < {}^{206}Pb/^{204}Pb < 19.150$; $38.450 < {}^{208}Pb/^{204}Pb < 38.950$[1]), whereas El Reventador lavas have the lowest $^{208}Pb/^{204}Pb$ and $^{206}Pb/^{204}Pb$ among all the other ecuadorian volcanoes (38.408-38.506 and 18.541-18.682, respectively). Even B isotopes are clearly distinct, with $\delta^{11}B$ ranging from -1.0 to -2.5 for El Reventador samples and -5.2 to -7.2 for the Sumaco samples.

All of this suggests that the erupted magmas of these rear-arc volcanoes represent two different mantle sources. The Sumaco product's source is consistent with very low degrees of partial melting due to the metasomatization of a supra-slab mantle wedge by small amounts of ^{11}B-depleted fluids released from subducted AOC and sediments. In contrast, under the El Reventador volcano a carbonatic sediment component (with low $^{206}Pb/^{204}Pb$ and high $\delta^{11}B$) is invoked as significant agent of mantle wedge metasomatization.

Carboxyl group $\delta^{13}C$ values of naphthenic acids: A novel approach to source discrimination

JASON M. E. AHAD[1*], HOOSHANG PAKDEL[2], MARTINE M. SAVARD[1], KERRY M. PERU[3], AND JOHN V. HEADLEY[3]

[1]Geological Survey of Canada, Natural Resources Canada, Québec City, Canada, Jason.Ahad@nrcan.gc.ca (* presenting author), MartineM.Savard@nrcan.gc.ca

[2]INRS Eau Terre Environnement, Québec City, Canada, Hooshang.Pakdel@ete.inrs.ca

Naphthenic acids (NAs) are a complex mixture of alkyl-substituted acyclic and cycloaliphatic carboxylic acids naturally present in bitumen that become concentrated in oil sands process waters (OSPW). Difficult to characterize and quantify, NAs are highly toxic to aquatic organisms and thus pose a significant threat to the environment. Here we report a novel method to isolate and characterize NAs for use in source apportionment studies. NAs were extracted from a range of water samples and isolated into different mass fractions using preparative capillary gas chromatography (PCGC) prior to carboxyl group carbon $\delta^{13}C$ analysis ($\delta^{13}C_{carboxyl}$) by thermal conversion / elemental analysis – isotope ratio mass spectrometry. As the processes involved with bitumen recovery may result in a unique isotopic fingerprint in OSPW, our goal was to understand the variability in $\delta^{13}C_{carboxyl}$ of NAs in order to determine their potential to discriminate sources.

Results and Conclusion

The $\delta^{13}C_{carboxyl}$ ratio showed little variation within a given sample, demonstrating no significant isotopic differences between various mass fractions of NAs. The $\delta^{13}C_{carboxyl}$ value for unprocessed oil sand was -22.6‰ and did not vary considerably from that measured in OSPW (-21.8 ± 0.5‰). These results suggest that $\delta^{13}C_{carboxyl}$ of NAs cannot be used to distinguish between process-derived and natural background NAs. However, in samples taken along an OSPW-impacted groundwater transect, $\delta^{13}C_{carboxyl}$ values show a slight yet significant ^{13}C-depletion (~3‰) down-gradient away from the source. In conjunction with data from high-resolution Orbitrap mass spectrometry analyses used to identify NAs in these samples, the isotopic results point to a potential contribution from an additional source of "acid extractable" organic matter other than OSPW-derived NAs. This research highlights the need for accurate characterization of naphthenic acids in order to distinguish between anthropogenic and natural organic matter sources.

The Role of Microorganisms in the diversity and distribution of siderophores in Podzolic Forest Soil

ENGY AHMED*, SARA J. M. HOLMSTRÖM, VOLKER BRÜCHERT AND NILS G. HOLM
Department of Geological Sciences, Stockholm University, Stockholm, Sweden
(* Presenting author): engy.ahmed@geo.su.se

Iron is a key component of the chemical architecture of the biosphere. Due to the low bioavailability of iron in the environment, microorganisms have developed specific uptake strategies. The most important one is the production of siderophores, which are operationally defined as low-molecular-mass biogenic Fe (III)-binding compounds which may greatly increase bioavailability of Fe [1]. One of the primary biogeochemical functions of siderophores is therefore to increase Fe bioavailability by promoting the dissolution of iron-bearing minerals [2]. This study aims to understand the role of microorganisms in the chemical diversity and distribution of siderophores in podzol soil and how this diversity can contribute to the bioavailability of Fe in forest soil.

Soil samples were collected from an experimental site in the area of Bispgården in central Sweden (63°07′N, 16°70′E) from the O (organic), E (eluvial), B1 (upper illuvial), and C (mineral) horizons. Concentration and chemical composition of dissolved and adsorbed siderophores in the soil samples were determined using colorimetric assays and high-performance liquid chromatography.

The highest siderophore concentrations were found in the O layer and thereafter decreased by depth. Concentrations of dissolved hydroxamate, catecholate and carboxylate siderophores were up to 84, 17 and 0.2 nmol/ g soil, respectively. In contrast, concentrations of adsorbed hydroxamates, catecholates and carboxylates were only up to 1.8, 3 and 0.2 nmol/ g soil, respectively.

Siderophore-producing microorganisms were isolated from the same soil samples. Viable fungi, bacteria and actinomycete counts ranged from 7 to 300, from 300 to 1800, and from 0 to 5 cfu/gm, respectively. The highest counts were found in the O and E layers. Only the E layer contained the three types of siderophore-producing microorganisms investigated in this study. Siderophores were extracted from culture filtrates of the isolated microorganisms when grown under iron-limited conditions. These extracts varied considerably in siderophore composition. Fungal isolates produced up to 183 µM of hydroxamates, especially those isolated from the O layer, whereas bacteria and actinomycete isolated from the O and E layers of the soil produced high amounts of carboxylate, catecholate and hydroxamate siderophores. Actinomycete produced up to 93 µM of hydroxamates and 47 µM of catecholates, while bacteria produced up to 34 µM of carboxylates and up to 14 µM of catecholates.

The depth variability in concentration and chemical composition and the good correlation between abundance of siderophore-producing microorganisms and siderophore soil concentrations strongly suggest that these siderophore-producing microorganisms play an important role in the mobilization of iron in the podzol soil that may be important in iron availability to plants in forest environment.

Adsorption of fecal microorganism on soils

HYANGSIG AHN[1*], CHANG HOON YOO[2], JEONG-HO LEE[1], HO YOUNG JO[1], SEONG-TAEK YUN[1], AND YONG SEOK JEONG[2]

[1]Korea University, Earth and Envionmental Sciences, Seoul, Republic of Korea, pl9ok8ij@korea.ac.kr (*presenting author)
[2]Kyunghee University, Biology, Seoul, Republic of Korea

Mobility of virus and microorganism through earth materials need to be investigated for evaluating soil and groundwater contamination. Surface charges of minerals or organic matters can vary with pH. When the surface charge polarity of soil particle is opposite to that of virus or microorganism, the virus or microorganism is adsorbed onto the soil particle by the electromagnetic attraction force [1]. Therefore, pH affects sorption characteristics of fecal virus or microorganism on the soil. This study investigated sorption characteristics of MS2 bacteriophage and E. coli on sorbents (i.e., quartz sand, iron oxide, and kaolinite) in aqueous solutions.

DI water was sterilized by filtering and then adjusted to pH 6~7 by adding the concentrated NaOH solution. Concentrated MS2 bacteriophage or E. coli was added to the pH adjusted solution. 1 g or 3.3 g of sorbent and the 10 ml of virus solution (10^3~10^8 PFU/ml) was reacted for 1~16 hours at 50 rpm and 15 ℃. After the reaction, the leachate was obtained by filtering the mixture of sorbent and virus solution using 0.22 ㎛ membrane filters. MS2 bacteriophage and E. coli concentrations of the leachate s were measured.

Sand and iron oxide adsorbed more MS2 bacteriophage than kaolinite. 1 g of sand or iron oxide removed almost completely MS2 bacteriophage from the 10 ml solution with 10^4~10^5 PFU/ml of MS2 bacteriophage. However, appromimately 20 % of MS2 bacteriophage was removed by kaolinite at the same condition. Iron oxide adsorbed more E. coli than sand and kaolinite. 1 g of iron oxide adsorbed 43~96 % of E. coli in the 10 ml solution with 10^3~10^5 PFU/ml for 1~16 hours, whereas no adsorption onto sand and kaolinite occurred. These results suggest that moblity of virus or mirooragnism can be affected by the soil constituents.

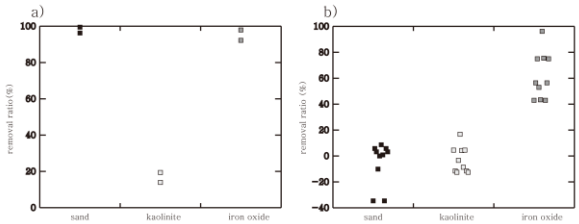

Figure 1: Removal ratio of a) MS2 bacteriophage and b) E. coli

The action of sulfur species and water on organic matter

WARD SAID-AHMAD[1,2], ALON AMRANI[2], ZEEV AIZENSHTAT[1*]

[1]Chemistry Institute The Hebrew University of Jerusalem, 91904 Israel, zeev@vms.huji.ac.il (* presenting author)

[2] Institute of Earth Sciences The Hebrew University of Jerusalem, 91904 Israel,wardsaid@gmail.com ;alon.amrani@mail.huji.ac.il

The incorporation of inorganic sulfur species into organic matter during early diagenesis stage has been studied and demonstrated by chemical analysis of sedimentary sulfurized organic matter (S-OM) and laboratory experiments. The importance of S-OM as one of the major quantitative and significant sinks of sulfur in sediments and its interaction with the global oxygen and carbon cycles is being recognized in recent years. Sedimentary OM reacts with S species (e.g. HS^-,S_x^{-2}, RS^-)in all stages of OM formation and thermal maturation. Recently, we have shown that elemental S is reactive even under mild temperatures (60-80ºC) and aquatic conditions. We have employed detailed chemical analyses and S-isotopic studies to decipher the mechanisms controlling these reactions. A variety of organosulfur compounds as well as oxidized compounds (non-S) such as ketones were formed by the reaction of elemental S and organic model compounds. The sulfurized and oxidized organic compounds seem to form in parallel. There is 5-13‰ isotopic fractionation; between elemental S and H_2S that decreases as a function of temperature. Organosulfur compounds and polysufides exhibit smaller fractionation relative to elemental S of 0-3‰. We suggest that the action of elemental S on organic matter is two folds: it activates water to produce hydroxyl radical that can oxidize organic compounds, and second, it reacts directly with organic matter to produce organosulfur compounds and H_2S. Similar effect was observed for polysulfides but not for H_2S or SO_2, suggesting that the catanated nature of S-S bonds has a decisive effect, probably through the formation of thyil radical ($SH^\cdot$) from the cleavage of these bonds. This in turn initiates a radical chain reaction that forms secondary radicals such as hydroxyl radicals. This species ($OH^\cdot$) was identified in our simulation experiments and are probably responsible for the ketones formation, demonstrating an important pathway for lowering the activation energy of water splitting and its subsequent reactions with OM. These findings improve our understanding of the intermediate temperature regime during OM thermal maturation that is mostly neglected in previous studies. It also provides new routes for hydrothermal processes such as thermochemical sulfate reduction. More importantly, this study shows the inherent connection of the carbon, hydrogen, oxygen and sulfur in the geosphere under much milder environmental conditions then previously thought.

Iron isotopic fractionation in tropical soils

A. AKERMAN[1,2*], F. POITRASSON[1,2], P. OLIVA[1], G. BOAVENTURA[2], L. C. VIEIRA[2], S. AUDRY[1] AND P. SEYLER[1]

[1]Laboratoire Géosciences Environnement Toulouse, IRD-CNRS, 14, av. E. Belin, 31400 Toulouse, France (* correspondence: alisson.akerman@get.obs-mip.fr)

[2]Instituto de Geociências, Universidade de Brasilia, Campus Universitario Darcy Ribeiro, 70904-970 Brasilia-DF, Brazil

Iron is the fourth most abundant element in the continental crust. It is particularly abundant in tropical environment due to the large amounts of poorly mobile oxidized Fe in lateritic soils. A better understanding of Fe biogeochemical cycle remains a major issue, particularly within the tricky problem of environmental change consequences (land use change, climate change, ...). This study focused on iron isotopic compositions of soils from three distinct toposequences in tropical environment: 1/ at the scale of the Nsimi experimental watershed in South Cameroon, 2 and 3/ in the Rio Capim's watershed in the northeast of the Brasilian Amazon, respectively in rainforest and pasture landscape. We worked both on ferralitic soils (i.e., the top of the hills), and on evolved/degraded soils present within the slopes and the bottom of the hills in connection with stream waters.

The objectives of this study were 1) to determine if significant isotopic differences in iron compositions exist between laterites and soils resulting from laterite degradation, 2) to investigate the processes responsible for these differences in isotope compositions, and 3) to evaluate to which extent Fe isotopes can be used as a proxy to understand metal cycling in the environment.

Iron isotope compositions were determined by MC-ICP-MS analysis after a complete microwave mineralization and iron purification.

Samples from evolved/degraded lateritic soils both in forest and pasture show important Fe loss compared to the reference feralitic soils (i.e., 30 to 90% estimated on the basis of a constant Zr concentration). Our first results on the Fe isotope compositions of these samples reveal that the δ^{57}Fe of the evolved/degraded soils ($\delta^{57}Fe = 0.6 \pm 0.1$‰ for soils at the bottom of the slope in forest and $\delta^{57}Fe = 0.4 \pm 0.1$‰ for soils under pasture) are isotopically heavier than the continental crust baseline and the reference lateritic soils (i.e; 0.1‰ in $\delta^{57}Fe_{IRMM-14}$). These results contrast with previous data published on the Fe isotopic compositions in lateritic soils showing no differences between soils and the continental crust [1]. Hence, our results suggest that chemical weathering and pedogenesis can significantly fractionate iron isotopes under tropical environments. This shows that Fe isotopes can be used as a new geochemical tool to study iron transfer during soil degradation and weathering processes in reponse to natural and anthopogenic processes.

Understanding the origin of porewater geochemical profiles in the Michigan Basin, southwest Ontario

TOM AL[1*], IAN CLARK[2], LAURA KENNELL[4], KEN RAVEN[3], MARK JENSEN[5]

[1]Earth Sciences, University of New Brunswick, Fredericton, New Brunswick, Canada, tal@unb.ca ([*]presenting author)
[2]Earth Sciences, University of Ottawa, Ottawa, Ontario, Canada
3Geofirma Engineering, Ottawa, Canada
[4]Nuclear Waste Management Organization, Toronto, Ontario, Canada

With a view toward establishing a deep geological repository for low- and intermediate-level radioactive waste, a geoscientific site characterization program has been conducted on the eastern margin of the Michigan Basin at the Bruce nuclear site. Drilling and collection of cores within an ~ 860 m near-horizontally layered Paleozoic sedimentary sequence, resting atop the Precambrian basement, has provided an opportunity for porewater and groundwater sampling and analysis with an unprecedented level of detail. Utilizing geochemical data from groundwater and porewater, this paper describes a natural analogue study in which the distribution of natural tracers within the sedimentary sequence is explored to develop insight regarding the timing and processes governing solute migration.

Depth profiles for the natural tracers $\delta^{18}O$, $\delta^{2}H$, Cl and Br in porewater and groundwater are presented and interpreted in terms of advection and diffusion processes that have caused them to evolve from initial conditions. Illustrative numerical simulations have been performed which support current interpretations of solute transport.

The tracer profiles are characterized by first-order trends that result from diffusive mixing near the top and bottom of the section over hundreds of millions of years. Near the top of the section, hypersaline evaporated seawater brine in the Silurian was in contact with porewater of normal marine salinity in the Ordovician. Contrasting chemical and isotopic compositions resulted in diffusive mixing across the Ordovician – Silurian boundary. Similarly, differences in isotopic composition between porewater in the Precambrian shield and the overlying Paleozoic sedimentary rocks resulted in diffusive mixing across the lower boundary of the basin.

These ancient first-order features in the tracer profiles have been disrupted by seemingly episodic events in the geologic past. The shallow groundwater system (<180 mBGS) shows evidence of a glacial meltwater component (decrease in $\delta^{18}O$ and $\delta^{2}H$), as does a thin, isolated, aquifer in the Salina A1 (~325-328 mBGS). The infiltration of fresh water in these intervals is manifest by dilution of salinity. At depth, in the Black River Group, the tracer profiles are deflected toward higher values that reach maxima in the Cambrian aquifer. The composition of porewater in the Cambrian is similar to deep groundwater from petroleum wells elsewhere in the Michigan and Appalachian basins and these deflections at the base of the tracer profiles are interpreted to represent fluids of deep basin origin. The results of numerical simulations conducted to date suggest that the disruptions at both the upper and lower boundaries could be explained as relatively recent events (e.g. during the Pleistocence). However, data evaluation is ongoing in efforts to advance understanding of the evolution of the profiles.

Indications of geochemical and C-O isotopic compositions in the origin of the UAE carbonatites

SULAIMAN A. ALAABED[1*] AND BAHAA EDDIN NAHMOUD[2]

[1]Department of Geology, FOS, United Arab Emirates University, AlAin, UAE, s.alaabed@uaeu.ac.ae (* presenting author)
[2] Department of Geology, FOS, United Arab Emirates University, AlAin, UAE, bahaa.mahmoud@uaeu.ac.ae

Carbonatite occurrences commonly associated with alkaline volcanic rocks in intracontinental rifting zones. In the UAE, few carbonatitic rocks occur as part of the metamorphic sole of the Semail ophiolite. They form pods, lenses and small layers within the deep sea meta-sediments and meta-volcanic rocks of Hawasina and Haybi Complexes at two different areas: Dibba and Hatta Zones. The previous little work attributed the UAE carbonatite existence to extrusive subaerial magmatic activities in an intra-oceanic setting associated with the Semail ophiolite emplacement. Although, they are internally undeformed, petrographic study reveals some metamorphic minerals in addition to the magmatic signatures. Geochemically, they show a significant enrichment in the REE and trace elements, close to but little above the average carbonatite composition. δ18O and δ13C analysis shows an increase in the isotopic composition of the studied rocks in array from the primary igneous carbonatite, indicating a heavier isotopic source affected these carbonatites. Combining field observation, petrographic study, geochemical and isotopic signatures, the UAE carbonatites might have formed in association with alkaline volcanic activities at the oceanic environment of the Semail ophiolite prior its obduction and final emplacement, and been affected by hydrothermal metasomatism .

Solar Nebulæ

FRANCIS ALBAREDE[1] AND FRÉDÉRIC MOYNIER [2]

[1] Ecole Normale Supérieure, Lyon, France, albarede@ens-lyon.fr
[2] Washington University in St Louis, MO, USA,

Lodders and Fegley [1] pointed out the necessarily multiple-component origin of the Solar System. Warren [2] argued for the bimodality in ^{50}Ti, ^{54}Cr, and O nucleosynthetic anomalies exhibited by planetary materials and suggested a division between carbonaceous and noncarbonaceous sources. Such a dichtomy is also visible in the Cu and Zn isotope compositions of the same material [3]. Using a novel presentation of oxygen isotope data, we show that all the analyzed material in the Solar Nebula can be accounted for by a component mixture not unlike Warren [2]'s two component mixture but involving three components. The new orthogonnal coordinates clearly separate mass-dependent from mass-independent fractionation and unveil well-defined mixing trends. Most of the accessible material in the Solar System may be accounted for by a mixture of a non-carbonaceous (L chondrite-like), a CV and a CI end-members. Similar components are also found when other nucleosynthetic anomalies (Ti, Cr, Ni) are plotted against water content of meteorites. It is arguable that the CV component is of solar origin. The most common proportions of CV and CI components in the mixture are reminiscent of a CM composition. We suggest the approximate contributions of the noncarbonaceous sources: 90% for L chondrites, 80% for H chondrites and Mars, 70% for E chondrites, the Earth, and Moon, and 20-40% for ureilites.

A first far-reaching consequence is that the Solar System is not well mixed and that accretion time scales are shorter than nebular mixing time scales. The Solar nebula does not represent the condensation of a homogeneous cloud of gas and dust, but the accretion of a number of genetically unrelated streaks, two of which (L-type and CI) having resisted full accretion to the central star.

In a session honoring Mike Drake's immense contribution, and more specifically to this issue [4], the origin of water in planets appears essentially pinned down on that of their CI component. Several correlation plots show that water is not a rogue component of the Solar System. It is remarkably well correlated with other gaseous (C, N) and lithophile (Zn) volatiles. Even if the history of water and of the CI component in terrestrial planets are intimately related, the timing of when the components discussed in this talk were mixed is still eluding final explanation.

Multiple age components in individual molybdenite grains

JOHN ALEINIKOFF[1]*, ROBERT CREASER[2], HEATHER LOWERS[1], CHARLES MAGEE[3], AND RICHARD GRAUCH[1]

[1]US Geological Survey, Denver, Colorado, USA jaleinikoff@usgs.gov (* presenting author), hlowers@usgs.gov, rgrauch@usgs.gov
[2]University of Alberta, Earth & Atmospheric Sciences, Edmonton, Canada robert.creaser@ualberta.ca
[3]Australian Scientific Instruments, Canberra, Australia cwmagee@gmail.com

Molybdenite occurs within a pod of unusual monazite-xenotime gneiss (MXG) that is part of a granulite-facies paragneiss in the Hudson Highlands, NY. Whereas both the paragneiss and MXG contain detrital zircon older than about 1170 Ma, only MXG has a population of irregularly zoned prismatic zircon (U-Pb age of 1036±5). This age is thought to date the formation of MXG, probably by metasomatic/metamorphic processes, rather than as a paleo-placer. Subsequent events at about 1010, 985, and 920-880 Ma formed rims on zircon, xenotime, and monazite in MXG.

Re-Os geochronology of multi-grain fractions composed of unsized, coarse, and fine molybdenite yielded dates of 950.5 ± 2.5, 953.8 ± 2.6, and 941.2 ± 2.6 Ma, respectively. These dates are not recorded by co-existing zircon, xenotime, or monazite. SEM-BSE imagery of molybdenite in thin section and as separated grains reveals that most molybdenite grains are composed of core and rim plates that are approximately perpendicular. Rim material invaded cores, forming irregular contacts that probably reflect dissolution/reprecipitation.

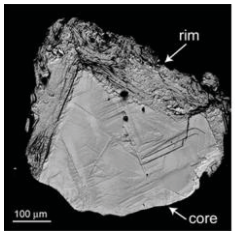

Figure 1: molybdenite grain showing core and rim.

Microanalysis for Re-Os geochronology of small volumes within individual grains was not attempted because parent ^{187}Re and daughter-product ^{187}Os can "decouple" [1, 2], yielding dates that can be too old or too young. However, EPMA and LA-ICP-MS analyses show that cores and rims have different trace element concentrations (for example, cores are richer in W). We conclude that the range of Re-Os dates on our multi-grain samples reflect mixing of at least two age components.

The discovery of cores and rims in individual molybdenite grains is analogous to multiple age components in U-Pb geochronometers such as zircon, monazite, and titanite. Thus, molybdenite, particularly of *metamorphic* origin, should be carefully examined prior to dating of multi-grain samples to ensure that the requirement of age homogeneity is fulfilled.

Strategies for the *in situ* immobilization of uranium aim to reduce oxidized and mobile U(VI) to relatively insoluble U(IV), a process long thought to result in the precipitation of the U(IV) mineral uraninite [$UO_{2(s)}$]. However, recent research indicates that non-crystalline products named monomeric U(IV) may form during the *in situ* reduction of U(VI)[1,2]. These products may form via uranium reduction by microbes, by Fe(II) minerals of biogenic origin[3], and in biostimulated natural sediments[4]. Monomeric U(IV) has garnered recent study because it is likely to be more susceptible to reoxidation and remobilization in the environment than uraninite.

To test its stability and possible transformations, two types of materials containing monomeric U(IV) were fixed in agarose gel pucks: (1) monomeric U(IV) produced via U(VI) reduction by *Shewanella sp.* CO-9, and (2) monomeric U(IV) produced by the reduction of U(VI) by phosphate-treated nanoparticulate magnetite of biogenic origin. These gel pucks were deployed in two groundwater wells at the Rifle, Colorado IFRC site for recovery after 1, 2, and 3 months. Digestions of the gels reveal that uranium is lost more rapidly from gels containing monomeric U(IV) than those containing biogenic uraninite. The monomeric U(IV) associated with biomass is more stable than that associated with magnetite. Uranium L_{III}-edge X-ray absorption spectroscopy (XAS) data point to a relative enrichment of uraninite in the gels as monomeric U(IV) species are selectively removed by the groundwater over time. Our results provide the first direct evidence of the *in situ* instability of monomeric U(IV) species relative to uraninite. Thus, the identification and quantification of these species at field remediation sites is likely to be critical in devising accurate uranium transport and fate models.

The origin of water in asteroids and the terrestrial planets

CONEL M.O'D. ALEXANDER[1], ROXANE BOWDEN[2], MARILYN L. FOGEL[2], KIEREN T. HOWARD[3] AND CHRISTOPHER D.K HERD[4]

[1]DTM, Carnegie Institution of Washington, Washington DC, USA, alexander@dtm.ciw.edu (* presenting author)

Introduction

Determining the source(s) of the volatile elements H, C and N in the terrestrial planet region is important not only for understanding the origin of life on Earth, as well as dynamical processes in the solar nebula and during planet formation. For instance, a massive influx of water ice from the outer Solar System is thought to have altered the O isotopic composition of the inner Solar System early in its history [1,2]. The bulk and secondary mineral O isotopic compositions of chondrites exhibit behavior that is at least consistent with this. It has also been proposed that C, D and P type asteroids, to which carbonaceous chondrites have been linked, were injected into the asteroid belt from the comet-forming regions prior to formation of Mars [3] and during the late heavy bombardment [4]. Equilibrium and kinetic factors should produce increasingly D-rich water with increasing radial distance from the Sun. In support of this, the water in all but one of the measured comets is significantly ($\delta D \approx 1000$ ‰) more D-rich than Earth. Here, we use the H, C and N elemental and isotopic compositions of chondritic water to determine its provenance(s).

Results

The bulk H abundances and isotopic compositions of CM and CR chondrites are produced by variable mixtures of a common organic component ($\delta D \approx 3500$ ‰) and water with δD values of about -450 ‰ and 100 ‰, respectively. After subtracting this common organic component from bulk analyses of the most primitive CIs, COs and CVs, as well as Tagish Lake, their estimated water δD values are in the same range as for the CMs. In contrast, the water in the ordinary chondrite Semarkona has a δD value of >800 ‰.

Discussion and Conclusions

The estimated H isotopic compositions of the water described above should all probably be regarded as upper limits since they may have been D enriched by oxidation of Fe by water during aqueous alteration [5]. Even the current estimates show that, with the possible exception of the CRs, the carbonaceous chondrites did not form in the same regions as known comets. This calls into question both the ice influx and dynamical models described above. Comparison of the H and N isotopic compositions of chondrites and Earth suggests that the Earth's composition is most simply explained as a mixture of CI and a small amount of solar material.

Grain size vs. multi-mineral $^{40}Ar/^{39}Ar$ thermochronology

PAUL ALEXANDRE[1*]

[1]Queen's University, Geological Sciences, Kingston, Canada, alexandre@geol.queensu.ca (* presenting author)

In the case of volume diffusion, the closure temperature of a mineral is function of, among other factors, the characteristic diffusion dimension, which can be approximated by the grain size of the mineral analysed for grains smaller than or similar in size to the diffusion domains. The theoretical possibility of single mineral grain size thermochronology had been demonstrated empirically in earlier studies, mostly using biotite. In order to examine the potential of this method, it was tested alongside the widely used multi-mineral $^{40}Ar/^{39}Ar$ thermochronology.

The sample comes from the granitic McLean pluton, in the south section of the Grenville orogeny. Seven grain size separates of biotite (ranging between 90 and 1000 μm), eight size fractions of amphibole (between 63 and 1000 μm), and three size fractions of K-feldspar (250 to 600 μm) were extracted and dated by the laser step-heating $^{40}Ar/^{39}Ar$ method. The total gas ages obtained behave as theoretically predicted, with increasing ages for increasing grain sizes, including for K-feldspar, but with the exception of the smallest and the largest grains for biotite and amphibole (Fig. 1). The calculated cooling rates are ca. 0.7 °C/Ma for K-feldspar, ca. 2.5 °C/Ma for biotite, and ca. 11 °C/Ma for amphibole, corresponding very well to a monotonic cooling of the McLean Pluton. A quick initial thermal re-equilibration with the cooler host-rocks is followed by a much slower cooling on a thermal path parallel to that of the Frontenac Terrain situated immediately to the southeast.

The validity of the single mineral grain size thermochronology is demonstrated by comparison with the thermal evolution of the adjacent units and with the cooling history derived from a multi-mineral thermochronology, suggesting that it can be routinely used. The application of this method can be hampered by insufficiently low analytical uncertainties.

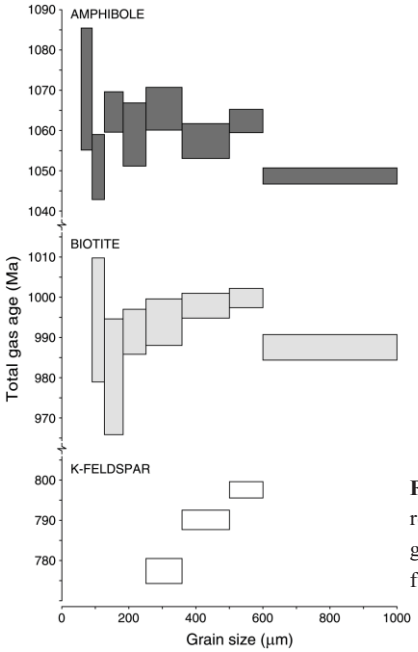

Figure 1: Analytical results, showing total gas $^{40}Ar/^{39}Ar$ ages as function of grain size.

Volcanic impact on the silicon isotope composition of natural waters during the 2010 Eyjafjallajökull eruption, S-Iceland

H. A. ALFREDSSON[1,3*], S. OPFERGELT[2,3], K. W. BURTON[3], F. MOKADEM[3], E. S. EIRIKSDOTTIR[1], AND S. R. GISLASON[1]

[2]Earth and Life Institute, Université catholique de Louvain, Louvain-la-Neuve, Belgium.

[3]Department of Earth Sciences, University of Oxford, Oxford, UK.

When Eyjafjallajökull volcano erupted in 2010, volcanic ash exploded through crater ice. The resulting fine grained ash and several *jökulhlaups* (glacial outburst floods), flushed volcanic material over the surrounding lowlands, towards the oceans and distributed atmospheric dust ash deposition over much of Europe. The ash and volcanic suspended matter, including dissolved solids and gases were incorporated into the surface waters surrounding the volcano and hence into the ocean. We collected natural water samples from the field, including *jökulhlaups* close to the vent south of the volcano (X), the big *jökulhlaups* in Markafljót river which is flowing from the north of the volcano, south towards the sea (Y), and ash contaminated surface waters (Z). In addition, flow-through plug experiments on pristine trachyandesitic ash samples, were performed in order to determine release rates of leachates from the ash [2].

The temperature of the natural waters ranged from 0.1 to 11°C and the pH from 5.86 to 7.95. The dissolved Si content ranged from 7 to 18 $mg \cdot l^{-1}$, with the highest value measured in the *jökulhlaups* during the first day of the eruption. The Si isotope composition ($\delta^{30}Si$) in the natural waters ranged from -0.45 to 1.38 ‰. Prior to the first flood, the Si isotope composition of the river (Y) was 0.84 ‰, very close to other surface waters in Iceland [1]. The lightest $\delta^{30}Si$ ratios were found in X. In contrast, waters from Y were isotopically heavier (0.35 – 1.17 ‰). The heaviest Si isotope signatures were measured in Z (0.51 to 1.38 ‰).

The ash experiments were conducted on single cell plug, with fixed flow rate of DI water. The experiment was run at ambient T/P. The pH in the collected leachates went up to 10.3 the first day, dropping to pH 9.2 after 1 week. The results showed higher release rates of most elements during dissolution of salt coatings found on the ash-grain surface [2]. The total Si release rate, normalized to the measured BET surface area, went from $10^{-7.6}$ mole Si $/m^2/sec$. at the beginning, reaching steady state at $10^{-8.6}$ mole Si $/m^2/sec$. The $\delta^{30}Si$ ratio measured was 0.28 ‰ in the first sample (after 13 min.) and then dropped down to -1.40 ‰ during dissolution of the salt coatings. It stabilazed at -0.60 ‰, closer to the isotope ratios of basalt [1].

These results show dramatic changes in the $\delta^{30}Si$ ratios of the surface waters and floods during the eruption. The waters directly linked to the erupting crater and pristine ash, had significally lighter ratios than recorded in waters accompanying basalt weathering [1]. The flooded rivers recovered quickly, within 11 days the Si isotopic composition was found to be similar to that prior to the eruption.

Abstract

We report multiple parameters used to describe the reactivity and diagenetic state of sediment organic matter (OM), including total hydrolysable amino acid (THAA), amino acid enantiomer, chlorin (CI) and amino acid degradation (DI) indices, along a transect between the Upper St. Lawrence Estuary and the Gulf of St. Lawrence, Canada. The study area is characterized by gradients in water oxygen concentration, water depth, OM source, primary productivity, and sedimentation rate. Both CI and DI indicate a decline in OM reactivity with the transition of a more terrestrial to a more marine-dominated sedimentation regime from the shallow Upper Estuary (23-95m) to the hypoxic, mid-depth Lower Estuary and to the deep (>400m), well-oxygenated Gulf. Systematic variations in the amino acid composition along the Laurentian Channel confirmed the increased diagenesis of OM with distance from the Upper St. Lawrence Estuary. The ratio of D/L stereoisomers of alanine increased along the transect, and the co-variation between DI and the D/L-Ala suggests a close coupling between the extent of diagenesis and the accumulation and selective preservation of bacterially-derived cell wall material in the sediments. The patterns observed along the estuarine transect were also present down-core in two sediment cores, confirming the robustness of our reactivity indices. Oxygen exposure time of the sediments appears to strongly determine sediment OM reactivity in the St. Lawrence Estuary. The sediment oxygen regime itself is related to the interplay between water column depth, vertical OM flux, and reactivity of settling OM.

Rare Earth Elements in the Misten peat bog (Belgium) as tracers of dust depositions and past environmental changes

The Misten peat bog representing 7.5 m of peat accumulation in the Hautes-Fagnes Plateau, Belgium, provides a record of Rare Earth Elements (REE) deposition since more than 7000 years. The analyses of REE and lithogenic element concentrations, as well as the Nd isotopes, were performed by HR-ICP-MS and MC-ICP-MS, respectively in peat layers previously dated by ^{210}Pb and ^{14}C. REE concentration variations in peat samples are correlated with Ti, Zr and Sc that are lithogenic conservative elements, suggesting that REE are immobile in the studied peat bogs [1] and can be used as tracers of dust deposition. Peat humification, C/N ratio, ash content and bulk density were used to evaluate hydroclimatic conditions. The εNd values show large variability, between +1 to –22, identifying three major sources of dusts falling into the peat: local soils, distal volcanic and desert particles. More recently, industrial emissions provide a fourth source of dusts [2], which is also clearly recorded in the last 200 years of the Misten peat profile.

The matrix effect as alpha dose: improving LA-ICP-MS Pb/U ages

CHARLOTTE M. ALLEN[1]* AND IAN H. CAMPBELL[1]

[1]Research School of Earth Sciences, Australian National University, charlotte.allen@anu.edu.au (*presenting author)

[1]Research School of Earth Sciences, Australian National University, ian.campbell@anu.edu.au

The Matrix Effect, New Experiments, and Results

Matrix effects are purported to be the cause of offsets of ages from spot (*in situ*) dating techniques relative to TIMS work in which zircons are dissolved and U and Pb are isolated and concentrated through column chemistry. Moreover they are thought to contribute to Pb/U differences in zircon spot dating. Age offset is the measured age minus the accepted age all divided by the accepted age. Black et al. (2004) showed that there are age offsets among TIMS, SHRIMP and LA-ICP-MS $^{206}Pb/^{238}U$ ages for well characterized zircons and suggested that Nd was a monitor for degree of offset [1]. Klötzi et al. (2009) showed in a LA-ICP-MS experiment using each of 4 standard zircons to deduce the age of a fifth produced a minimum precision of 3-4%, prescision worse than that generally ascribed to the technique [2]. Klötzi's work (rastering not drilling) shows that understanding, minimizing and/or eradicating the matrix effect is vital for truly accurate and precise LA-ICP-MS $^{206}Pb/^{238}U$ ages.

We have shown by 2 different LA-ICP-MS round robin experiments on 6 well characterized zircon standards with TIMS ages (OG1, FC1, 91500, Temora, R33 Plesovice, and LP521) that the matrix effect is not chemical but physical in nature. We have expanded our database to include Miocene zircons with high precision $^{40}Ar/^{39}Ar$ ages (Cougar Point Tuff) as well as some other zircons [3]. Briefly our system consiststs of an Agilent ICP-MS and Excimer 193 nm wavelength laser with in-house ablation chamber. In a He atmosphere we drill 30 µm spots to 20 µm depths while measuring 18 masses. Of these only one variable showed a strong correlation with age offset, radiogenic Pb. The cause of the matrix effect is not the presence of the Pb itself, but what the Pb represents – the accumulated decay of U and Th since zircon crystallization. Our results show that if a zircon is substantially older and/or more radiogenic than the standard (Temora in this study) then the measured ICP-MS age is too old by up to 3%. More startlingly, if the unknown is substantially younger and/or less radiogenic than the standard then the age obtained is too young by up to 8%. We surmise that in grains that have had higher alpha particle doses, Pb escapes the ablation site with greater ease relative to U. The exponential fit of percent age offset vs alpha dose$*10^{-15}$ for 14 populations given below can be used to correct our existing work.

$$y=382.68e^{0.8331x} \quad r^2=0.96.$$

In experiment 2 we have demonstrated that annealing the same 6 standards to the same conditions (850°C for 48 hours) obliterates the matrix effect. Age offsets are then about the uncertainty expected from counting statistics (<1%). We highly recommend annealing standards and unknowns before LA-ICP-MS dating.

Influence of seawater carbonate chemistry on B/Ca in cultured planktic foraminifera

KATHERINE ALLEN[1*], BAERBEL HOENISCH[1], STEPHEN M. EGGINS[2] AND YAIR ROSENTHAL[3]

[1]Columbia University, Earth and Environmental Science, katallen@ldeo.columbia.edu (* presenting author) hoenisch@ldeo.columbia.edu

[2]The Australian National University, Research School of Earth Sciences, Stephen.Eggins@anu.edu.au

[3]Rutgers University, Institute of Marine and Coastal Science, rosentha@marine.rutgers.edu

The ratio of boron to calcium (B/Ca) in fossil calcite tests of planktic foraminifers has recently been used to investigate the carbonate chemistry of ancient oceans. The theoretical basis for this proxy is rooted in the pH-dependent concentration of dissolved borate ($B(OH)_4^-$) and its subsequent incorporation into foraminiferal calcite (Hemming and Hanson, 1992). Here, we present new insights into B incorporation from laboratory culture experiments with live specimens of *Globigerinoides ruber* (pink) and *G. sacculifer*. We find that in *G. sacculifer*, B/Ca increases with pH (higher $[CO_3^{2-}]$ and $[B(OH)_4^-]$, lower $[HCO_3^-]$), but decreases with total dissolved inorganic carbon (DIC) (higher $[CO_3^{2-}]$ and $[HCO_3^-]$, constant $[B(OH)_4^-]$). This suggests competition between aqueous boron and carbon species for inclusion into the calcite lattice. Similar to previous experiments with cultured *Orbulina universa*, B/Ca increases with salinity, but not with temperature. We evaluate possible control parameters, including $[B(OH)_4^-]/[HCO_3^-]$ and $[B(OH)_4^-]$/DIC. Our culture calibrations are broadly consistent with field data, including new core-tops from the Gulf of Mexico. Some discrepancies may indicate the presence of unidentified controls, and more work is needed to probe specific controls on B/Ca and to test culture calibrations in the open ocean.

Submarine weathering of detrital silicates simulated in the laboratory

G. ALOISI[1], C. ALBRECHT[2], M. HAECKEL[2], S. KUTTEROLF[2], C. DEUSNER[2*], K. WALLMANN[2]

[1]LOCEAN, CNRS UMR, Université Pierre et Marie Curie, Paris, France, galod@locean-ipsl.upmc.fr (* presenting author)
[2]GEOMAR Helmholtz Centre for Ocean Research Kiel, Kiel, Germany, calbrecht@geomar.de, mhaeckel@geomar.de, skutterolf@geomar.de, cdeusner@geomar.de, kwallmann@geomar.de

Silicate detritus is transported from the continents to the oceans by rivers. Although it is a major component of marine sediments, its reactivity in the oceanic environment has only been scarcely investigated. Wallmann et al. (2008) [1] propose that significant weathering of detrital silicates takes place in the anoxic sediments of the Sakhalin Slope, Sea of Okhotsk.

We carried out batch experiments with these sediments to further test this idea. In our experiment the sediments reacted with the artificial seawater in a matter of minutes to days, releasing dissolved compounds, such as TA (total alkalinity), Ca, K, Si, B, Sr, Li, Mn, Fe, and Ba. Applying a numerical biogeochemical model, we show that organic matter degradation and dissolution of carbonates can account for only a part of the observed TA increase. Detailed mineralogical analyses suggest that the only alternative source for TA is the weathering of primary silicates and clay minerals which are abundant in Sakhalin Slope sediments. Thermodynamic modeling of silicate solubilities shows that the experimental fluids are undersaturated with respect to a wide range of chemically diverse silicates which potentially contribute to the TA build-up. The weathering rate in our experiment is only one order of magnitude larger than in the natural setting, suggesting that in-situ dissolution of silicates takes place at a high degree of undersaturation.

Since the ocean is also highly undersaturated with respect to a wide variety of primary silicates and clay minerals, weathering of detrital silicates in oceanic and sedimentary environments could be a widespread process.

Methane biogeochemistry in anoxic marine sediments: insights from reaction-transport models applied to $\delta^{13}C\text{-}CH_4$ and $\delta^{13}C\text{-}\Sigma CO_2$ depth distributions

MARC J. ALPERIN

Department of Marine Sciences, Univeristy of North Carolina at Chapel Hill, Chapel Hill, NC 27599-3300, USA (correspondence: alperin@email.unc.edu)

Three fundamental questions regarding the methane cycle in anoxic marine sediments are: (1) what are the pathways of methane production; (2) how are methane production, methane oxidation, and sulfate reduction zoned within the sediment column; and (3) how much of the sulfate reduction is coupled to methane oxidation? Stable carbon isotopes in CH_4 and ΣCO_2 have been used to address each of these questions. However, simple isotope mass-balance calculations that ignore the effect diffusive transport on isotope distributions can be misleading. I will present an advection-diffusion-reaction model that is suited for quantitative interpretation of stable isotope depth distributions in marine sediments where molecular diffusion is the dominant transport process. The model is driven by organic matter remineralization via sulfate reduction and methane production and can reproduce the features in $\delta^{13}C\text{-}CH_4$ and $\delta^{13}C\text{-}\Sigma CO_2$ profiles that are characteristic of marine sediments. A detailed comparison of predicted stable isotope distributions with methane production pathways and rates of processes illustrates the insights into the sedimentary methane cycle that can be derived from $\delta^{13}C\text{-}CH_4$ and $\delta^{13}C\text{-}\Sigma CO_2$ profiles.

Approaching acid gas - fluid interactions

T. ALPERMANN[1]*, C. OSTERTAG- HENNING[1]

[1]Federal Institute for Geosciences and Natural Resources, Stilleweg 2, 30655 Hannover, Germany
(* correspondence: Theodor.Alpermann@bgr.de)

Acid gases like CO_2 and H_2S as well as organo-sulfur compounds are common components in natural gas and oil reservoirs originating from a variety of sulfate reduction processes. Depending on the composition of a hydrocarbon reservoir, significant amounts of these objectionable compounds might have to be removed from the hydrocarbons during the refinery process.

Therefore, new disposal practices for acid gases and organo-sulfur compounds are needed due to the projected exploitation of giant hydrocarbon reservoirs with exceptionally high amounts of sulfur-containing compounds. One option for the disposal may be the geological sequestration within suitable strata. Although mixtures of H_2S/CO_2 have been injected into deep geological formations in Canada for more than 20 years,[1] little is known about possibly occurring geochemical reactions in the underground.

In order to contribute to a better understanding of chemical processes under geological storage conditions, interactions of CO_2/H_2S, low-molecular organo-sulfur compounds and brines of different composition were investigated. Typically, experiments are conducted in sealed gold tubes at a temperature of 120°C and a pressure of 100 bar.

The experimental outcomes may provide a basis for a more detailed evaluation of the underground storage potential of organo-sulfur compounds and acid gases.

Understanding the behavior of arsenic (As) during weathering of sulfide-bearing mineral deposits and associated mine wastes is important with regard to minimizing the exposure of humans and wildlife to this carcinogenic element. In low-sulfide gold-quartz vein deposits of the Mother Lode region of California, As occurs predominantly in the primary sulfide minerals arsenopyrite (FeAsS) and arsenian pyrite ($Fe(S,As)_2$). Detailed characterization of As- and iron- (Fe-) bearing primary and secondary minerals in mine waste piles at the Empire Mine State Historic Park (EMSHP), Grass Valley, California, was done as part of a larger study designed to evaluate the influence of mineralogy and speciation of As on bioaccessibility in mineralized environments and abandoned mines.

On the basis of electron microprobe analysis, arsenian pyrite at Empire mine has 0 to 5 wt. % As and arsenopyrite has 41 to 43 % As; secondary weathering products include hydrous Fe oxides (HFO, ferrihydrite and goethite, 0 to 18 wt. % As), hydrous Fe arsenates (HFA, including scorodite, $FeAsO_4 \cdot 2H_2O$, and related phases, more than 20 wt. % As), As-bearing jarosite ($KFe_3(SO_4,AsO_4)(OH)_6$, 0.2 to 0.8 wt. % As) and unidentified Ca-Fe-arsenate minerals. The speciation of As in the seconary minerals is predominantly As(V) (at least 90%), based on x-ray absorption spectroscopy. The molar ratio As:Fe in HFO is about twice as high as that in arsenian pyrite grains in close spatial association; most likely, this reflects adsorption or coprecipitation of arsenate from solution on HFO. Based on electron microprobe analysis, HFO from Empire mine has a minimum of 1 wt.% SiO_2.

Bioaccessible As, measured using *in vitro* methods simulating conditions in the human stomach and small intestine, ranged from 1.4 % to 11% of total As in 25 samples of mine waste from the EMSHP area. In addition, a sequential extraction procedure [1] was applied to the 25 samples. The first two fractions (F1, 0.05 M ammonium sulfate; F2, 0.05 M ammonium phosphate) liberated sorbed As; the sum of F1+F2 concentrations was less than the *in vitro* test results for all samples. The third fraction (F3, 0.2 M oxalate at pH 3) liberated As associated with amorphous and poorly crystalline oxides of Fe and aluminum (Al). The sum of F1+F2+F3 concentrations was consistently higher than results from the *in vitro* tests, suggesting that some As associated with amorphous and poorly crystalline Fe and Al oxides is not bioaccessible. Adsorbed SiO_2 tends to lower the dissolution rate of HFO [2], reducing bioaccessibility.

He and Ar diffusivity in naturel MORB glasses

JULIEN AMALBERTI[1*], PETE BURNARD[1]

[1] CRPG-CNRS, Vandoeuvre-lès-Nancy, France, *
amalbert@crpg.cnrs-nancy.fr (* prensenting author)

Diffusion in glasses

Given the short timesacales implied for the creation and seperation of a volatile phase during magmatic degassing, it seems likely that disequilibrium processes could fractionate the noble gases as well as other volatiles [1, 2, 3]. In order to document the diffusivity of noble gases in basaltic systems, we present a study of He and Ar diffusion by stepwise degassing. He and Ar analyses were performed on natural fresh MORB glasses (*AMK 3375,* mid-Atlantic Ridge).

Results

The results produce linear trends in a plot of ln(D) vs. 10000/T (Fig. 1). We observe high Ar diffusivity at low temperature. This behaviour is not well understood but may reflect a specific diffusion path of Ar into MORB glass. Further work is planned to determine the origin of this behaviour. Nevertheless, there is a convergence of He and Ar diffusivities consitent with a 'compensation' temperature [4] where He and Ar diffusivities are equal.

Implications

The experimental data show a compensation temperature for He and Ar diffusion at ~750°C. The implications of this are that there will be no kinetic fractionnation during magmatic processes. From Fig. 1 Ea = 192,16 kJ.mol^{-1} and Do = 9,91E^{-4} cm².s^{-1} for He and 67.73 kJ.mol^{-1} and Do = 1.68E^{-4}cm².s^{-1} for Ar in natural MORB glasses. In order to apply these results to natural magmatic systems there are two important caveats to consider:- 1) In our samples, He and Ar were originally present predominantly as gases in vesicles, and therefore extraction consists of two steps: solubilisation of vesicle gases into the glass and then volume diffusion of dissolved He or Ar through the glass itself. The diffusivities measured (Fig. 1) will reflect the slowest of these processes, and it seems possible that this is the reason behind rapid Ar diffusion at low T. 2) Our experiments were carried out below the glass transition temperature and diffusivities may be different in true liquids. Further work is planned to constrain both of these issues.

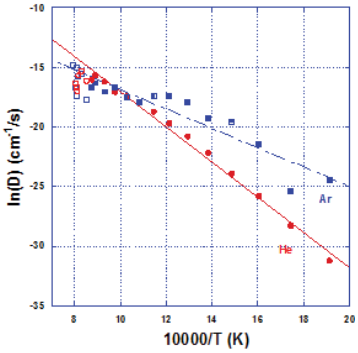

Figure 1 : He (circles) and Ar (squares) diffisivities in MORB glass which was heated between 150 and 950°C for 20 mins; diffusivities are for spherical geometry. The compensation temperature is estimated at ~1000K where ln(DHe) = lnD(Ar)

Cosmogenic ^{3}He in calcite: under what conditions is it useful?

WILLIAM AMIDON[1*], DANIEL HOBBS[1]

[1]Middlebury College, Middlebury, VT, USA
wamidon@middlebury.edu

Abstract

Spallation produced ^{3}He has recently been explored as a dating tool in a variety of non-traditional mineral phases, including apatite, garnet, hornblende, titanite, and zircon. Three problems limit the utility of these phases to differing degrees: 1) nucleogenic Li-produced ^{3}He, 2) redistribution of Li-produced ^{3}He between small crystals, and 3) presence of large amount of radiogenic ^{4}He. Calcite is less vulnerable to these problems because it is generally very low in Li, U, and Th, it has a very low He closure temperature, and it occurs in very large crystal sizes. Here we build on recent work[1] by exploring the apparent retentivity of calcite formed in different aqueous environments. Results comparing ^{36}Cl against ^{3}He in micritic limestones from the Dead Sea and Aegean regions show that ^{3}He is not quantitatively retained in calcite from these limestones over 10 kyr timescales. In contrast, results from hydrothermal vein calcite from multiple sites on the Pamir and Tibetan Plateaus suggests quantitative retention over at least 20 kyr timescales. Cross-calibration of ^{3}He against ^{36}Cl in these sample suggests reasonable ^{3}He production rates between 130-160 at g^{-1} yr^{-1}. Step-wise diffusion experiments of the same vein calcite reveals complex arrhenious relationships characterized by a decrease in diffusivity during successive degassing steps at the same temperature. This behavior is consistent with the presence of multiple diffusion domains, which may reflect the size of calcite growth pyramids or "hillocks." [1] Ongoing work seeks to establish whether diffusivity of ^{3}He depends on the size of calcite growth pyramids, which are in turn dependent on the CO_3 saturation level and the presence of impurities in the crystallizing fluid. Ultimately, we hope to define a set of growth conditions under which the resultant calcite crystal is likely to be retentive to ^{3}He over timescales and surface temperatures suitable for cosmogenic dating.

Modeling plastic deformation of minerals under mantle strain-rates

AMODEO J.[1], CARREZ PH.[2] AND CORDIER P.[3*]

[1]University of Lille, Villeneuve d'Ascq, France, jonathan.amodeo@yahoo.fr
[2] University of Lille, Villeneuve d'Ascq, France, philippe.carrez@univ-lille1.fr
[3] University of Lille, Villeneuve d'Ascq, France, patrick.cordier@univ-lille1.fr (* presenting author)

Mantle convection involves plastic deformation of minerals and rocks under extreme conditions that are very difficult to reproduce in the laboratory. In particular, experimental strain-rates are at least 6 orders of magnitude larger than in nature. Extrapolation to natural conditions of semi-empirical constitutive flow laws parameterized on laboratory data is thus very unsafe and leads to significant discrepencies with observations (e.g. post-seismic deformation). Here we describe a physically-based model able to describe the rheology of MgO (the magnesium end-member of the second most abundant phase of the lower mantle) under very low strain-rates representative of mantle convection. Our multiscale numerical model involves : (i) dislocation core modeling based on the Peierls-Nabarro-Galerkin model, (ii) thermal activation modeling of dislcoation glide based on the kink-pair theory, (iii) critical resolved shear stress modeling based on the Orowan equation (in ther thermally-activated regime) or on Dislocation Dynamics modeling (in the athermal regime). The kink-pair theory allows to describe the mobility of dislcoations under very low stresses without extrapolations. We show that decreasing the strain-rate counteract the influence of high-pressure and emphasizes the athermal regime for MgO in lower mantle conditions.

This approach will be further applied to other phases of the Earth's mantle within the ERC-funded *RheoMan* project (wwww.rheoman.eu)

Reactive Trasnsport Modelling of Gas Formation and Mineral Precipitation in a Granular Iron Column

RICHARD T. AMOS[1*], SUNG-WOOK JEEN[1,2], DAVID W. BLOWES[1]

[1]University of Waterloo, Waterloo, Ontario, Canada, ramos@uwaterloo.ca (* presenting author), blowes@uwaterloo.ca
[2]Atomic Energy of Canada Limited, Chalk River, Ontario, Canada jeens@aecl.ca

The (bio)geochemical reactions resulting in the degradation of contaminants in aquifers and remediation systems are often coupled to physical processes that can affect the rate of reaction or the rate of solute transport. In granular iron permeable reactive barriers (PRBs), the precipitation of secondary minerals can lead to armoring of the iron surfaces, reducing reactivity, and also reducing permeability due to the reduction in porosity [1-3]. The generation of hydrogen gas in granular iron PRBs can lead to the production of gas bubbles that can also reduce permeability due to pore blocking [3-5].

Processed-based reactive transport modelling was used to simulate the coupling of these proceses to the treatment of trichloroethene (TCE) with granular iron in a laboratory column experiment. This was carried out with the multi-component reactive transport model MIN3P [6], which was enhanced to couple gas formation and release, secondary mineral precipitation, and the effects of these processes on hydraulic properties and iron reactivity.

The simulation reproduced the observed temporal and spatial trends in gas formation, permeability changes, and TCE degradation. The simulation showed an initial sharp decrease in permeability due to hydrogen gas production and gas bubble formation throughout the column. Over time, as the reactivity of the granular iron decreased due to armoring by secondary minerals, the degree of gas saturation throughout the column decreased, but the porosity of the column also decreased as a result of the secondary mineral formation. The result is a steady decrease in permability. The simulation demonstrated that after 704 days, armoring by carbonate mineral precipitation resulted in TCE breakthrough at 473 days followed by a steady increase in TCE concentrations in the column effluent.

The enhanced MIN3P model effectively demonstrated the coupling of geochmical and physical processes in this system. The simulation results suggest that the spatial and temporal evolution of gas formation and secondary mineral precipitation are critical factors in determing the effectiveness and longevity of granular iron PRBs.

[3] Equipe Environnement et Microbiologie, IPREM, CNRS-UPPA-UMR-5254, IBEAS, Pau, France

Hg methylation and demethylation pathways in aquatic ecosystems are kinetically controlled mechanisms, which critically affect monomethylmercury (MMHg) occurrence and accumulation in food webs. Various biotic, chemical and physical parameters can thus influence the overall net methylation of inorganic Hg(II) in aquatic systems [1]. Because Hg isotopic composition in environmental samples may allow tracking Hg sources and cycling, laboratory experiments on Hg species kinetics and isotopes fractionation during the main Hg transformations are essential. The aim of this study was to investigate Hg reversible methylation/demethylation mechanisms via 1) metabolic pathways using sulphate-reducing bacteria (SRB) cultures and 2) chemical non-enzymatic pathways by naturally occurring methyl group donor methylcobalamin (MeCo). Kinetics of the transformations and related Hg compounds isotope fractionation were measured and compared between the different experimental conditions.

Abiotic methylation processes driven by MeCo showed production of both MMHg and DMHg (dimethylmercury). Successive and reversible kinetics of methylation and demethylation were identified. Hg(II) methylation rate constants were 10 to 100 times higher than dimethylation and demethylation ones. Under dark conditions DMHg isotopic composition varied significantly during the time course of the experiment (48 h), being progressively enriched in heavier isotopes (δ^{202}DMHg varied from -1.37 to +0.66‰). Demethylation of DMHg was then identified to promote Hg isotopes fractionation when compared to MMHg methylation. Presence of chloride (0.5M) avoided DMHg production but enhanced Hg species fractionation (δ^{202}Hg from -1.44 to 2.48‰ for inorganic Hg and MMHg, respectively). Pure cultures of SRB incubated with Hg(II) produced significant amounts of MMHg and were also capable of MMHg oxidative degradation. Rate constants were 100-times lower and to the same order of magnitude, for methylation and demethylation respectively, than in abiotic experiments. Physiologies and global metabolism of the bacteria (i.e. fermentative or sulphate-reducing activity) did not affect significantly Hg species production/degradation kinetics and isotope fractionation. At steady state, 20% of MMHg was produced by SRB activity, resulting in MMHg enriched in lighter isotopes (δ^{202}MMHg between -0.88 and -0.45‰) and inorganic Hg enriched in heavier isotopes (δ^{202}IHg between +0.32 to +0.62‰).

Overall, both abiotic / biotic pathways of methylation and demethylation induced Hg mass-dependent isotopic fractionation which was influenced by the respective kinetics of these reversible pathways. Our results exhibit that isotopic composition of Hg in aquatic natural samples (biota, sediments) should be interpreted with care since reversibility of main Hg transformations need to be taken into account.

Abstract

The mobility of neptunium (V) in high ionic strength aqueous environmental systems, such as in the vicinity of salt-based nuclear waste repositories and high ionic-strength groundwater at Department of Energy sites, may be strongly influenced by adsorption to the cell wall of halophilic bacteria. This is the first study to evaluate the adsorption of neptunium (V) to the surface of a halophilic bacterium as a function of pH at the relatively high ionic strengths of 2 and 4 M. The experimental adsorption data were incorporated into a surface complexation model that was adapted for high ionic strength conditions where traditional corrections for aqueous ion activity are invalid.

Adsorption was significant over the entire pH range evaluated for both ionic strength conditions and was shown to be dependent on the speciation of the sites on the bacterial surface and neptunium (V) in solution. Strong electrostatic attraction controlled the adsorption behavior of the positively charged neptunyl ion to the negatively charged bacterial surface at pH below circum-neutral. At pH above circum-neutral, the influence of negatively charged neptunium (V) carbonate complexes resulted in decreased, although still significant, adsorption. Adsorption in 4 M $NaClO_4$ was enhanced relative to adsorption in 2 M $NaClO_4$ over the majority of the pH range evaluated, apparently due to the effect of increasing aqueous ion activity at high ionic strength.

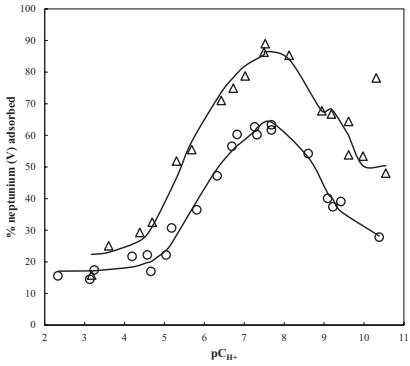

Figure 1: Experimental data for neptunium (V) adsorption onto *Chromohalobacter* sp. in 2 (open circles) and 4 (open triangles) M $NaClO_4$. Solid curves represent calculated surface complexation models. The adsorption data were modeled by testing likely reaction stoichiometries involving the adsorption of neptunium aqueous species (neptunyl: NpO_2^+, hydroxyl: NpO_2OH^0, $NpO_2(OH)_2^-$, and carbonate: $NpO_2CO_3^-$, $NpO_2(CO_3)_2^{3-}$, $NpO_2(CO_3)_2^{5-}$) to the four bacterial surface sites determined from bacteria titration modeling.

Salts and Water: Stable Isotope Evidence for the Direction of Solute Flow in Deserts

RONALD AMUNDSON[1]* AND STEPHANIE EWING[2]

Abstract

Soil is the epidermis of a planet, bearing chemical and physical properties that reflect the processes driven by its surroundings. Due to heat, gas, and water/solute transport between soil and the atmosphere, its properties are highly depth dependent. Soil forms with or without biology, and while life imparts unique characteristics to soils, its absence does not impinge on many geophysical processes that constitute soil formation. In that vein, soils found in the lifeless or nearly lifeless places on Earth are highly illuminating as analogs for the now dry and abiotic soils of Mars.

One of the key revelations of isotope research in arid and hyper-arid soils on Earth is that *stable isotopes in soils are rarely conservative tracers of elemental source*, and instead reflect complex post-depositional processes caused by aqueous or gaseous transport. Research in the past decade in both the warm and cold hyperarid regions of the world show distinctive depth trends in both the mass and the isotope composition of calcium and sulfates (Ewing et al., 2008), as well as chlorides (Amundson et al., in review). These profiles, resulting from aqueous transport, can be mimicked by physical models that describe the processes, and the direction of solute flow.

Based on our understanding from these dry environments, the exploration of the chemistry and isotope composition of salts on the Mars surface must rely on careful observation strategies to minimize ambiguities in interpretation. Chemical profiles of Mars soils record a history of aqueous processes that can be revealed through our better understanding of similar processes that occur here on Earth (Amundson et al., 2008).

The boron isotope ratio ($\delta^{11}B$) of marine carbonate has been proposed to record seawater pH [1], and thus has the potential to provide information about the evolution of the ocean carbonate system and atmospheric pCO_2 [2]. Here we discuss calibrations based on distinct skeletal sampling strategies of this pH proxy in the deep sea coral *Desmophyllum dianthus* (*D. dianthus*). Ten modern corals from a depth range of 274-1470m in the Atlantic, Pacific, and Southern Oceans were analyzed using multi-collector ICP-MS (Neptune), and the measured $\delta^{11}B$ was regressed against ambient pH taken from hydrographic data sets (range pH 7.6 to 8.1) [3]. The array of $\delta^{11}B$ values for these corals plots above the seawater borate $\delta^{11}B$ vs. pH curve [4] by an apparently constant value of 11‰, well above the range of values seen in foraminifera and surface corals. This offset is attributed to physiological manipulation of the calcifying fluid to pH 8.7-9.0. The uncertainty in estimation of seawater pH from $\delta^{11}B$ currently limits the precision of absolute pH reconstructions to ±0.05-0.10pH units. To reduce potential uncertainty resulting from spatial heterogeneities among skeletal sub-structures, we compare $\delta^{11}B$ made on bulk septal skeleton to $\delta^{11}B$ of fibrous aragonite regions. Fibrous aragonite boron isotope data plot somewhat below those of bulk analyses and suggest a stronger dependence on ambient seawater pH. Finally, we discuss our findings with reference to 2-D maps of $\delta^{11}B$ across distinct skeletal features.

Accuracy of Lu-Hf and Sm-Nd garnet dating

ROBERT ANCZKIEWICZ[1*], SUMIT CHAKRABORTY[2], SOMNATH DASGUPTA[3], DILIP K MUKHOPADHYAY[4]

[1]Polish Academy of Sciences, Kraków, Poland, ndanczki@cyf-kr.edu.pl (* presenting author)
[2]Ruhr Universität, Bochum, Germany
[3]Indian Institute of Science Education & Research-Kolkata, India
[4]Indian Instituite of Technolohy Roorkee, Roorkee, India

Lu-Hf garnet dating provides high precision age information, which is competitive even for the most precise geochronometers. Accuracy of garnet geochronology, however, may suffer from several obstacles such as protracted garnet crystallization, resorption or different diffusivities of REE and Hf. In this study we demonstrate the potential of Lu-Hf system for high precision dating of metamorphism and deformation, and show the influence of the above mentioned obstacles on precision and accuracy of garnet geochronology. We compare bulk and high spatial resolution dating of metapelites from the inverted Barrovian metamorphic sequence of the Sikkim Himalaya in India, and migmatites from the Red River shear zone in Vietnam in the context of major and trace element distribution.

Lu-Hf bulk garnet dating of the inverted Barrovian sequence of the Lesser Himalaya in Sikkim yielded Lu-Hf dates from 10.6±0.2 to 14.6±0.1 Ma with uncertainty smaller than 2% achieved for all samples. Such high precision of bulk garnet dates may be significantly underestimated due to uncertainty about the duration of garnet growth. This was verified by chemically controlled, high spatial resolution dating of synkinematically grown garnet. Lu-Hf analyses did not show resolvable time difference between core and rim. Instead, all analysed fractions define an isochron age of 13.3±0.5 Ma, which points to fast crystallization and rather short lasting early deformation phase. Dating of the post-kinematic outer rim in the same crystal gave a 9.4±1.5 Ma age, which additionally brackets timing of deformation. All obtained ages reflect the time of prograde garnet crystallization, which is indicated by Rayleigh-like zonation profiles of Lu and Hf up to the silimanite zone.

Under migmatitic conditions garnets from the Red River shear zone display strongly disturbed Rayleigh zonation trends. Light REE, and to a lesser extent, heavy REE rim-to-rim zonation profiles show progressive flattening with the decreasing garnet size. Nd and Sm are completely homogenized in the smallest crystals, while Lu always preserves variable degree of core-to-rim concentration gradient. The observed REE patterns are interpreted as resulting from the combination of protracted garnet growth of progressively smaller crystals and intracrystalline diffusion. This had profound influence on Sm-Nd and Lu-Hf geochronology and resulted in a wide range of the obtained dates. The youngest age was obtained for a sample, where all garnet crystals are smaller than 2 mm and light REE profiles are completely or nearly completely homogenized. Very old apparent Lu-Hf ages are interpreted as being the consequence of variable degree of intracrystalline Lu diffusion and preservation of the original Hf distribution. Commonly observed back diffusion of Lu during resorption typically affected very narrow garnet rims and played subordinate role in modifying the isotope systematics.

The Influence of Recycling on Mantle 238U/235U?

M. B. ANDERSEN[1*], T. ELLIOTT[1]

[1]Bristol Isotope Group, School of Earth Sciences, University of Bristol, Wills Memorial Building, BS8 1RJ, United Kingdom (*morten.andersen@bristol.ac.uk)

The sub-chondritic Th/U (~2.5) of typical mid-ocean ridge basalts (MORB) is puzzling a much higher integrated Th/U (~3.8) evident from 208Pb/206Pb measurements [1,2]. A popular explanation of this problem has been to invoke recycling of U from the surface into the mantle since the Great Oxidation Event [e.g. 3]. It is intriguing that the lowering of Th/U seems concentrated in the upper mantle, such that MORB have lower Th/U than ocean island basalts (OIB), which are thought to be derived from deeper seated upwellings. This observation potentially informs on the style and vigour of mantle convection. Although an attractive hypothesis, it is uncertain if the recycled U fluxes over the last 2Ga are sufficient to lower the Th/U of MORB to 2.5 [4], despite recent improvements in estimates of modern recycling rates [5].

Mass-related variations in the natural 238U/235U ratio [6,7] offer a new means to test this model and we present new data that pertains to the problem. Variations in 238U/235U are related to low-temperature fractionation processes on Earth, with some of the largest variations observed in oceanic material (e.g. black shales). Thus, recycled material may have 238U/235U that deviates significantly from bulk Earth. We initially contrast the isotopic composition of seawater U, as might be quanitatively transferred to oceanic crust by high temperature alteration and Ocean Island basalts (OIB). Such measurements allow us to discern if we will be able to resolve 238U/235U differences between high Th/U OIB and low Th/U MORB as a result of recycling. We have measured the 238U/235U compositions of a suite of well-characterised OIB and related samples with high precision (±20, 2 SD). The measured OIBs include samples from La Palma, Azores and Iceland, spanning a wide range of U/Th compositions. The measured OIBs have identical 238U/235U compositions within ± 25 ppm (2 SD) and these are ~100 ppm heavier than modern seawater. Furthermore, preliminary measurements of hydrothermal altered MORB yields a weigthed 238U/235U mean simliar to seawater. This indicates that MORB should have 238U/235U ~50ppm ligther than the OIB if the recycling hypothesis is correct. We are currently undertaking the challenging task of making high precision 238U/235U measurements on MORB.

Are crystal-rich inclusions in spodumene crystallized aliquots of boundary-layer melt?

ALAN J. ANDERSON[1*]

[1] St. Francis Xavier University, Earth Sciences, Antigonish, Canada, aanderso@stfx.ca*

The constitutional zone-refining model for the crystallization of granitic pegmatites stipulates that a highly-fluxed and incompatible element-enriched boundary-layer liquid develops at rapidly advancing crystal growth fronts in undercooled granitic melts. It has been argued that crystal-rich inclusions in granitic pegmatites represent the products of entrapped boundary-layer melts and are thus not representative of the bulk-melt composition. A key example given in support of this claim is the crystal-rich inclusions in spodumene from the Tanco pegmatite, Manitoba. According to London [1], boundary layer melts are erratically variable and chemically more evolved than the bulk-melt, and this is precisely the characterization that describes the silicate-rich inclusion at Tanco. However, at Tanco, inclusions of the same character and composition occur in two types of spodumene: 1) primary magmatic spodumene laths, and 2) secondary spodumene, formed together with quartz by the isochemical breakdown of petalite. Although it is conceivable that a boundary-layer melt developed at the growth front of primary magmatic spodumene and petalite, it is unlikely that this ephemeral and spatially-restricted melt was available for entrapment in secondary spodumene during the transformation of petalite to spodumene + quartz.

Inclusions in both secondary and primary spodumene contain an assemblage of minerals (mainly quartz, cookeite and zabuyelite, with rare cesium analcime, albite, nacohlite, and Ca-Mn carbonates) that is essentially identical to the alteration assemblage in the lithium-rich zones at Tanco [2]. Image analysis measurements of 450 inclusions reveal a positive correlation between volume percent of solid phases in an inclusion and inclusion size, indicating extensive necking after precipitation of the solids. These observations suggest that the crystal-rich inclusions are not crystallized aliquots of boundary-layer melts but are instead samples of aqueous-carbonic fluid that had dissolved spodumene and precipitated quartz, cookeite and zabuyelite during and after entrapment.

Dissolved $^{231}Pa/^{230}Th$ in the U. S. GEOTRACES North Atlantic Zonal Transect

ROBERT F. ANDERSON[1*], CHRISTOPHER T. HAYES[1], MARTIN Q. FLEISHER[1], LAURA F. ROBINSON[2], KUO-FANG HUANG[2], HAI CHENG[3,4], R. LAWERENCE EDWARDS[4], AND S. BRADLEY MORAN[5]

[4]University of Minnesota, Minneapolis, MN, edwar001@umn.edu
[5]University of Rhode Island, Narragansett, RI, moran@gso.uri.edu

The North Atlantic Ocean displays zonal gradients in many of its properties. The western basin has more recently ventillated deep waters [1] and also a greater standing crop of suspended particulate material [2]. Both of these factors have the potential to induce zonal concentration gradients in ^{231}Pa and ^{230}Th. These radionuclides are produced uniformly throughout the water column by the decay of U. The balance between their subsequent redistribution by adsorption onto sinking particles (scavenging) and ocean circulation is not well known and incites debate over the interpretation of sedimentary $^{231}Pa/^{230}Th$ ratios with significant paleoceanographic consequences.

New results from the U. S. GEOTRACES North Atlantic Zonal Transect, completed over two legs in 2010 and 2011, will be presented that highlight the contrast between east and west $^{231}Pa/^{230}Th$ distributions. Furthermore, the deconvolution of the influences of deep water ventillation and scavenging intensity on $^{231}Pa/^{230}Th$ distributions can be discussed in light of indicators of particle concentrations from transmissometry and indicators of ventilation such as chlorofluorocarbons and ^{14}C [3]. Nepheloid layers, or more turbid waters containing resuspended sediments near the seafloor, were sampled in both the eastern and westwern basins. The increased scavenging intensity associated with these layers in environments of contrasting circulation patterns further informs our deconvolution of the two effects. These observations contribute to a more complete understanding of the chemical cycling of ^{231}Pa and ^{230}Th in the modern ocean and may inspire new directions for the interpretation of sedimentary records.

Hydrochemistry of a variably snow-covered catchment

SUZANNE PRESTRUD ANDERSON[1*], TAYLOR J. MILLS[1] AND RACHEL GABOR[1]

[1]INSTAAR, University of Colorado, Boulder, CO, USA, suzanne.anderson@colorado.edu (* presenting author)

Streamwater chemistry is useful for measuring contemporary weathering in a catchment. However, streamwater composition can vary seasonally, modulated by evapotranspiration, flow rate, flow paths, and biogeochemical processes within the watershed. We explore the seasonal dynamics of streamwater chemistry in a variably snow-covered catchment in the Boulder Creek Critical Zone Observatory as a foundation for understanding both hydrologic flowpaths and weathering in the catchment.

Gordon Gulch watershed

Gordon Gulch is a 2.7 km^2 forested catchment at ~2600 m a.s.l. in the Colorado Front Range, underlain by Precambrian gneiss and granodiorite. Mobile regolith depths are typically less than 1m, but bedrock tors dot the slopes; depth to fresh rock is ~8-10 m [1, 2]. Snowpack on N-facing slopes melts in spring, pushing groundwater levels up and fueling the annual discharge peak. Snow melts intermittently on S-facing slopes throughout fall, winter, and spring. Solute concentrations in streamwater vary by factors as high as 4 (Cl) to as little as 1.3 (Si), in seasonal patterns.

Cl concentrations shed light on the source of water discharging at different times in the year. Early fall and spring snowmelt produces high Cl concentrations in runoff, which appear to reflect throughfall traveling shallow paths to the stream. Cl peaks are accompanied by high dissolved organic matter (DOM) concentrations [3]. For more than a month after spring snowmelt, water sources are in transition. Cl dips to an annual minimum, approaching the low concentrations seen in precipitation, and lower than groundwater values. Only in very late summer (August) is Cl in streamwater the same as in groundwater. This suggests that late summer is the best time to analyze bedrock weathering from streamwater in this catchment. Perhaps not surprisingly, alkalinity, Ca and Na all rise to steady high concentrations during this time of groundwater fed baseflow.

Watershed dynamics

Streamflow, water-table heights, and water chemistry yield a picture of the watershed "breathing" on an annual basis. A "breath" begins with fall snow, which melts on S-facing slopes. This induces a small rise in water-table height and a dramatic streamwater flush of Cl and DOM. Early spring produces a more sustained rise in Cl, DOM, and the water table. Discharge and the water-table height rise to a dramatic peak during the sustained snowmelt from the N-facing slope. By the time of this crescendo, however, Cl and DOM are in precipitous decline. In midsummer minimally altered precipitation water is expelled during the long summer decline in discharge. The bottom of the breath is late summer, when only groundwater emerges. We will assess solute fluxes and mineral weathering variations during each stage of the annual watershed breath cycle.

Spectroscopic study of aluminum and gallium complexation by aquatic organic matter

K. ANDERSSON[1]*, P. PERSSON[1] AND T. KARLSSON[1]

[1]Department of Chemistry, Umeå University, 901 87 Umeå, Sweden *kristoffer.andersson@chem.umu.se (presenting author)

The fate and behavior of aluminum (Al) in aquatic systems is largely influenced by pH and interactions with natural organic matter (NOM). However, knowledge on the molecular structure and hydrolysis of Al species in presence of aquatic NOM is still limited. In this study Extended X-ray Absorption Fine Structure (EXAFS) and Infrared (IR) spectroscopy was used to characterize Al and gallium (Ga) interactions with organic matter from the Suwannee River at varying metal concentrations and pH. There are relatively few studies of Al interactions with NOM using these techniques [e.g. 1], one reason being the difficulty of analyzing Al in aqueous samples using EXAFS due to its low K-edge energy (1.5596 keV). Ga (K-edge at 10.367 keV), on the other hand, is readily accessible to EXAFS, and could serve as a model for Al because of the similar coordination chemistries of Al(III) and Ga(III). Indeed, previous studies of Al(III)- and Ga(III)-carboxylates have shown that these complexes can be considered analogous with respect to thermodynamic and spectroscopic properties [2, 3].

Our IR spectroscopic results showed that Al(III)- and Ga(III)-NOM interactions occur mainly via carboxylic functional groups, as indicated by characteristic shifts of the carboxyl stretching frequencies in presence of the metal ions. Overall, the behavior of the two systems was very similar, thus supporting our idea that Ga can be used as a model to study the complexation of Al by aquatic NOM.

The EXAFS results indicated that Ga formed chelate complexes in association with aquatic NOM. At low Ga concentrations (≤16 000 μg g^{-1}; pH 5) mononuclear Ga(III)-NOM complexes dominated the speciation while at higher pH values and high Ga concentrations (60 000 μg g^{-1}; pH 5-7) there was a mixture of mononuclear Ga(III)-NOM complexes and a polymeric Ga(III) (hydr)oxide phase. Thus, the organic Ga complexes formed were sufficiently strong to suppress hydrolytic polymerization even at pH 7.0 and high Ga concentrations. An additional finding was that the local structure of the Ga(III)-NOM complexes formed at the lowest concentration (100 μg Ga g^{-1}) clearly differed from those at higher Ga concentrations, which might indicate involvement from different functional groups.

Our combined EXAFS and IR results highlight the significant effects on metal ion speciation induced by the Al(III) and Ga(III)-NOM interactions. Accordingly, these interactions may exert a substantial control over the geochemistry of Al in aquatic systems, and the distribution between mononuclear complexes and polymeric species is likely to influence the toxicity and mobility of Al. Furthermore, the interactions with NOM may play a key role in determining the properties of the solid Al phases e.g. particle size.

Pb-Tl chronology of IIAB and IIIAB iron meteorites

RASMUS ANDREASEN[1,2*], MARK REHKÄMPER[1], GRETCHEN M. BENEDIX[3], KAREN J. THEIS[4], MARIA SCHÖNBÄCHLER[4], AND CAROLINE L. SMITH[3]

[1]Imperial College London, Earth Science and Engineering
[2]University of Houston, Earth and Atmospheric Sciences, randreas@central.uh.edu (* presenting author)
[3]Natural History Museum London, Department of Mineralogy
[4]University of Manchester, School of Earth, Atmospheric and Environmental Sciences

The short-lived ^{205}Pb-^{205}Tl system ($t_{½}$= 15.1 My) is the only decay system in which the parent nuclide is an s-process only nuclide, and thus the Solar System initial abundance of ^{205}Pb provides unique constraints on the amount of AGB star material injected into the Solar Nebula shortly before its collapse. The Pb-Tl system is furthermore one of few that can be used to date metal crystallization and hence provide independent age constraints on the core crystallization and thermal history of planetary bodies.

Measured Pb concentrations vary widely—from 0.5 ppb to more than 1 ppm due to terrestrial Pb contamination, which was not removed despite repeated leaching. The fraction of primordial Pb is calculated assuming deviation in the Pb isotope composition of the iron meteorites from primordial Pb is due to terrestrial Pb contamination. The concentration range of primordial Pb is very limited—from 0.1 ppb to 1.7 ppb. Concentrations of Tl range from 2 ppt to 485 ppt, with most samples below 20 ppt. This gives ^{204}Pb/^{203}Tl ratios for the IIABs from 0.05 to 5.8, and from 1.6 to 14 for the IIIABs, close to the chondritic ratio of 1.4. Values of ε^{205}Tl range from -18 to +23 and correlate with ^{204}Pb/^{203}Tl ratios, suggesting that the ε^{205}Tl variations are from the decay of ^{205}Pb at different Pb/Tl ratios. The IIAB isochron has an intercept, $\varepsilon^{205}Tl_0$ = -12±1 that is more negative than that of the carbonaceous chondrites, $\varepsilon^{205}Tl_0$ = -7.6±2.1.

This may imply that metal/silicate separation of the IIAB parent body was associated with mass-dependent Tl isotope fractionation of ~7 ε-units. However, experimental data suggest that a fractionation of this magnitude is not likely. Alternatively, if the carbonaceous chondrite isochron is recalculated rejecting samples suffering from large terrestrial Pb contamination, the slope of ε^{205}Tl vs. ^{204}Pb/^{203}Tl is steeper, with $\varepsilon^{205}Tl_0$ = -13±6. This gives Pb-Tl ages for the IIAB and IIIABs of around 15 Ma after carbonaceous chondrites.

The IIAB isochron intersects the carbonaceous chondrite isochron at ^{204}Pb/^{203}Tl = 0.15. This indicates that metal-silicate segregation took place around 2 Ma after carbonaceous chondrites, and that the metal portion of the IIAB parent body had a low Pb/Tl ratio. The latter conclusion is in agreement with previous work that inferred that IIAB irons had sulphur-rich metal compositions, and with existing experimental partitioning data suggesting that a sulphur-rich metal phase should be significantly enriched in Tl compared to Pb. The reinterpreted carbonaceous chondrite isochron gives a Solar System initial ^{205}Pb/^{204}Pb ratio of 2±1 x 10^{-3}.

Laboratory mesocosm experiments to quantify effects of elevated CO_2, plant evolution, and mycorrhizal status on carbon flux and weathering.

MEGAN Y. ANDREWS[1,2*], JONATHAN R. LEAKE[2], GABRIELLA KAKONYI[3], MARIA ROMERO-GONZÁLEZ[3], STEVEN A. BANWART[3], AND DAVID J. BEERLING[2]

[1]Department of Soil Science, North Carolina State University, Raleigh, USA, myandrew@ncsu.edu (* presenting author, current institution)
[2]Department of Animal and Plant Sciences, University of Sheffield, Sheffield, UK
[3]Cell-Mineral Research Centre, Kroto Research Institute, North Campus, University of Sheffield, Sheffield, UK

The evolution of vascular land plants in the Paleozoic is hypothesized to have enhanced weathering of Ca and Mg bearing silicate minerals (e.g. [1]). However, this plant-centric view neglects the co-evolution of plants and their associated mycorrhizal fungi. Indeed, many weathering processes usually ascribed to plants may actually be driven by the combined activities of roots and mycorrhizal fungi [2]. Here we present results from a novel mesocosm-scale laboratory experiment designed to allow investigation of plant-driven carbon flux and mineral weathering at different soil depths, and under ambient (400 ppm) and elevated (1500 ppm) atmospheric CO_2.

We selected plant species to quantify the effects of mycorrhizal type (arbuscular, AM, vs. ectomycorrhizal, EM), rooting depth, and angiosperms vs. gymnosperms on carbon flux and biological weathering. These species included the AM *Sequoia sempervirens, Osmunda regalia, Magnolia grandiflora*, and *Ginkgo biloba,* as well as two EM species, *Pinus sylvestris* and *Betula pendula*. Two long-term (7-13 months) experiments were conducted under similar environmental conditions with one exception: Experiment 1, focused on rooting depth, used a low nutrient substrate and Experiment 2, studying angiosperms vs. gymnosperms, used an organic-rich substrate.

Only under low nutrient conditions did we observe increased biomass in plants and bulk fungus grown under elevated CO_2. For the two species grown in both experiments, mineral core fungal biomass and the magnitude and timing of carbon flux from plant to belowground biomass seemed to be more correlated to soil organic content than CO_2. Fungal activity was related to plant carbon flux and was not proportional to fungal biomass, which may be important for biological weathering. Bulk and mineral core solution chemistries differ between plant-free controls, plant species, minerals, and CO_2 levels, potentially giving insight into mechanisms and degree of mineral weathering. Ongoing measurements will further assess mineral weathering and quantify biomass element uptake in these systems.

Anatexis in K-poor and Si-Rich migmatites

MICHAEL ANENBURG[1*] AND YARON KATZIR[1]

[1]Ben-Gurion University of the Negev, Geological and Environmental Sciences, Beer Sheva, Israel,
michaela@bgu.ac.il (* presenting author)
ykatzir@bgu.ac.il

K-poor and Si-rich pelites are potential protoliths of migmatites, but often lack clear mineralogical indicators for anatexis. This is due to the limited number of peritectic phases, and because the products of melting reactions tend to be erased by retrograde deformation and recrystallization. Thus the pre- and post-peak assemblages may be almost identical and evidence for migmatization is overlooked.

The Roded migmatites of southern Israel were previously thought to form by subsolidus metamorphic differentiation based on the lack of K-feldspar in leucosomes and similarity of plagioclase compositions in coupled leucosomes and melanosomes [1]. Geochemical analysis of carefully sampled palaeosomes shows that the protoliths of Roded migmatites were K-poor and Si-rich metapelites. Nonetheless relict textural evidence for melting is found in the Roded migmatites including quartz-filled embayments in plagioclase crystals, and newly formed euhedral crystals of plagioclase in leucosomes. Likewise lenticular K-felsdpar occurs within melanosome biotite indicating muscovite dehydration melting. Thermodynamic analysis of specific palaeosome compositions show that anatexis should have occurred at peak P-T conditions estimated for the Roded migmatites (Fig.1; 4.5 kbar; ~650ºC). Petrographic and microstructural observations suggest that potassium was mobilized from the leucosomes to the melanosomes during melt crystallization: Leucosome K-feldspar was replaced by myrmekite and melanosome sillimanite was replaced by symplectites of muscovite and quartz.

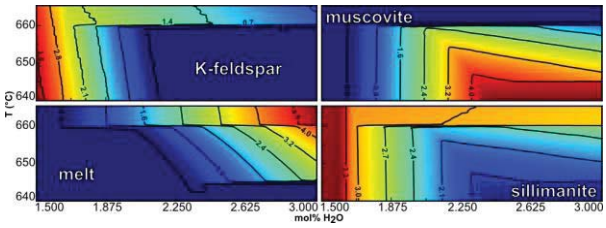

Figure 1: Modelled modes of key phases in melting reactions displayed on T vs. whole-rock H_2O content diagrams calculated for a specific rock composition of Roded migmatites. P=4.5 kbar.

Wider neosomes are characterized by diatexitic microstructures and by lower amount of myrmekite suggesting channeled influx of water resulting in higher degree of anatexis and dilution of potassium in the melt.

K-feldspar and muscovite+quartz symplectites in melanosomes, and myrmekite in leucosomes are established as criteria for inferring partial melting in heavily overprinted and retrogressively deformed K-poor, Si-rich migmatites.

Cation substitution in Iron Oxides in BIF-hosted Iron Ore: the Role of Inheritance and Fluids

THOMAS ANGERER[1*], STEFFEN HAGEMANN[1]

[1]Center for Exploration Targeting, University of Western Australia, thomas.angerer@uwa.edu.au (*presenting author)

Little is known about the chemisty of the often complex iron oxides paragenetic sequences in BIF-hosted high-grade iron ore, and its potential use for genetic modelling (e.g., iron oxide and fluid origin) and exploration (e.g., as chemical tracer towards ore). In order to investigate this, minor and trace elements (lithophile: Ti, V, Cr, Sc, Al, Ga, Mg, Mn, and chalcophile: Ni, Cu, Zn, As, Co) in magnetite, hematite, and goethite species in the Koolyanobbing and Windarling iron ore deposits located in the Yilgarn Craton, which are hosted in lithostratigraphic unit of same Age (3.0 Ga), but in different greenstone belts, were analysed by means of laser ablation ICPMS.

Early very-low to low metamorphic grade magnetite (M-1) in least-altered BIF have lithophile element contents between 1 and 1000 ppm (Mg>Al>Mn>Ti>V>Ga) and chalcophile element contents between 0.1 and 100 ppm (Zn≥Ni≥Cu>Co±As). Compared to other hydrothermal deposit classes, magnetite types in BIF-hosted iron ore are poor in most substituting cations, especially Cr, V, and chalcophile elements (up to three magnitudes). The analytical precision decreases with lower element concentration (<100 ppm), but due to these very low concentrations, laser ablation is the only method to measure indicative chemistry of BIF-related iron oxides.

Hydrothermal magnetite (M-2) types in hydrothermal carbonate- and quartz-altered BIF (both are most prolific protoliths to ore) show typically even lower concentrations of most lithophile elements (Mg, Al, Ga, ±V, ±Ti) than M-1, but higher concentrations of Mn and chalcophile elements, most prominently Co. This suggests that in both deposits M-2 precipitated from fluids of a common type, probably low T (limited element substitution), sulphide-rich, and with a redox condition in which Mn substitution was favored. A partial inheritance of M-2 from disolved M-1 may be concluded from similar immobile element (V, Ti, Al, Ga) ratios.

Both, hydrothermal and supergene-related martite (after M-1 and M-2) do not involve significant changes of the chemistry, except a Mg (±Zn) loss (due to the exclusion of solely II-valent elements from hematite). A mineral chemical differentiation between hypogene and supergene martite is presently difficult, mainly due to the inheritance.

Intermediate to late stage hydrothermal hematite types show commonly a decrease of Mg, Mn, Zn, Ni, Cu, Co. In Koolyanobbing a remarkably similar content of other lithophile elements with respect to M-1 and/or M-2 points to a chemistry inheritance from (proximal) dissolved or in-situ replaced BIF magnetite.

Supergene goethite chemistry is distinct when comparing different goethite types (goethite after siderite vs quartz). For example, goethite after siderite shows similar Ni, Cu, and Co concentrations when compared to the replaced siderite.

In conclusion, cation substitution of hydrothermal and supergene iron oxides in BIF-related iron ore systems of the Yilgarn craton show that iron oxides are capable of capturing chemical signatures that help deciphering geological/fluid regimes.

([*] presenting author)

Epithermal uranium deposits of the Sierra Peña Blanca are classic examples of volcanic-hosted deposits and have been used as natural analogues for radionuclide migration in volcanic settings. We present a new genetic model that incorporates both geochemical and tectonic features of these deposits, including one of the few documented cases of a geochemical signature of biogenic reducing conditions favoring uranium mineralization in an epithermal deposit. Four tectono-magmatic faulting events affected the volcanic pile. Uranium occurrences are associated with breccia zones at the intersection of fault systems. Periodic reactivation of these structures associated with Basin and Range and Rio Grande tectonic events resulted in the mobilization of U and other elements by meteoric fluids heated by geothermal activity. Focused along breccia zones, these fluids precipitated under reducing conditions several generations of pyrite and uraninite together with kaolinite. Oxygen isotopic data indicate a low formation temperature of uraninite, 45–55°C for the uraninite from the ore body and ~20°C for late uraninite hosted by the underlying conglomerate. There is geochemical evidence for biological activity being at the origin of these reducing conditions, as shown by low δ34S values (~ -24.5 ‰) in pyrites and the presence of low δ13C (~ -24 ‰) values in microbial patches intimately associated with uraninite. These data show that tectonic activity coupled with microbial activity can play a major role in the formation of epithermal uranium deposits in unusual near surface environments.

(U)SANS analysis of experimental dissolution and formation of quartz overgrowths in St. Peter Sandstone

Introduction

The microstructure and evolution of porosity in time and space play a critical role in many geologic processes, including migration and retention of water, gas and hydrocarbons, the evolution of hydrothermal systems, weathering, diagenesis and metamorphism, as well as technological processes such as CO_2 sequestration, shale gas and secondary oil recovery. The size, distribution and connectivity of these confined geometries collectively dictate how fluids migrate into and through these micro- and nanoenvironments, wet and react with mineral surfaces. To interpret the time-temperature-pressure history of a geological system the physical and chemical "fingerprints" of this evolution in the rock should be interrogated from the nanoscale to the macroscale.

Description

We have performed a series of experiments to understand the effects of quartz overgrowths on nanometer to centimeter scale pore structures of sandstones. Blocks from two samples of St. Peter Sandstone with different initial porosities (5.8 and 18.3 %) were reacted from 3 days to 7.5 months at 100 and 200°C in aqueous solutions supersaturated with respect to quartz by reaction with amorphous silica. Porosity in the resultant samples was analyzed using small and ultrasmall angle neutron scattering and SEM/BSE-based image processing techniques.

Results and Conclusion

Significant changes were observed in the multiscale pore structures. By 3 days the overgrowths in the low-porosity sample dissolved away. The reason for this is uncertain, but the overgrowths can be clearly distinguished from the cores in the BSE images. At longer times the larger pores are observed to fill with needle-like precipitates. As with the unreacted sandstones, porosity is a step function of size. Grain boundaries are typically fractal, but no evidence of mass fractal or fuzzy interface behavior was observed [cf.1] suggesting a structural difference between chemical and clastic sediments. After the initial loss of the overgrowths image scale porosity (> ~ 1 μm) decreases with time, while submicron porosity (typically ~25 % of the total) is relatively constant or slightly decreasing, and the fraction of small pores increases.

Experimental results that are environmentally relevant are needed to predict transient diagenetic processes. For that, we developed a designed reactor for the examination of diagenetic processes [1]. We present here the results from two independent experiments with sediment slurries collected the Arcachon bay and the macrotidal Adour estuary. Slurries and in-situ water were mixed to give a SPM concentration of 150 g/l. Sediments were submitted to redox oscillations at the tidal and neap-spring time scales to assess the diagenetic mechanisms that affect N, P, Fe, Mn and S species. The experiments started in anoxic conditions during one week. Then oxic conditions were obtained by purging with air. After one week of oxic conditions, anoxic conditions were recovered by purging with N2.

From anoxic to oxic conditions : We observed rapid oxidation of dissolved Fe(II). Dissolved phosphorus was trapped with new Fe-oxides. It was totally titrated in Arcachon sediments, but not in Adour sediments. Because of the strong control of P by Fe, the N/P ratio was never constant and did not reflect the N/P of the mineralized organic matter. Mn(II) was slowly oxidized. A major part of Mn(II) was rather adsorbed on new Fe-oxides. In Arcachon sediments, ammonium remained constant in oxic conditions. Nitrate was produced from organic-N mineralization. In Adour sediment nitrate was produced from ammonium nitrification.

From oxic to anoxic conditions : A part of newly precipitated Fe-oxides was reduced, another part was trapped with sulfides. Dissolved P concentrations were not recovered. P was probably trapped in an authigenic phase. In Adour sediments, high concentrations of Mn-oxides prevented Fe(II) accumulation. In Arcachon sediments, direct reduction of nitrate to ammonium, rather than denitrification occurred. Anammox probably occurred in anoxic conditions of Adour sediments. Anaerobic production of nitrate also occurred in Adour sediments, probably because the concentration of Mn-oxides was high

These experimental results show that nutrient dynamics in oscillatory redox enviromnents such as estuary turbidity zone, bioturbated sediment or tidal permeable sediments strongly depend on reactive Fe and Mn content.

We have studied the deformation, metamorphic, and cooling history of the Himalayan suprastructure (Tethyan sedimentary sequence – TSS) and infrastructure (Greater Himalayan sequence – GHS) preserved in the most southward and foreland part of the orogen in west Nepal, to better understand the relationship between hinterland and foreland deformation in a mid-crustal flowing orogen.

The studied N-S profile (28 km) transverses the Dadeldhura klippe. The klippe is characterised by an early to late Miocene syncline structure bound to the north and south by the folded Dadeldhura Thrust, regionally correlated to the Main Central thrust. The northern limb is characterised by medium metamorphic -grade rocks (mylonitic augen gneiss ± garnet, mica-schist ± garnet ± staurolite, muscovite bearing quartzite) with south-dipping foliation and down-dip elongation lineation. The southern limb exposes ca. 4 km-thick medium metamorphic-grade rocks, structurally overlain by ca. 9 km-thick meta-igneous rocks (augen gneiss) with north-dipping and down-dip elongation lineation. Rocks of both limbs are regionally correlated to the GHS and are characterized by pervasive S-C-C′ fabrics, σ and δ porphyroclasts, and mica-fish consistent with top-to-the-south shear. Close to the contact with the overlying TSS meta-pelites, the GHS displays top-to-the-north sense of shear, which is likely related to the southern extent of the South Tibetan Detachment system. Microstructural analyses of quartz-rich units suggest the GHS underwent non-coaxial top-to-the-south sense of shear at temperatures between 450 ºC and 550 ºC.

Meso and microstructural analyses performed on the TSS meta-pelites outcropping in the core of the syncline highlights a polyphase deformation history characterized by two main cleavage development phases. Illite crystallinity measured on <2 µm and <0.2 µm size fractions and the corresponding $^{40}K/^{40}Ar$ ages of the meta-pelites show that the samples are dominated by newly formed white mica. Illite crystallinity values range from Kübler Index 0.136 to 0.238 suggestive of epizonal conditions to lower greenschist facies (min. 350 ºC). Illite-muscovite $^{40}K/^{40}Ar$ ages are interpreted as cooling ages after peak metamorphic conditions and range between 18.2 ± 0.8 Ma close to the STDS to 26.6 ± 1.3 Ma in the core of the syncline.

Despite its structural similarity, the Dadeldhura GHS rocks differ from the GHS rocks described in the higher Himalaya 100 km to the north by the absence of migmatite and sillimanite-bearing rocks. This difference might be a field expression of telescoped and folded metamorphic isograds at the frontal part of the extruded GHS. Future work in the Dadeldhura GHS, including U-Pb in-situ dating of deformation fabrics and ^{40}Ar-^{39}Ar analyses, will assist in testing links between hinterland-style deformation (e.g. channel-flow) in the higher Himalaya with foreland-style deformation (e.g. critical-taper) in the external klippes of the Himalayan system.

Fate of groundwater-derived nutrients in tidally influenced coastal aquifers: numerical simulations

NAWRIN ANWAR[1*], AND CLARE ROBINSON[1]

[1]The University of Western Ontario, London, Canada, nanwar3@uwo.ca ; crobinson@eng.uwo.ca (* presenting author)

Introduction

The flow, transport and transformation processes in a subterranean estuary strongly control the exit conditions for groundwater-derived nutrients discharging to coastal waters. While several studies have examined the fate of nutrients in subterranean estuaries [e.g., 1, 2], the impact of oceanic fluctuations including tides is often neglected. These water level fluctuations however can induce a highly dynamic surficial mixing and reaction zone in the near-shore aquifer and significantly alter the subsurface flow paths for discharging nutrients. In this study the variable density groundwater flow model SEAWAT-2005 is used in combination with the reactive multi-component transport model PHT3Dv2.10 to examine the influences of tide on the transport and transformation of nutrients (ammonium, nitrate, and phosphate) in this dynamic zone. Reactions considered in the model include denitrification, nitrification, aerobic degradation of dissolved organic carbon, iron oxidation and reduction, and phosphate adsorption [1].

Results and Conclusion

SEAWAT combined with PHT3D provides a powerful modeling platform for simulation of the multi-component reactive transport processes occurring in a tidally-influenced subterranean estuary. Simulations reveal that tidal fluctuations significantly alter the transport pathways of the groundwater-derived nutrients and the mixing between the groundwater and recirculating seawater in the near-shore aquifer. This alters the biogeochemical reactions occurring in this region and thus impacts the nutrient transformations and subsequent loading rates to coastal waters (e.g., Figure 1). Tide-induced recirculation also leads to the precipitation of iron oxides around the upper mixing zone and this may act as an important geochemical barrier for accumulating chemicals including phosphate in the intertidal sediments. A sensitivity analysis is presented for the governing parameters.

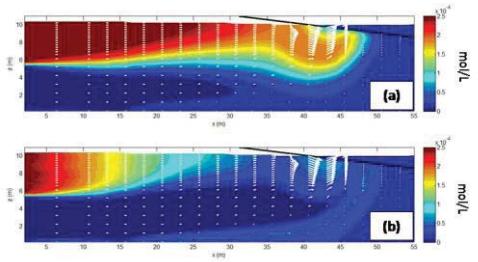

Figure 1: Nitrate concentrations ina nearshore aquifer exposed to tidal fluctuations (amplitude 0.5 m) (a) without, and (b) with reactions considered.

Abstract

Thermodynamic properties of metals with common ligands under hydrothermal conditions are needed to model the geochemistry metal ore deposits and the chemistry of Generation IV super-critical water nuclear reactor designs. While the thermodynamic stability of copper (I) and copper (II) chloro complexes are quite well established over a wide temperature range [1,2], the structure of some of these species is a subject of active investigation [3].

This study uses Raman spectroscopy as a tool to identify the structure, speciation and thermodynamic properties of copper complexes. Briefly, polarized Raman spectra, collected parallel and perpedicular to the orientation of the exiting beam as a function of molality and temperature, relative to an internal standard (ClO_4^-), were used to determine reduced isotropic spectra [4]. The spectra are very weak, and this technique yields an accurate baseline correction. Ab initio calculations, using methods similar to those for Zn-Cl [5], have been used to predict the stability, structures and Raman spectra of all the possible chloro and aquo complexes with Cu^+ and Cu^{2+}. The Cu-Cl vibrational frequency for Cu^+ complexes was sensitive to the hydration number and the type of calculation (HF,MP2,B3LYP).

Based on these *ab initio* calculations, and the temperature dependent spectra in H_2O and D_2O, vibrational bands were assigned to the copper (II) species Cu^{2+}, $CuCl^+$, $CuCl_2^0$ and $CuCl_3^-$. While the spectra for copper (I) species were much less intense, there is strong evidence for $CuCl_2^-$ and $CuCl_3^{2-}$.

Origin of Mississippi Valley-type deposits in the Ozark and Interior Low Plateaus, U.S. mid-continent: constraints from fluid inclusions

MARTIN S. APPOLD[1]*, ZACHARY J. WENZ[2] AND MICHAEL A. PELCH[1]

[1]Dept. of Geological Sciences, University of Missouri, Columbia, MO 65211, USA, appoldm@missouri.edu (* presenting author)
[2]Minnesota Dept. of Natural Resources, St. Paul, MN 55155, USA

Mississippi Valley-type (MVT) deposits have long been understood to be products of sedimentary basinal brines based on the bulk salinity, temperature, and major element composition of their fluid inclusions. Whether MVT mineralizing fluids resemble typical sedimentary brines with respect to ore metal content has until recently been far less certain and was a major concern of the present study. A further motivation for determining ore metal content in MVT mineralizing fluids is that ore metal content, together with pH, redox potential, and sulfur content, largely governs precipitation mechanism, which is also uncertain for many MVT deposits. Major element concentrations in MVT fluids reported in previous studies have largely been determined from bulk leachate analysis of fluid inclusions, where mixing of primary and secondary fluid inclusions and mineral matrix contributions are likely to have affected the reported results. Thus, another goal of the present study was to obtain improved measurements of major element concentrations, along with ore metal concentrations, through in situ analysis of individual fluid inclusions. These major element concentration data provide additional constraints on precipitation mechanism, fluid flow paths, and genetic relationships among deposits.

The focus of the present study was on fluid inclusions from the Southeast Missouri, Tri-State, Northern Arkansas, and Central Missouri districts of the Ozark Plateau, and the Illinois-Kentucky district of the Interior Low Plateau. A consistent feature found for these districts is that they contain populations of Pb-rich sphalerite-hosted fluid inclusions (containing 100's to 1000's of ppm Pb) that probably reflect the intermittent invasion of Pb-and possibly overall metal-rich ore fluid into the districts during sulfide mineralization. High methane concentrations in both sphalerite- and gangue-hosted fluid inclusions indicate that mineralizing conditions were predominantly reducing, such that sulfide mineralization was probably caused by mixing of Pb-rich ore fluid with a sulfide-rich fluid. Methane concentrations in fluid inclusions could be used to calculate minimum mineralization depths, which yielded a range from about 100 to 1500 m. Pb-rich ore fluids in all of the districts had dolomitizing Ca/Mg ratios, indicating that the the fluids did not travel very far through the predominantly limestone aquifers in which sulfide mineralization is presently hosted. The Pb –rich ore fluids in the districts differed from one another with respect to major element composition, indicating that although all of the districts may have been formed from the same physical flow system, this fluid was chemically heterogeneous. In the Illinois-Kentucky district, the compositional distinctives of the ore fluid are consistent with inputs expected from local igneous activity contemporaneous with MVT mineralization.

Pressure dependence of enthalpy, viscosity and diffusivity of olivine and its constituent minerals near melting

SAYYADUL ARAFIN*, RAM N. SINGH AND ABRAHAM K. GEORGE

Physics Department, College of Science, Sultan Qaboos University, P.O. Box: 36, Al-Khoudh 123, Sultanate of Oman, sayfin@squ.edu.om (*presenting author)

Introduction

Olivine, the major mineral of the Earth's upper mantle, plays a key role in the mineralogical models for the Earth's mantle. It is greatly appreciated that rheological properties of olivine are important ingredients in modeling the geodynamic processes in the upper mantle such as convective flows, evolution of subduction zones, deep seismicity patterns and post-seismic mantle relaxation. Our knowledge of crystallographic orientaion of olivine can help interpret the seismic anisotropy of the upper mantle in terms of mantle flow[1]. The physical and chemical conditions of deformation mechanisms control the crystallographic and shape preferred orientations of olivine.

We have derived a mathematical expression for the melting temperature, T_m and its pressure dependence by extending the Lindemann's melting law. Seismic p- and s-wave velocities and density data as a function of pressure were used as inputs to compute Debye temperature, Θ_D, which forms the important ingredient of the empirical relation for the melting temperature. We have applied the formalism to estimate T_m and its pressure dependence, which in turn has been used to estimate enthalpy, viscosity and diffusivity of olivine and its constituent minerals such as foresterite (Mg_2SiO_4) and fayalite ($Fe_2\ SiO_4$).

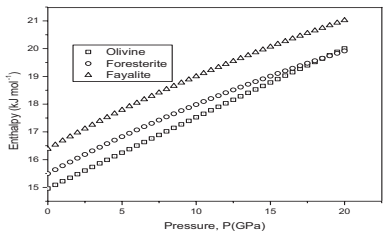

Figure 1: Enthalpy of olivine and its constituent minerals as a function of pressure

Results and discussions

We present here in Figure 1 only a part of the results. Our preliminary results show linear increase of enthalpy, viscosity and diffusivity for olivine and non-linear increase for foresterite and fayalite with increasing pressure. At room temperature and atmospheric pressure, the values of enthalpy, viscosity and diffusivity are found to be 14.96 kJ mol^{-1}, 2.58 mPa s and 1.69 x 10^{-4} m^2 s^{-1} for olivine , 15.50 kJ mol^{-1}, 2.58 mPa s and 1.75 x 10^{-4} m^2 s^{-1} for foresterite and 16.38 kJ mol^{-1}, 3.07 mPa s and 1.53 x 10^{-4} m^2 s^{-1} for fayalite respectively.

Lithium is a useful and worth element for industrially purposes. Lithium has unique characteristics such as lowest Oxidation-reduction potential among all elements and the third-lightest element after hydrogen and helium. These properties are valuable for lithium-ion secondary battery that is non-memory-effect, high-power and the highest energy density among batteries in practical use.

Salt lakes are the most major lithium resources on earth. Highly concentrated lithium resources were formed in salt lakes by repetition of water evaporation and inspissation with an arid climate. As a result of rising consumption of lithium carbonate, lithium-rich brine in salt lakes have been developed all over the world. Therefore, it is essential for revealing the origin of highly concentrated lithium in salt lakes for future exploration.

Lithium isotope ratio is known for newly useful tool understanding water-rock interaction. Moreover, lithium isotopic fractionation is dependent on temperature and its compositions are strongly affected by initial values of host rocks. We report lithium and strontium isotope ratio, as well as major and trace element compositions, of samples collected from some salt lakes at Nevada, USA. These lithium isotopic values (δ^7Li) of samples have a large variation among each sample, however all the values are much lower than the values of river water reported previously [1], and are close to values of upper continental crusts [2]. These results suggest that highly concentrated lithium in salt lakes were not formed during surface weathering processes, but were supplied by the result of water-rock interaction below the surface of the earth at high temperature.

We demonstrated that lithium isotope ratio has a potential for tracing lithium origin in salt lakes and further detailed studies must be required such as the values of host rocks.

Mg/Ca Paleothermometry in *G. ruber* (white): mechanisms and calibration

Jennifer A. Arbuszewski[1*], Peter B. deMenocal[2]

[1]Woods Hole Oceanographic Institute, Woods Hole, USA, [*]jarbuszewski@whoi.edu

Abstract

Paired planktonic foraminiferal Mg/Ca and δ^{18}O analyses are frequently applied to jointly estimate sea surface temperature and $\delta^{18}O_{seawater}$, a proxy for ocean salinity. The relationship between shell Mg/Ca and temperature is rooted in thermodynamic theory; Mg/Ca increases as temperature increases as a result of the endothermic substitution of Mg^{2+} into the calcite lattice[1-2]. While temperature has previously been indicated as the main controlling factor in foraminifera, there is significant biological mediation[1,3-6].

Recent results suggest that ocean salinity may also be a significant influence on shell Mg/Ca ratios[7-9]. This influence was noted in our findings from an Atlantic meridional coretop sample transect, where we found that *G. ruber* (white) shell Mg/Ca values were significantly elevated in higher salinity gyre waters. This "excess Mg/Ca" (the residual between the observed and expected Mg/Ca composition at the δ^{18}O calcification temperature) is well correlated with surface salinity[7]. We investigated the nature of this "excess Mg/Ca" signal for the planktonic species, *G. ruber* (white). We employ multiple techniques including scanning electron microscope imaging, flow through ICP-MS, and electron microprobe elemental mapping, with a goal of separating potential mechanisms for the observed enhanced uptake of shell Mg/Ca at high salinity.

In addition, we will present our latest global calibration efforts. Our global database consists of 301 coretops, and is growing, composed of both new and published data for the surface-dwelling planktonic foraminifer, *G. ruber* (white). We use multivariate regression analyses to produce new global equations relating shell Mg/Ca, δ^{18}O, and bottom water ΔCO_3^{2-} to ocean temperature and salinity. Our goal is to better understand how environmental (and biological) conditions influence shell chemistry and to use this knowledge to improve calibration equations. We will discuss the validation of these new equations and their applicability to downcore paleoclimate reconstructions.

Mo and Ni isotope systematics in petroleum fluids across subsurface alteration gradients

COREY ARCHER[*1], TIM ELLIOTT[1], SANDER VAN DEN BOORN[2], PIM VAN BERGEN[3]

[1]Bristol Isotope Group, School of Earth Sciences, University of Bristol, BS8 1RJ, UK (*c.archer@bristol.ac.uk)
[2] Shell Projects and Technology , Rijswijk, The Netherlands
[3] Shell Upstream International Europe, Aberdeen, UK

The presence of trace metals in oils has long been of interest for both their beneficial and detrimental effects during hydrocarbon exploration and processing, respectively. For example, the diagnostic potential of trace metals incorporated in fluids and source rocks has been successfully applied in various fingerprinting studies. The majority of work to date has focussed on the two most abundant metals in oils, vanadium (V) and nickel (Ni), where abundances and elemental ratios have been used as tools in correlation and fingerprinting, and provide information on redox conditions during source rock deposition [1]. Here, we focus on the molybdenum (Mo) isotope system, well known to display a bi-polar redox chemistry [2], and similarly explore the potential of Ni isotopes, with the aim of developing valuable new tools to exploit in petroleum systems' studies.

We have developed techniques for the determination of Mo and Ni isotopes in hydrocarbon (HC) fluids. The analyte is extracted from its complex organic fluid matrix, through high pressure ashing, which renders the complete decomposition of the HC fluid, allowing the Mo and Ni from the same sample fraction to be purified via conventional ion-exchange methods. Data from replicate analyses of both samples and an NIST HC standard suggest a precision of better than 0.1‰ in both $\delta^{98/95}$Mo and $\delta^{60/58}$Ni. These techniques are applied to co-genetic oil samples from a well characterised petroleum system to investigate Mo and Ni isotope systematics across subsurface alteration gradients (e.g maturation, biodegradation and migration).

The co-genetic samples thus far analysed show remarkably invariable $\delta^{98/95}$Mo values along various alteration gradients, such as maturation. This is in contrast to many organic geochemistry proxies which are traditionallly employed to examine these changes in HCs, and an overall $\delta^{98/95}$Mo range of ~1.5‰ for the entire HC dataset (incl. samples from other petroleum systems). Ni is much more variable along the studied gradients, displaying a range in $\delta^{60/58}$Ni from -0.5‰ to +0.8‰, suggesting a different mechanistic behaviour to Mo. These results highlight the potential of Mo isotopes to be used as a new tool in oil-oil/source rock correlations on a basin-wide scale, whereas Ni isotopes may prove to be useful in the characterization of processes operating on more restricted spatial scales.

Stable isotope geochemistry and the optimization of hydraulic fracturing of petroleum wells – lessons from the Bakken Formation in Canada and the USA

SERGUEY ARKADAKSKIY[1*] AND BEN ROSTRON[2],

[1]Isobrine Solutions Inc., Edmonton, Canada, serguey@isobrine.com (*presenting author)
[2]University of Alberta, Earth and Atmospheric Sciences, Edmonton, Canada, ben.rostron@ualberta.ca

Hydraulic fracturing (a.k.a. fracing) is an established method for petroleum well stimulation used to enhance reservoir permeability through the creation of artificial fractures by injecting aqueous fluid under high pressure in the target zone. Recent developments of that technology have allowed petroleum production from low permeability reservoirs previously considered uneconomic. Hydraulic fracturing combined with precise horizontal drilling has provided access to tens, perhaps hundreds of Bbls of high quality light crude oil in the late Devonian/early Mississippian Bakken Formation in the Williston Basin [1]. The Bakken reservoir is a thin (13 m on average) dolomitic silt/sandstone horizon sandwiched between two organic-rich marine shales. Oil and gas generated in the shales migrated to and remained for the most part within the Middle Bakken reservoir [2], which close to the basin center (USA) is largely water unsaturated but exhibits various degrees of water saturation in the thermally immature parts near the edges of the basin (Canada). Unexpected and/or excessive water co-production following high volume multistage fracing of horizontal wells drilled throughout the basin has been of concern lately. Since both the overlying (i.e., the Mississippian Lodgepole) and the underlying (the Devonian Torquay and Nisku/Birdbear) formations are water-saturated, it has been hypothesized that fracing may have resulted in fracture propagation into these formations. Questions have also been raised about the presence and/or apportioning of fracing fluids and/or other service/maintenance fluids in the co-produced waters. While standard formation water identification techniques have been largely unable to provide unambiguous answers to those questions, stable isotope geochemistry and other geochemical techniques have met with greater success. In this presentation we will discuss the application of stable isotope geochemistry and other geochemical methods for identifying the source(s) of different fluids in waters co-produced from horizontal Bakken wells stimulated with hydraulic fracturing. We will also discuss the impact our findings have been having on petroleum producers in the basin and the changes these have made to their hydraulic fracturing practices in order to minimize unwanted water co-production.

Evaluating ocean acidification using stable isotope fractionation of fossil scallop shells

JILL ARRIOLA[1*], BRYANNA BROADAWAY[1]

[1]University of Massachusetts-Boston, Boston, USA, jill.arriola001@umb.edu (* presenting author)

As ocean pH declines, due to increased atmospheric carbon dioxide, the saturation states of carbonate polymorphs is expected to decline. Fractionation of oxygen, carbon, and sulfur stable isotopes in growing shells in response to these changes, whether direct or indirect, could provide a new tool for reconstruction of paleoenvironments. In the laboratory bay scallops were reared (*Argopecten irradians*) under low pH conditions induced by high CO_2 (pH = 7.8, 7.6, 7.4, and 7.2). Carbonate chemistry was measured/modeled as well as other water quality parameters. Animals were sacrificed over a 1 month period and growth (length, buoyant weight) was measured. New shell was excised and $\delta 1^3C$, $\delta^{18}O$, and $\delta^{34}S$ as well as total C and S were measured. Fractionation of C and O associated with pH was observed as was fractionation of S though, in the case of S, the fractionation was not significantly associated with pH. A C-O fractionation model was developed that predicted pH treatment. This model was then tested on Pliocene scallop fossils (*Carolinapecten eboreus*; Pinecrest Sand, Florida). The Pinecrest was deposited in the Late Pliocene as the final closure of the Central America Isthmus was occuring and ocean circulation patterns were changing as a result. Decline in pH associated with these changes has been suggested. Given the exceptional preservation of these fossils we tested our experimentally determined pH stable isotope model and evaluated the potential for this model to predict changes in pH in the Late Pliocene ocean.

Large Mo isotope variations before the Great Oxidation Event

D. ASAEL[1]*, O.J. ROUXEL[2], A. BEKKER[3] AND C.T. SCOTT[4]

[1]Université de Bretagne Occidentale, IUEM, UMR 6538, 29280 Plouzané, France (*dan.asael@univ-brest.fr)

Molybdenum (Mo) isotopes are efficiently removed under euxinic conditions and therefore may directly record contemporaneous seawater in ancient organic-rich shales. Removal of Mo in other environments (i.e., anoxic and oxic) is less efficient and accompanied by a significant negative isotope fractionation, where $\Delta^{98}Mo_{SW\text{-}SED}$ is typically 1 to 3 ‰ [1,2]. It is generally accepted that before the Great Oxidation Event (GOE) at ca. 2.3 Ga the transfer of Mo to the oceans was primarily in detrital form. This is in accordance with the available sedimentary data showing a narrow range of isotopic compositions corresponding to the crustal reservoir. As atmospheric oxygen started to rise, Mo was chemically weathered from continental sources and transported to the oceans as oxidized molybdate (MoO_4^{2-}). There, it was removed to sediments via several fractionating mechanisms, depending on the redox conditions. Consequently, Proterozoic and Phanerozoic black shales record a wide range of Mo isotopic values, reflecting variations in the isotopic composition of seawater as determined by the mass balance between the different sinks.

We measured Mo concentrations and isotopic compositions of black shales from several Neoarchean and Paleoproterozoic sections (2.7 Ga - Belingwe Fm., Zimbabwe; 2.63 Ga - Jeerinah Fm., Western Australia; 2.52 Ga - Gamohaan Fm., South Africa; 2.15 Ga - Sengoma Argillite Fm., Botswana; 2.06 Ga – Zaonega Fm., Karelia). The data show large isotopic variations and significantly elevated $\delta^{98}Mo$ values in sections dated up to 400 Myr before the GOE. Moreover, these pre-GOE sections show Mo concentrations which are higher than those typically found in older sections [3,4], but still lower than those found in post-GOE Proterozoic sections[5,6]. These observations imply a process of chemical weathering, transport and sedimentation of Mo, which was accompanied by significant isotope fractionation. We propose that such a process may be driven by either (a) low and fluctuating oxygen levels which led to episodes of continental Mo weathering, or (b) enhanced atmospheric sulfur levels after volcanic events which may initiate removal of Mo from the continental crust to the oceans.

Macromolecular organic substances in atmospheric aerosols have been termed humic-like substances (HULIS) and it can influence functions of aerosols, such as cloud nucleation, absorption of solar radiation, and transportation of pollutant. However, despite its importance in environment, a comprehensive understanding of the structure of the HULIS remains elusive. We therefore studied the structural features of the HULIS in urban aerosols and compared it with those of soil and aquatic humic substances (HS).

Samples and Experiment

Water soluble HULIS (WS-HULIS) was obtained from aerosol sample, which was collected in Osaka city, Japan in summer and autumn 2010, and was analyzed using high-performance size-exclusion chromatography (HPSEC), pyrolysis gas chromatography (py-GC), and liquid-state ^{13}C NMR spectroscopy.

Results and Discussion

A weight-averaged molecular weight of the WS-HULIS was estimated 800–950 by HPSEC and molecular size distribution of the WS-HULIS was similar to that of the aquatic HS, particularly to fulvic acids. ^{13}C NMR spectroscopy showed lower aromatic (16–19% of total C) and higher aliphatic carbon content (35–45%) of the WS-HULIS (Fig.1) as compared to those of the soil HS. This result also suggests the structural similarities between the WS-HULIS and the aquatic HS. However, contrary to previous study [1], signals of lignin derived structure (55, 150ppm), which are generally detected in the soil and aquatic HS, were not observed in the NMR spectra of the WS-HULIS in both summer and autumn. This observation is supported by py-GC using tetramethylammonium hydroxide.

In conclusion, average chemical structure of the WS-HULIS in aerosols is relatively similar to that of the aquatic HS rather than soil HS. However, the WS-HULIS used in this study has no lignin derived component, indicating that the origin of the WS-HULIS may differ from that of the soil and aquatic HS. The structural features of alkaline extractable HULIS will also be presented.

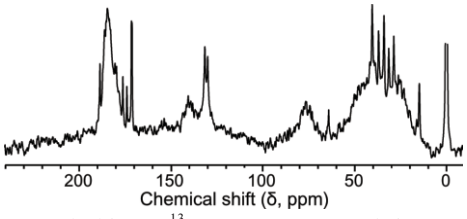

Figure 1: Liquid-state ^{13}C NMR spectrum of the water soluble humic-like substances in aerosols collected in summer 2010

The role of contamination in the genesis of shoshonitic volcanism, central Pontide, Turkey

KÜRŞAD ASAN[1,2*], HÜSEYIN KURT[1], DON FRANCIS[2], AND GANERØD MORGAN[3]

[1]Selçuk University, Geological Engineering Department, Konya, TR kasan@selcuk.edu.tr (* presenting author), hkurt@selcuk.edu.tr
[2]McGill University, Earth and Planetary Sciences, Montreal, QC, CA donald.francis@mcgill.ca
[3]Geological Survey of Norway, Trondheim, NO morgan.ganerod@ngu.no

Late Cretaceous (~ 80 Ma) subduction-related volcanic rocks are widespread in the central Pontides of Turkey, both in the Sinop area to the North and in the Alaçam-Dikmen-Durağan areas to the South. There are two distinct groups of lava in both areas in terms of K_2O. The northern area rocks display high-K calcalkaline or shoshonitic affinities, whereas the southern area rocks have either medium-K calcalkaline or shoshonitic affinities. The shoshonites are younger than calcalkaline rocks in both areas, but the northern shoshonites are more potassium-rich than the southern shoshonites. The chondrite-normalized trace element patterns of all the lavas are characterised by strong enrichments in LILE (Rb, Ba, K and Sr) and LREE (La, Ce) and prominent negative Nb, Ta, and Ti anomalies, all typical of subduction-related lavas. There is a systematic increase in the REE fractionation from calcalkaline (La_N/Yb_N: 4-5) to high-K calcalkaline (La_N/Yb_N: 6-10) to shoshonitic (La_N/Yb_N: 4-19) lavas.

The calcalkaline rocks from the northern and southern areas have similar $^{87}Sr/^{86}Sr_{(i)}$ (0.705764-0.706959) and $^{143}Nd/^{144}Nd_{(i)}$ (0.512402-0.512531) isotopic ratios. The shoshonitic rocks from the two areas, however, have different Sr-Nd isotopic systematics. The shoshonites from the southern area have relatively low $^{87}Sr/^{86}Sr_{(i)}$ (0.704541-0.705022) and high $^{143}Nd/^{144}Nd_{(i)}$ (0.512589-0.512797) ratios that are independent of SiO_2 content and plot near Bulk Earth in a Sr-Nd correlation diagram. The shoshonites from the northern area, however, have high $^{87}Sr/^{86}Sr_{(i)}$ (0.706664-0.708340) and low $^{143}Nd/^{144}Nd_{(i)}$ (0.512266-0.512364) ratios plotting in enriched mantle quadrant of a Sr-Nd correlation diagram (Figure 1). Furthermore, $^{87}Sr/^{86}Sr$ increases and $^{143}Nd/^{144}Nd$ decreases with increasing SiO_2 content, suggesting progressive contamination with crystal fractionation. Thus, crustal contamination appears to have played an important role in the genesis of the northern shoshonites and was responsible for their higher K contents, but contamination was apparently not involved in the genesis of the southern shoshonites. This suggests that crustal contamination is not essential for the genesis of shoshonitic volcanism.

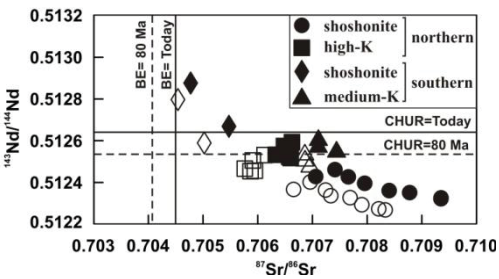

Figure 1: Sr-Nd correlation diagram of the volcanites (closed symbols: measured, open symbols: age corrected ratios for 80 Ma).

P-T-D Histories and Reequilibration of Ti in Quartz: Using the TitaniQ Thermobarometer in Poly-Deformed Tectonic Terranes

KYLE T. ASHLEY[1*], LAURA E. WEBB[2], FRANK S. SPEAR[3], AND JAY B. THOMAS[3]

[1]Dept. of Geosciences, Virginia Tech, Blacksburg, USA, ktashley@vt.edu (* presenting author)
[2]Dept. of Geology, University of Vermont, Burlington, USA, lewebb@uvm.edu
[3]Earth and Environmental Sciences, Renssaelaer Polytechnic Institute, Troy, USA, spearf@rpi.edu, thomaj2@rpi.edu

Constraining *P-T* conditions of deformation is essential in understanding lithospheric processes at all scales. The Ti-in-quartz ("TitaniQ") thermobarometer [1] has the potential to constrain either T or P if the other is known and if titania activity (a_{TiO2}) can be estimated. The extensive petrologic and structural framework previously established for the Strafford Dome, coupled with abundant quartz in various microstructural settings, provides and excellent case study for investigating use of the method in poly-deformed terranes. Two nappe emplacements (D_1 and D_2) and a following doming event (D_3) resulted in three schistositities (S_1-S_3) that provide a framework to investigate whether [Ti] of quartz in different microstrucural settings records *P-T* conditions of fabric formation. We conducted cathodoluminescence (CL) imaging to observe Ti-zoning in quartz grains and seconadry ionization mass spectrometry to determine [Ti].

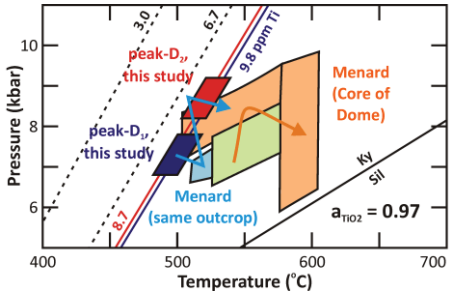

Figure 1: *P-T* paths calculated by TitaniQ from this study compared to proximal samples constrained in previous studies.

Results from these analyses coupled with previously established *P-T* paths [2] indicate that quartz preserves evidence for five recrystallization or reequilibration periods: 1) prograde (dark cores in CL, [Ti] = 2–3 ppm); 2) peak D_1 reequilibration (bright rims on quartz inclusions, [Ti] = 5.5 ppm); 3) dark rims on D_1 rims due a quartz-producing, kyanite-in reaction (sharp zonal sector contact); 4) peak D_2 in matrix quartz ([Ti] up to 9.8 ppm); and 5) retrograde reequilibration (darker rim in CL due to reduced T conditions). Rapid exhumation prevented extensive retrograde overprinting. This study has shown that TitaniQ coupled with microstructural analysis can provide insight into prograde conditions and reequilibration relative to deformation in poly-deformed terranes.

Equation of state for CaO-FeO-MgO-Al_2O_3-SiO_2 melts and evolution of a whole-mantle magma ocean

PAUL D. ASIMOW[1*], CLAIRE W. THOMAS[1], CARL B. AGEE[2], QIONG LIU[3] AND REBECCA A. LANGE[3]

[1]California Institute of Technology, Pasadena, CA, USA, asimow@gps.caltech.edu (* presenting author)
[2]Univ. of New Mexico, Albuquerque, NM, USA, agee@unm.edu
[3]Univ. of Michigan, Ann Arbor, MI, USA, becky@umich.edu

Understanding the consequences for Earth evolution of formation and crystallization of a magma ocean – plausibly involving the entire silicate earth, e.g. after a moon-forming impact – requires detailed knowledge of the physics and thermochemistry of multi-component silicate liquids at all mantle pressures (*P*), near-liquidus temperatures (*T*), and a range of candidate bulk silicate Earth compositions. Also, a grasp of deep mantle partial melting (e.g. at the core-mantle boundary (CMB)) requires simlar information for a wider range of liquids (with high volatile and incompatible concentrations) at near-solidus *T*.

There are sufficient constraints from shock wave data and first principles molecular dynamics to define the thermal equation of state (EOS) of end-members spanning the five oxides CaO-FeO-MgO-Al_2O_3-SiO_2. FeO-bearing compositions (Fe_2SiO_4 and $CaFeSi_2O_6$) have recently had their Hugoniots defined to CMB *P*; Fe_2SiO_4 results agree well with new simulations [1]. We still need to assume ideal mixing of volumes (except along MgO-SiO_2 [2]) to fill composition space, but two intermediate compositions that have been determined are consistent with this approximation. Hence, the data support construction of a liquid EOS able to describe density and compute isentropes for ultramafic to mafic liquids of varying composition.

The thermal EOS of each of five endmembers – $CaMgSi_2O_6$, $CaAl_2Si_2O_8$, $MgSiO_3$, Mg_2SiO_4, Fe_2SiO_4 – can be fit to one of several formalisms: (1) 4th order Birch-Murnaghan isentrope with Mie-Grüneisen (M-G) thermal pressure and constant heat capacity; (2) a linear shock wave EOS with M-G thermal offset; or (3) de Koker and Stixrude's fundamental relation [3]. Properties of other liquids are derived by assuming constant partial molar volume and heat capacity of the five endmembers at each *P* and *T*. Isentropes of intermediate compositions can be computed iteratively.

The liquidus curve for KLB-1 peridotite of [4] gives a critical isentrope with potential temperature 2800 K for onset of perovskite crystallization in the mid-lower mantle at ~80 GPa. But the steeper liquidus curve for model chondritic mantle by [5] gives a critical isentrope with potential temperature 2600 K for crystallization at the CMB. We find the neutrally buoyant liquids at the CMB as a function of Mg# and (Mg+Fe)/Si: at perovskite stoichiometry, liquid Mg# $\leq$ 0.55 is needed for liquid density to exceed that of $MgSiO_3$ perovskite, whereas at olivine stoichiometry only Mg# < ~0.9 is needed.

A low flow desolvating nebulizer system as a tool for calibration in LA-ICP-MS

DHINESH ASOGAN[1*], DAVID CLARKE[1],

[1] CETAC Technologies, Omaha, NE, USA dasogan@cetac.com

Calibration for laser ablation inductively couple plasma mass spectrometry is a continuing challenge to analysts. Precise matrix matching is required to ensure ablation characteristics and subsequent plasma dynamics are consistent between calibrants and samples.

On-line additions of liquid standards to ablated aerosol streams has been shown to elminate the need for precise matrix matched standards and still provide good calibration.[1–4] In this paper, the authors present a technical overview of the technique of on-line additions and a comparison with traditional, matrix matched calibration for the analysis of Arkansas Womble Shale.

Carbon isotope constraints on degassing of MORB from the Southwest Indian Ridge (32-50°E)

CYRIL AUBAUD[1*], EILEEN GÜTTLER[1], PIERRE CARTIGNY[1]

[1]Laboratoire de Geochimie des Isotopes Stables, Institut de Physique du Globe, Sorbonne-Paris Cité, Paris, France, aubaud@ipgp.fr (*), guttler@ipgp.fr, cartigny@ipgp.fr

The Southwest Indian ridge is remarkable for its slow spreading rate and large radiogenic isotope anomalies. It is therefore ideal to test possible carbon isotope variations in the mantle. However, due to its low solubility in basalts, CO_2 is affected by strong degassing processes which must be precisely characterised before investigating compositional variation of the mantle source. In this study, we analyzed 28 SWIR basaltic glasses for their vesicularity, CO_2 vesicle content, and $\delta^{13}C$ of CO_2 in vesicles. The samples were collected on the SWIR axis from 32 to 50°E and in a range of depths from 1320 to 3850 m.

These data are discussed in the light of an improved mass balance model that takes into account: (1) variable initial CO_2 contents, (2) a deep degassing step, (3) isobaric loss of vesicles at crustal level, (4) the depth of magma storage in the crust, (5) the effect of crystal fractionation on degassing, and (6) the full range of degassing regimes between the magma chamber and the eruption depth (closed vs. open system degassing and equilibrium to kinetic degassing regimes).

Vesicularities show a large range: from 0 to 9.15 vol%, most samples having less than 4% vesicles. Carbon isotopic compositions of CO_2 in vesicles extracted by crushing in vacuo show a relatively large range of $\delta^{13}C$-values from –1.26 to –13.36‰ with most values between –4 and –8‰. The measured $\delta^{13}C$-values are similar to those observed for other ridges (Atlantic and Pacific).

The computed results show that approximately half of the dataset can be explained by a shallow stage of degassing occurring as a closed system after total loss of the first generation of vesicles in axial magma chambers. The second half of the dataset requires that the shallow degassing stage occurred as an open-system degassing process. One sample requires the stage of open-system degassing to start much deeper than 6 km depth (below sea floor) or to be strongly kinetic. The few remaining samples are best explained by kinetic open-system degassing in order to fit their relatively high $\delta^{13}C$ values.

The model shows that the mode of the last degassing step and the extent of isobaric degassing at crustal level exert a strong control on the volatile characteristics of the erupted melts, the other processes having minor effects. If carbon content and/or carbon isotopic ratio anomalies exist below the SWIR, these are either small in magnitude or masked by degassing processes.

Yttrium and rare earth element composition of the Rapitan Iron Formation (Northwest Territories, Canada)

NATALIE R. AUBET[1]*, ERNESTO PECOITS[1], LUKE OOTES[2] AND KURT O. KONHAUSER[1]

[1]University of Alberta, Edmonton, Canada, aubet@ualberta.ca (* presenting author)
[2]Northwest Territories Geoscience Office, Yellowknife, Canada, Luke_Ootes@gov.nt.ca

The Neoproterozoic represents a time in Earth's history when significant environmental changes took place, including global glaciations that led to ocean stagnation and an apparent build-up of dissolved ferrous iron. As the ice receded and ocean circulation became re-established, the iron became oxidised and formed a suite of iron formations (IFs) in the oxic zone of upwelling areas. However, the ultimate source of iron is still a matter of intense debate.

Rare earth elements plus yttrium (REY) concentrations in IFs have been successfully used as proxies to study secular trends in Precambrian ocean chemistry. Despite a number of previous geochemical studies on Cryogenian IFs, complete REY datasets are virtually absent. Here we examine bulk and mineral phase trace-element geochemistry (REY) of the Rapitan Iron Formation, Northwest Territories, Canada. Samples for geochemical analysis were selected on the basis of extremely low, if any, Th, Zr, Hf and Sc concentrations and lack of co-variations between Zr vs. Y/Ho, Y/Ho vs. Ce/Ce* and Th vs. La/La*. The results show: (1) REY profiles with distinctive seawater-like signatures (i.e., LREE-depletion relative to HREE, superchondritic Y/Ho ratios and positive anomalies of both La and Gd); (2) precipitation under oxygen-deficient conditions (no to slightly positive Ce anomaly); and (3) iron being sourced from hydrothermal vents (positive Eu anomaly). Of particular interest, along with Ce, is the identification of an Eu anomaly in all of the samples analyzed. The latter might be explained either by precipitation in an open stratified ocean involving ferruginous deep waters -through which hydrothermally sourced Eu (and iron) could travel long distances- or by deposition taking place in a somewhat restricted basin where the Eu signature is more easily retained. In the first scenario, our results might confirm, as previously proposed, that ferruginous conditions dominated during the Sturtian "snowball glaciation". Alternatively, a semi-isolated basin should be considered for the deposition of the Rapitan IF.

Zinc sorption on carbonate reservoir system, implications on CO_2 geological storage.

BAPTISTE AUFFRAY[1A*], BRUNO GARCIA[1A], CHARLES-PHILIPPE LIENEMANN[1B] AND ADRIAN CEREPI[2]

[1A]IFP Energies nouvelles, Rueil-Malmaison, France, baptiste.auffray@ifpen.fr (* presenting author) bruno.garcia@ifpen.fr
[1B]IFP Energies nouvelles, Solaize, France, charles.lienemann@ifpen.fr
[2]EA 4592 G&E, ENSEGID, University of Bordeaux, Pessac, France, adrian.cerepi@egid.u-bordeaux3.fr

Geological storage is one of the solutions envisaged to reduce greenhouse gases concentration in atmosphere, and storage in underground saline aquifers is of major interest considering their high storage capacity. One of the main question still unanswered regards the consequences of the supercritical CO_2 injection on the metals mobility; from the storage formation to the sub-surface. Indeed, supercritical CO_2 injection (over 31 °C and 74 bar) acidifies the aquifer and induces metals release from rock matrix. In consequences, geochemistry (dissolution/precipitation phenomena, sorption of metals...) and petrophysical properties (porosity and permeability) of each compartment impacted will be changed.

In this study, two natural carbonates (from Lavoux and St-Emilion) were used to carry out zinc sorption experiments (initial concentration equal to 10^{-5} mol/L) at 40 °C and four different CO_2 pressures ($3.5e^{-4}$, 30, 60 and 90 bar) in saline solutions (100g/L NaCl) in batch reactors.

Results obtained for the different pressure conditions investigated on Lavoux carbonate show that: (i) in atmospheric conditions, the zinc adsorption phenomenon is clearly put in evidence and matches well with a Freundlich adsorption isotherm model [1]; (ii) at 30 bar of CO_2, the dissolution of Lavoux carbonate [2] induces a zinc release in the system, with no adsorption observed; (iii) at 60 bar, a strong decrease of zinc concentration is observed (factor 2) over 70 days and after, it goes back close to its initial value; (iv) with a CO_2 pressure of 90 bar, adsorption is observed but in lower proportions and slower kinetic than in atmospheric conditions. Comparative studies with St-Emilion carbonate are being carried out and will be discussed with these previous results obtained with the Lavoux carbonate.

Though more investigations have to be carried out to better understand the coupling and competition of rock dissolution and metals adsorption phenomenons, these results are very important in order to better understand the behavior of metals in the {carbonate/saline-solution/CO_2} system in a geological storage context. Indeed, the CO_2 pressure implies very different comportment on metals sorption, which will occur in natural context. These results will allow us to predict by reactive modelling the future behavior of metals in CO_2 geological storage sites, their potential mobilization up to surface aquifers and their impact on surface potable aquifers.

Hatiba to Port Sudan Deep (Red Sea) Imaging a growing Ocean

N. AUGUSTIN[1*], C.W. DEVEY[1], R. BANTAN[2], F. M. VAN DER ZWAN[1], P. FELDENS[1] AND T. KWASNITSCHKA[1]

[1]GEOMAR | Helmholtz Centre for Ocean Research Kiel, Germany, naugustin@geomar.de (* presenting author)
[2]King Abdulaziz University, Jeddah, Saudi Arabia

The current knowledge of the bathymetry of one of the youngest oceans on earth, the Red Sea, and its spreading centres is poor and mainly based on several low resolution maps of a few deeps of higher interest, like the Atlantis II Deep [e.g., 1, 2]. During the RV Poseidon cruise 408 we collected a continuous bathymetric dataset of Red Sea deeps from the Hatiba Deep via Atlantis II Deep to the Port Sudan Deep over a total N-S distance of 300 km between 22°28´N and 19°59´N along the Red Sea rift with a resolution of 25-30 m.

The bathymetric data visualize very well tectonic features (complex fault and rift structures) and related volcanic edifices, in Hatiba, Atlantis II as well as Port Sudan Deep. The position of the rift axis can be determined for the Hatiba Deep and Atlantis II Deep based on graben fault symmetry and slope angle calculations, together with the recovery of fresh basalts. The models demonstrate that especially the tectonic setting of the comparatively large Hatiba Deep is much more complex than previously thought and reveal evidence for a rift-axis-jump to the south. Basalts with characteristic flow textures and enclosed sediments, recovered from the southwestern Hatiba basin, give strong indications for rupturing in an environment, where possibly magma interacted with wet sediments. Thermobarometry calculations based on geochemical analyses (EMP, FTIR) of basalt glass from Hatiba deep reveal generally variable depths of last equilibration with a gabbroic mineral assemblage of about 6 to 14 km for samples from different locations in the deep, whereas samples from the assumed actual spreading center point to a crystalization depth of about 8 km at 1170°C.

Distinct tectonic features as visible in the Hatiba Deep become less prominent to the south. Therefore, the bathymetry of the Port Sudan Deep marks the changeover from the rifting in the northern Red Sea to the drifting in the southern Red Sea. For all mapped deeps, the bathymetric data show strong influence of salt/sediment flow as well as land slides into the deeps, which in some cases cover large parts of the graben structures. Due to sedimentation, indications of ridge offsets between the deeps are covered by sediments and the tectonics of ridge transition are not visible in the recently available dataset.

We present a unique collection of bathymetric models and volcanic/tectonic interpretations. Combined with data about ground truthing, geological mapping and geochemical data this work provides a detailed look into the structure, tectonics, magmatic centres and evolution of Red Sea deeps in larger detail than observed before.

Siderophile element redistribution during mantle metasomatism

SONJA AULBACH[1*], LARRY HEAMAN[2], VLADIMIR MATJUSCHKIN[1], JOHANNES HOFMANN[1], THOMAS STACHEL[2] AND GERHARD BREY[1]

[1]Goethe-University, Facheinheit Mineralogie, Frankfurt, Germany, s.aulbach@em.uni-frankfurt.de
[2]University of Alberta, Department of Earth and Atmospheric Sciences, Edmonton AB, Canada

During subduction zone processing, highly siderophile elements (HSE) including Re-Os may be mobilised differentially from different parts of the slab, with consequences for their transfer into the mantle wedge and retention in deeply subducted residual eclogites [e.g. 1]. The Slave craton in northern Canada was affected by Paleoproterozoic subduction, leading to emplacement of gabbroic materials, eclogitisation during interaction with deserpentinisation fluids and associated diamond formation [2]. Pristine sulphide inclusions in these 1.9 Ga eclogitic diamonds have HSE and other trace metal concentrations attesting to conservative behaviour during dehydration-induced metasomatism and metamorphism of their subduction-related gabbroic source rocks. This is taken to indicate that the fluids involved were reducing and Cl-poor, and therefore unable to mobilise HSE from the gabbroic portion of the slab into the supra-subduction zone.

Contrary to sulphide included in diamond, sulphide of the same composition and inferred age in eclogite xenoliths have been exposed to mantle metasomatic processes since their 1.9 Ga emplacement into the cratonic lithosphere. Such metasomatism may lead to introduction and/or remobilisation of HSE, either as sulphide melts or dissolved along with oxidised S species in silicate or carbonate melts or related fluids [e.g. 3]. Earlier investigation of sulphide minerals in these eclogite xenoliths has revealed three of five samples to be too Ni-rich to be in equilibrium with a meta-basaltic source, and to have disturbed Re-Os isotope systematics. By contrast, the silicate portion of the eclogites does not show evidence for metasomatic overprint. This may indicate introduction of mobile Ni-rich sulphide melts derived from surrounding mantle peridotite [4].

We are in the process of measuring HSE and other trace metal contents of sulphide minerals in these rocks, and in a pyroxenite giving a 1.9 Ga sulphide-derived Re-Os isochron age. This will enable us to compare HSE signatures of sulphide in eclogite xenoliths with corrupted Re-Os isotope systematics to primary sulphide included in diamond and in the pyroxenite. We anticipate there will be differences in HSE abundances and/or ratios that will afford insights into the nature and effects of mantle metasomatic agents that lead to redistribution of HSE and disturbance of primary Re-Os isotope signatures.

Chemical and Sr-Nd-Pb isotopic data of the Pliocene-Quaternary mafic lavas of Gran Canaria (Canary Islands, Spain) reported in Aulinas et al. (2010) are used to investigate the composition of their mantle source. The isotopic differences between the Plio-Quaternary (Post-Roque Nublo Group) and the older Pliocene (Roque Nublo Group) mafic parental magmas reflect small-scale mantle heterogeneities. Two distinct mantle components were involved in partial melting to form the Pliocene-Quaternary magmas of Gran Canaria, the first being isotopically more depleted and similar to the DMM type and the second being more radiogenic in Pb-isotope ratios comparable to an HIMU type. Geochemical variations show that the Pliocene-Quaternary mantle source is not only compositionally but also lithologically heterogeneous and supports the presence of a silica-deficient pyroxenite mantle component. Calculation of its contribution in the generation of the Pliocene-Quaternary magmas is estimated to be in the range from 50 to 70%. However, no significant differences between the Roque Nublo and the Post-Roque Nublo Groups are detected, suggesting that pyroxenite-derived melts played a similar role in both groups. Trace element ratios support mixing between the two mantle components (a silica deficient pyroxenite and a peridotite) which obscure the original chemical and isotopic compositions of these two end-members. The proposed scenario for the generation of the Pliocene-Quaternary magmas involves a lithologically heteorogenous mantle plume consisting of pyroxenite veins in a peridotite matrix which melted and mixed both mantle components during its ascent until the base of the lithosphere.

This research was funded by the Spanish projects CGL2004-04039BTE and CGL2011-28022 and it was carried out in the framework of the PEGEFA Research Group (SGR2009-972) and GEOVOL Research Group.

The analysis of the specific properties of nanomaterials compared to bulk material has already received ample attention and generates research in a vast array of directions, including the design of new materials. One innovative approach is to introduce a life cycle perspective in the design of products containing nanomaterials. At the current stage of knowledge and scientific advancement, this approach includes examining the interactions between all sorts of nanomaterials and the surrounding biota during the entire life cycle of a product with an objective of designing new nanomaterials that minimize potential adverse effects.

The task of researchers is immense because of the absence of data concerning the life cycle of nanomaterials and their transformation over time. However, since the 1990s they have made significant progress in their understanding of microscopic design as well as of interactions at the nanoscale, notably concerning surface areas, and they can now envisage a true paradigm change in the management of innovation.

One important aspect of their work is that they operate in a regulatory context where the life cycle-based methodology has so far not been taken into account. After establishing a panorama of all mandatory regulatory options that frame the development of nanoproducts [1], our study aims to identify inconsistencies and gaps to fill in regulation in order to accompany this paradigm change. In other words, we seek to contribute to the development of a benchmark to foster new processes of nanomaterial design based on life cycle assessments.

From partly serpentinized peridotite to continental crust through weathering and recycling processes

H. AUSTRHEIM[1*] A. PUTNIS[2], C.V. PUTNIS[2] AND B.GRGURIC[3]

[1] PGP, University of Oslo, Norway, h.o.austrheim@geo.uio.no (* presenting author)
[2]Institut für Mineralogie, University of Münster, Münster, Germany putnis@uni-muenster.de
[3]Norilsk Nickel Australia, Perth, Australia ben.grguric@nornik.com.au

Partial melting of peridotite is a fundamental process in forming continental crust. However ultramafic material are also added to the crust through obduction of ophiolites and extrusion of komatitic lavas. Such olivine rich rocks are highly reactive and so prone to weathering. In a tropical climate they are known to develop into a thick Ni-laterite zone, hosting some of the worlds largest Ni-deposits. In order to evaluate the role of weathered peridotites on the composition of both the continental crust and the oceans, we need to understand how weathering of peridotites can fractionate elements and how the various components involved are incorporated in continental sediments or alternatively transported to the oceans. That is, a knowledge of the mechanisms involved in weathering processes and element mobilization is essential for the understanding of the continuous redistribution of elements within the Earth.

We present microtextures and mineral and whole rock chemistry from a weathering profile through the Goliath laterite of the Archaean Agnew-Wiluna Greenstone belt of Western Australia, to show that the protolith was a strongly serpentinized peridotite and that weathering involved removal of Mg, leaving behind a 20 m thick residue of quartz hematite with high Ni/Mg and Cr/Mg ratios. Rocks with similar geochemical and textural signatures are also present in clast material from three studied Devonian sedimentary basins of S-Norway[1]. Weathering of peridotite to form quartz-hematite rocks may explain that the average Cr and Ni values of continental crust are higher than those of andesite and this deviation may be used to estimate that ca 5 % of the crust may have formed from weathered peridotite. Consequently the removed Mg may contribute to the Mg budget of the Oceans.

Zircon and baddeleyite solubility in alkaline aqueous fluids

J.C. AYERS [1*], L. ZHANG [1], Y. LUO[1], AND T. PETERS[1]

[1]Vanderbilt Univ., Nashville, TN, USA, john.c.ayers@vanderbilt.edu (* presenting author)

Field evidence and thermodynamic data at ambient conditions suggest that complexing of Zr with hydroxyl ions at high pH enhances the solubilities of Zr-bearing minerals. We tested this hypothesis by measuring the solubilities of baddeleyite (ZrO_2) and the assemblages zircon ($ZrSiO_4$) + baddeleyite (Z + B) and zircon + quartz (Z + Q) in neutral to alkaline fluids at 0.2 GPa. Measured solubilities expressed as molality (*m*) of Zr in the fluid are very low, close to procedure detection limits.

We measured the solubility of baddeleyite in alkaline fluid (0.1, 1*m* NaOH) at 600°C. Solubilities measured in 1*m* NaOH using the single crystal weight loss method were higher than double capsule values, possibly due to recrystallization in a temperature gradient. For double capsule measurements the average measured Zr concentration in equilibrium with baddeleyite was 1.8 x 10^{-5}*m* in 0.1*m* NaOH and 5.8 x 10^{-5}*m* in 1*m* NaOH, suggesting that baddeleyite solubility increases with increasing hydroxyl concentration in the fluid, presumably due to formation of the $Zr(OH)_5^-$ complex.

In neutral to alkaline fluids (0, 0.1, 1*m* NaOH) zircon dissolved incongruently in quartz-undersaturated fluids to form baddeleyite. At 450°C vlasovite ($Na_2ZrSi_4O_{11}$) also precipitated from fluids saturated and undersaturated in quartz. We observed no significant dependence of solubility on temperature. Ion microprobe analysis showed that the oxygen isotope compositions of zircon grains in the starting material and run products were similar, indicating that zircon dissolution-reprecipitation did not occur during the experiments.

The solubility of zircon increases with increasing fluid silica concentration, suggesting that zirconium complexes with silica in the fluid. At 600°C linear regression of experiment results yielded:

ln (Zr) = -3.9 + (1.9 * ln (Si))

where terms in parentheses represent molal concentrations. Zircon solubility also seems to increase with increasing hydroxyl concentration in the fluid.

At low silica activities the solubility of Zr-minerals is enhanced at high pH through complexing of zirconium with hydroxyl. Alkaline fluids may therefore dissolve zirconium minerals such as baddeleyite and zircon and mobilize Zr. At high silica activity zircon solubility is enhanced by complexing of zirconium with silica, suggesting that zirconium may also be mobile in silica-rich fluids. Fluids without high concentrations of hydroxyl or silica are not responsible for the rare observed occurrences of Zr metasomatism, but they may still catalyze recrystallization of zircon grains because recrystallization does not require high solubility.

Sources of Pb contamination in well water and soil at former orchards in the Mid-Atlantic, USA

ROBERT A. AYUSO[1]*
[1]U.S. Geological Survey, Reston, VA, 20192, USA,
rayuso@usgs.gov (*presenting author)

Lead and strontium isotopes, rare earth element, and trace metal compositions were measured to infer the sources of anomalously high concentrations of Pb in residential water wells and soils in former fruit orchards in Pennsylvania. The results were used to characterize potential anthropogenic and geogenic sources of lead, to evaluate specific contributions from various distinct sources, and to assess the geochemical relationship between water, soil, bedrock, and anthropogenic materials.

Groundwater from residential wells, in-line well water filters, surface water, Pb-arsenical pesticides, orchard and garden soils, the Ordovician carbonate-dominated bedrock, and coal deposits in the region display variable $^{206}Pb/^{207}Pb$ (1.16862-1.2236), $^{208}Pb/^{207}Pb$ (2.43551-2.46570) and $^{87}Sr/^{86}Sr$ (0.709030-0.730596) isotope signatures. Waters have variable Pb (up to 200 ppb) and As (up to 11 ppb) contents, and mostly low REE contents (La <0.096 ug/L; Yb ~ 0.027 ug/L). Soils are enriched in Pb (up to 2452 ppm) and As (up to 450 ppm), which might be caused by past use of lead arsenical pesticides applied to orchard crops. Rare earth element contents of soils resemble those of bedrock; however, the abundances of Pb and As in bedrock are much lower than in the soils. Pb isotope signatures of all ground and surface waters closely match, however, the waters do not match the Pb (or Sr) signatures of bedrocks, soils, or lead arsenical pesticides. Residential well waters show a broad linear trend in Pb isotope composition and match Pb isotope signatures of sediments captured in water filters. Surface water matches the Pb isotopic signature of the residential well waters. Depth-constrained water samples obtained from new monitor wells sited in bedrock (Martinsburg Fm., Jacksonburg Limestone, and the Epler Member of the Beekmantown Group) generally overlap the trend of the residential well waters, although some samples extend to lower Pb isotope ratios. Soils and well waters plot in broad fields along contrasting slopes in standard Pb isotope diagrams; the isotope fields do not overlap. Contributions of soil-Pb are apparently limited to wells having shallow water-bearing zones and significant sediment content. As a consequence, neither soils nor bedrock can be the exclusive or dominant source of Pb in the majority of the residential or monitor well waters.

Comparison of the Pb isotope data for the well waters, orchard soils, bedrock, and regional and local anthropogenic sources suggests the lasting impact of industrial lead from past leaded gasoline use, power plants, and various near-by metal manufacturing and processing facilities (e.g., smelters, lead-acid battery production), and waste disposal activities. Thus, the groundwaters are thought to have a regional industrial Pb isotope signature before arriving at the former orchard areas. The Pb in water is thought to be derived by mixing of lead from various industrial origins together with a contribution of labile lead from bedrock, rather than from historical application of pesticide in the region.

Rationalising nanoparticle sizes measured by AFM, FlFFF and DLS: sample preparation, polydispersity and particle structure

MOHAMMED BAALOUSHA* AND JAMIE LEAD

1 School of Geography, Earth and Environmental Sciences, College of Life and Environmental Sciences, University of Birmingham, Birmingham, United Kingdom, m.a.baalousha@bham.ac.uk (* presenting author)

8e.Towards the fundamentals of nanoparticle interactions with the living world: a life cycle perspective.

This presentation will discuss the sources of variability in the measured nanomaterial (NM) size by different analytical tools including atomic force microscopy (AFM), dynamic light scattering (DLS) and flow-field flow fractionation (FlFFF). The results suggest that differences in NM size measurements between different analytical tools can be rationalised by taking into consideration (i) sample preparation, (ii) sample polydispersity and (iii) structural properties of the NMs.

Appropriate sample preparation is a key to obtain representative particle size distributions (PSDs), and this may vary on a case by case basis. For AFM analysis, an ultracentrifugation method is the optimal method to prepare samples from diluted suspensions of NMs (<1 mg L-1). For FlFFF, the overloading effect, particle-particle and particle-membrane interactions as well as nature of the calibration standards are important determinants of the quality of data. For DLS, the quality of the fitting of the autocorrelation function is a key issue in obtaining correct estimates of particle size. Conversion of intensity PSD to number or volume PSD is promising for determination of number and volume PSD, but hampered by uncertainties in solving and optimizing the autocorrelation function fit.

The differences between the z-average hydrodynamic diameter by DLS and the particle height by AFM can be accounted for by sample polydispersity. The ratio of z-average hydrodynamic diameter: AFM particle height approaches 1.0 for monodisperse samples and increases with sample polydispersity. A polydispersity index of 0.1 is suggested as a suitable limit above which DLS data no longer remains accurate. Conversion of the volume PSD by FlFFF-UV to number PSD helps to rationalise for some of the variability in the measured sizes. The remaining variability in the measured sizes can be attributed to structural variability in the particles and in this case is mainly attributed to the thickness and permeability of the particles/surface coating. For citrate coated NMs, the dFlFFF/dAFM approaches 1 and the particles are described as hard spheres, whereas for PVP coated NMs, the dFlFFF/dAFM deviates toward values greater than one, indicating that these particles are either permeable or non-spherical.

Yttrium mobility during weathering: implications for riverine Y/Ho

MICHAEL G. BABECHUK[1*], BALZ S. KAMBER[2], MIKE WIDDOWSON[3]

[1]Laurentian University, Sudbury, ON, Canada (* presenting author)
[2]Trinity College Dublin, Dublin, Ireland
[3]The Open University, Milton Keynes, United Kingdom

Yttrium has similar geochemical properties to the lanthanides and closely mirrors the behaviour of its geochemical twin, Ho, in anhydrous magmatic systems. In the hydrosphere, however, Y is noteably less particle reactive than the lanthanides [1] and is more mobile during chemical weathering as a result [e.g., 2]. Here, this behaviour is further explored using chemical transects through two basaltic weathering profiles in India that are preserved in different stages of alteration: the Bidar laterite profile (~50 m) and an incipient to intermediately weathered profile developed across two lava flows (~5 m) near Chhindwara. Both profiles were characterized using major element and high-precision trace element data to establish the progressive compositional changes during chemical weathering.

The parent rock Deccan Traps basalt of both profiles is chemically similar with an average Y/Ho ratio of 25.2 ± 1.1 in the least-weathered samples. In the Chhindwara weathering profile, the enhanced mobility of Y relative to the lanthanides is observed already at the incipient stages of weathering. The preferential loss of Y continues during increasing weathering intensity in the profile as demonstrated by a strong anti-correlation between the chemical index of alteration (CIA; ranging from 35-80) and the Y/Ho ratio (ranging from ~25-23). Yttrium mobility is evident at the scale of the profile as well as across a corestone-saprolite interface (< 1 m). The Bidar laterite profile (CIA>90) has highly subchondritic Y/Ho ratios (19.4-14.7) with the exception of one sample in the mottled zone with highly enriched REE abundances and a superchondritic Y/Ho ratio of 30.1.

River waters have superchondritic Y/Ho ratios prior to reaching the estuary (where additional, much more extreme Y/Ho fractionation occurs due to the higher particle reactivity of the HREE), indicating that the greater mobility of Y relative to the HREE during weathering may be sufficient to affect mass balance. Care must be taken to correctly identify the Y/Ho ratio of river water due to the possibility of marine chemical sedimentary rocks in the drainage area and/or contamination from phosphate fertilizers. Using previously published Y/Ho data from eastern Australia rivers [3,4] screened based on P content and salinity to minimize the influence of these complications, a net superchondritic Y/Ho ratio remains. Thus, the weathering behaviour of Y may be more important to the interpretation of riverine Y/Ho ratios than previously considered.

Abstract

Following the December 2008 rupture of a coal fly ash retaining pond at the Tennessee Valley Authority (TVA) Kingston Fossil Plant near Harriman, Tennessee, a comprehensive monitoring effort was intiated to evaluate impact of the release on the surrounding aquatic environment. The sequential extraction procedure developed by Querol et. al [1] was utilized by TVA's contracted laboratory and by Appalachian State University (ASU) researchers to evaluate bioavailability of ash-related trace metals in sediments impacted by the release.

Sediment samples collected in 2009 were split and submitted to ASU and to TVA's contracted laboratory for sequential extraction and subsequent metals analysis. This paper presents a comparison of the laboratories' data using the same method.

In 2011, several of the 2009 sediment sampling locations were revisited; these 2011 sediment samples were subjected to sequential extraction by ASU following the same procedure as used for the 2009 samples. This paper also includes comparisons of the data for the 2009 and 2011 sediment samples collected at similar locations.

In 2011, TVA collected and homogenized surface sediment samples in bulk quantities at several locations for several purposes. Sub-samples were submitted to ASU for sequential extraction; these samples were air-dried prior to extraction and between extraction steps. TVA also submitted these surface sediment samples to TVA's contracted labroatory for sequential extraction; these samples were not dried prior to or during the extraction process. A third part of this paper compares sequential extraction data generated with and without drying prior to and during extraction.

Conclusion

This paper evaluates interlaboratory precision for the Querol et al. sequential extraction method; presents temporal trends in bioavailability for several locations; and evaluates the impact of the sampling, handling, and extraction environments on metals leaching during the sequential extraction process.

Electron transfer and atom exchange among Fe and Mn phases

JONATHAN E. BACHMAN[1]*, DREW E. LATTA[2], MICHELLE M. SCHERER[1], AND KEVIN M. ROSSO[3]

[1]The University of Iowa, Civil and Environmental Engineering (*jonathan-bachman@uiowa.edu)
[2]Argonne National Laboratory, Biosciences (dlatta@anl.gov)
[3]Pacific Northwest National Laboratory, Chemical and Material Sciences (Kevin.Rosso@pnnl.gov)

Fe and Mn are both common redox-active metals in environmental systems, and Fe-Mn redox chemistry is an important consideration when predicting fate and transport of contaminants. Recent work has shown that electron transfer and atom exchange occurs between aqueous Fe(II) and Fe(III) oxides and results in extensive recrystallization both with and without secondary mineral formation [1]. It is unclear, however, whether similar redox processes occur among Fe and Mn phases that might result in incorporation and release of Fe in Mn oxides, or conversely, incorporation and release of Mn in Fe oxides. Furthermore, it appears unknown whether the reaction of aqueous Mn(II) with Mn oxides leads to similar atom exchange and recrystallization as has been observed for the reaction of aqueous Fe(II) with Fe(III) oxides [2].

We are exploring the mechanisms driving the redox reactions of Mn(II)/Fe-oxides, Fe(II)/Mn-oxides, and Mn(II)/Mn-oxides using 57Fe Mossbauer spectroscopy and isotope tracer approaches. We have found that Mn-incorporated in goethite is released in the presence of aqueous Fe(II), similar to what has recently been demonstrated for Ni in goethite [3]. These experiments will provide a more fundamental understanding of the reactivity at mineral-water interfaces, in addition to providing a model for trace metal incorporation and release in Mn and Fe oxides.

The Marmion Shear Zone: A kinematic study of Archean terrane boundaries

N. R. Backeberg[1*], C. D. Rowe[1]

[1] McGill University, Earth and Planetary Science, Montreal, Canada, nils.backeberg@mail.mcgill.ca (* presenting author)

Introduction

The Marmion Shear zone marks the Archean terrane boundary between the ~3.003 Ga Marmion tonalite-trondhjemite-granodiorite (TTG) gneisses and the 2.931 – 3.003 Ga Finlayson Lake greenstone belt [1]. The shear zone is intruded by younger undeformed granites. They have not been dated, but petrologically similar units in the Eye Dashwa pluton have been dated at 2.665 Ga [1]. The low-grade (< 1 g/t) Hammond Reef gold deposit is hosted within a network of fractures and alteration zones parallel to the Marmion Shear within the Marmion gneiss and *not* in a major fault or shear zone at the boundary nor within the mafic greenstone belts as seen in most Archean gold deposits, for example in Abitibi [2,3].

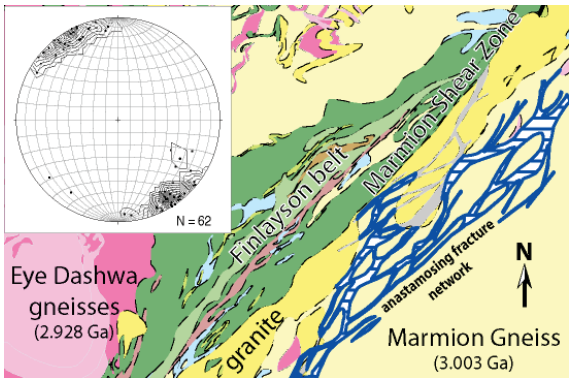

Figure 1: Geological map of the Marmion Shear area [1], showing the location of the anastamosing fracture and alteration zone (blue). The shear zone is intruded by a granite (yellow). Stereonet shows poles to flattening foliation (N = 62) across the Finlayson belt (green).

Preliminary Results and Observations

The Finlayson belt is divided into three parallel belts with different inherited ages (2.931 – 3.003 Ga [1]). At exposure level the belts are parallel to the northeast structural grain of the Marmion Shear (Figure 1). Penetrative flattening foliation is developed across the Finlayson belt (Figure 1). There are no spatial gradients in the strength of the foliation, which deforms all discontinuous lenticular lithologic units. Displaced lithologic unit boundaries demonstrate the presence of discrete faults.

The younger granite crosscuts the shear zone and ductile fabrics in the Marmion Gneiss, and has no penetrative deformation fabrics. It obscures the core of the shear zone. The deformation fabrics in both terranes bounding the Marmion Shear show a transition from ductile to discrete brittle structures, suggesting a common deformation path. The distinct anastamosing fracture network and zone of alteration which hosts the gold in the Marmion Gneiss is not seen in the Finlayson belt. This may be attributable to preferential fracturing and fluid migration within the gneiss during ore formation.

A cooling history for the Nicola Horst, British Columbia.

David Bacque[1*] and Bernard Guest[1]

[1]University of Calgary, Calgary, Canada, dpbacque@ucalgary.ca (* presenting author)

Introduction

The Nicola Horst (NH), is located in the Intermontane belt of British Columbia. It is bound along the east and west by steep post-Paleocene faults [1] (Fig 1). The faults are boundries between undeformed, low grade metamorphic rocks and deformed medium grade metamorphic rocks within the NH [2]. It has been suggested by some authors that the medium grade rocks are mid-crustal and are part of an antiformal thrust duplex [2,3]. The medium grade rocks, amphibolite facies, became exposed via unroofing along the steep post-Paleocene faults. This study aims to determine both the timing of the faults and model the isostatic response caused by the unroofing along the steep post-Paleocene faults using thermochronometry.

Thermochronology and geochronology

Most of the ages gathered in and around the NH have been for determining the absolute ages (geochronology) of the rocks. To understand how the NH formed, we are using thermochronometry, which records various closure temperatures depending on the mineral and system. Previous work done by Simon Fraser University produced four, unpublished, biotite Ar-Ar ages (50.3, 50.3, 56.5, 63.8 Ma, located in the northern, western, eastern, and southern areas respectively). Our samples (Fig 1) are located along a horizontal transect in the central area of the NH and along a vertical transect in the southern area of the NH. These samples are collected for purposes of producing a complete suite of ages, spanning temperatures from 900-60°C. By comparing cooling curves around the NH to ones within, we will determine a better age of the faults around the NH and model the response of the mid-crustal rocks exposed in the NH to the unroofing along the two post-Paleocene faults.

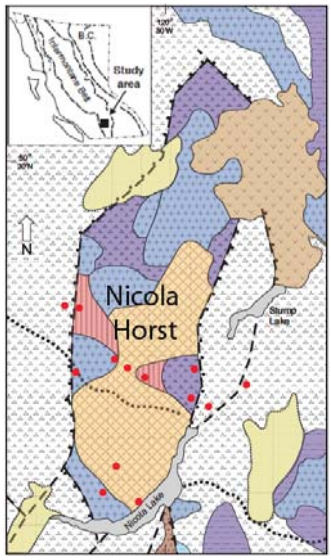

Figure 1: Nicola Horst is located in south central British Columbia. Blues, purples and red are Jurassic, Triassic and older, respectively. Browns, tans and yellows are Eocene, Tertiary and Quaternary, respectively. Red dots indicate locations of samples collected. Image modified from [2].

The importance of accurate and precise temperature reconstruction for alkenone paleobarometry

MARCUS P. S. BADGER[1*], RICH D. PANCOST[2]

[1]Department of Earth Sciences, University of Bristol, Wills Memorial Building, Queen's road, Bristol, BS8 1RJ, U.K., marcus.badger@bristol.ac.uk (* presenting author)

[2]Organic Geochemistry Unit, Bristol Biogeochemistry Research Centre, University of Bristol, Cantock's close, Bristol, BS8 1TS, U.K., r.d.pancost@bristol.ac.uk

By measuring the carbon isotope ratio of long chain ketones produced by haptophyte algae (alkenones) the isotope fractionation during photosynthesis (ε_p) can be determined. Fractionation is dependent on the concentration of carbon dioxide in surface waters, thus, past atmospheric CO_2 can be reconstructed. Recent studies have successfully applied this technique at across several intervals of rapid climatic change in the Cenozoic [1-4], and efforts have been made to use alkenone paleobarometry to constrain climate (or Earth system) sensitivity [2].

Several factors are important to the accurate and precise determination of atmospheric CO_2; for example, recent work has focussed on the effect of changes in algal cell size [5, 6]. However, reconstructions are also highly dependent on the accurate and precise determination of sea surface temperature (SST), as this effects both the determination of ε_p from alkenone $\delta^{13}C$ values, and the conversion of $[CO_2]_{(aq)}$ to atmospheric pCO_2. This has become of paticular importance given the multitude of proxies now applied to the reconstruction of SST, and uncertainty about exactly what each proxy represents.

Here we assess the sensitvity of alkenone pCO_2 estimates to innaccurate and/or inprecise SST reconstructions using new high resolution data from the Pliocene, and investigate the possible implications for previously published records. We highlight the importance of these results, especially the revised uncertainties of paleo-pCO_2 estimates, to understanding climates of the past and estimating climate sensitivity (or Earth system sensitivity) for models of the future.

The Major Element Composition of Earth's Core

JAMES BADRO[1*], JOHN BRODHOLT[2], ALEXANDER COTE[1,2]

[1]IPGP, Paris, France, badro@ipgp.fr (* presenting author)

[2]UCL, London, UK, j.brodholt@ucl.ac.uk

Earth's core formed as a results of a major chemical differentiation event; the melting of accretionary building blocks (meteorites, planetesimals, protoplanets) leads to a separation of the metal from the silicate, ensued by a gravitationally-driven segregation of a dense metal-rich core at the centre of the planet, with the lighter buoyant silicates remaining on top to form the mantle and crust. The bulk composition of the core depends on the path and conditions (pressure, temperature, redox) at which core formation took place; the process also leaves an imprint on the residual bulk silicate Earth, a record that is observable in present-day mantle rocks.

Constraining experimental and theoretical data with geophysical (core density and velocity profiles) observations provides a robust way to estimate the present day composition of the core, as well as the conditions under which it formed.

We will present results obtained from ab initio molecular dynamics calculations to estimate outer-core density and seismic velocity, and combine it with mineral physics on the inner core to define a range of possible compositions of the core that satisfies the observations. We will interpret these results and propose a consistent compositional model, and formulate plausible scenarios for core formation.

Lower crustal Archaean rocks in South-East Greenland

LEON BAGAS[1], TOMAS NÆRAA[2*], BARRY L. RENO[2,3], JOCHEN KOLB[2]

[1] Centre for Exploation Targeting, University of Western Australia Perth, Australia
[2] Geological Survey of Denmark and Greenland, Copenhagen, Denmark, tomn@geus.dk (*presenting author)
[3] Institute for Geography and Geology, University of Copenhagen, Denmark

The Skjoldungen region in South-East Greenland is characterised by felsic gneisses and granites that often contain abundant mafic and ultramafic inclusions (agmatitic) with only minor amounts of mainly mafic but also ultramafic gneisses occurring in narrow belts. The gneisses are commonly migmatitic and mafic gneisses often contain abundant intrusive felsic sheets. The gneissic basement is intruded by a ca. 2.7 Ga alkaline complex and preliminary age data suggest that regional migmatisation occurred during a period from 2.8 to 2.7 Ga [1].

The mafic gneisses group into calc-alkaline and tholeiitic suites, suggesting a heterogeneous mantle source. The felsic gneisses divide into a group with a adakite-like composition and a group characterised by large positive Eu anomalies and often depleted and fractionated HREE. Felsic gneisses formed during at least two stages: 1) an early phase of crustal differentiation of a mafic proto-crust possibly starting at ca. 2.86 Ga and, 2) a late stage related to crustal thickening and remelting which seems to relate to a prolonged stage of high grade metamorphism at ca. 2.8-2.7 Ga [1]. The regional crust is dominated by granites formed during the second stage. The early felsic gneisses have adakitic chemistry and aparrantly formed in the presence of residual garnet whereas the later felsic gneisses formed from an already differentiated lower crust with accumulated plagioclase. The tectonic setting during the early crust forming episode is envisaged to range from a magmatic-arc to the mid-ocean ridge setting. The later stage probably occurred during crustal thickening in a collision orogen involving the root zone of a magmatic arc at the base of the crust (Fig. 1).

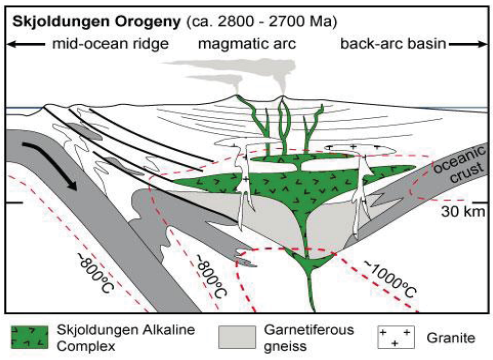

Figure 1: Model for the formation of the protoliths for gneisses in southeastern Greenland

(* presenting author)

Sulfide mineral oxidation is catalysed by microorganisms, increasing oxidation rates by orders of magnitude, releasing SO_4, Fe and H^+ [1]. Sulfide mineral oxidation rates decrease with decreasing temperature. Seasonal temperature fluctuations influence the rate of release of sulfide oxidation products from waste rock stockpiles over time [2]. Iron and sulfur oxidizing bacteria contribute to the oxidation of mine tailings in Arctic environments at temperatures as low as -11°C [2,3]. Yet, limited information exists on the importance of bacterially-catalysed oxidation of sulfide minerals in waste-rock stockpiles and their role in the generation of acid mine drainage in Arctic conditions.

Two large-scale waste-rock test piles, one with 0.035 wt. % S (Type I test pile) and another with 0.058 wt. % S (Type III test pile), located in the continuous permafrost region at the Diavik Diamond Mine were studied to examine the role of microoganisms in the biochemical evolution of test-pile drainage. Three groups of bacteria in test pile drainage were quantified using most probable number techniques [4] for neutrophilic and acidophilic sulfur oxidizers (SOBn and SOBa, respectively), and iron oxidizers (IOB). The media compositions, incubation conditions, and enumeration procedure are described in detail by Hulshof et al. [5]. The monitoring of populations present in test-pile drainage began in 2007 and a microbial succession was observed over time.

Drainage from the Type I test pile maintained a near neutral pH with low concentrations of SO_4 and Fe for the duration of this study. A population of SOBn was present from 2009 through 2010, with the exception of one sample in September 2010. Acidophilic sulfur oxidizers were only detected at very low numbers ($< 10^2$ bacteria/mL). IOB were detected in June 2009 and late 2010, but at low numbers ($< 10^3$ bacteria/mL).

Every year, the pH of the drainage from the Type III test pile decreased from near neutral in May to acidic conditions by October. Concentrations of SO_4 increased with decreasing pH. A population of SOBn were observed in the Type III test-pile drainage in 2008, however, population numbers decreased in late 2009 as the pH decreased. Acidophilic S oxidizers were only detected in 2009 after the drainage pH had decreased. In addition, the population of IOB increased with decreasing pH.

These results suggest bacteria populations evolved with changes in the drainage chemistry. Continued monitoring with more detailed analysis is required to better understand the biogeochemical evolution of these waste-rock test piles.

Geodynamic regimes of intra-oceanic subduction: Thermomechanical modeling of geochemical signatures

B. BAITSCH GHIRARDELLO[1*], A. STRACKE[2], AND T.V. GERYA[1]

[1]ETHZ, Switzerland, Institut f. Geophysik (*), baitsch@erdw.ethz.ch

[2]Westfälische Wilhelms-Universität Münster, Institut f. Mineralogie, Germany, stracke.andreas@uni-muenster.de

The aim of this study is to investigate isotope signatures in different geodynamic regimes of intra-oceanic subduction processes with our 2D coupled geochemical-petrological-thermomechanical numerical model (I2ELVIS). We investigated systematically influences of fluid and melt weakening effects, which are responsible for the degree of plate coupling/decoupling and the mechanical strength of the overriding plate. Based on results of systematic experiments we distinguish the following three geodynamic regimes a) retreating regime, b) stable regime and c) advancing regime.

a) Retreating subduction regime is characterized by a strong rheological weakening of the overriding plate mantle by hydration/serpentinization and melt propagation processes. A necking of the (fore) arc causes the onset of decompression melting in the mantle wedge. Differently to the isotope signatures in the magmatic arc, decompression melting causes a MORB-like isotope signatures in the newly formed crust.

b) The volcanic rocks in a stable subduction regime are mainly produced from the subducted oceanic crust and molten hydrated mantle. Some of the stable subduction regimes are characterized by development of a broad area of subduction mélange in which subducted basaltic crust is strongly mechanically mixed with the serpentinized fore-arc mantle. These intense mixing is promoted by increased degree of fluid related weakening. The correspondent isotopic signature in the arc depends on the degree of fluid related weakening that controls intensity of flux melting.

c) Advancing subduction regime develops under condition of notably reduced fluid-related weakening that results in strong coupling between the plates in the fore-arc region. Strong coupling between plates produces large stresses that are able to overcome the mechanical resistance of the serpentinized fore-arc mantle that starts to subduct together with the plate. Large amount of new basaltic crust forms at the surface as the result of enhanced fluid-fluxed melting of the mantle wedge that coins the isotope signature of the arc.

Diffusion of water through quartz: a fluid inclusion study

RONALD J. BAKKER*, MIRIAM BAUMGARTNER, GERALD DOPPLER

Resource Mineralogy, University of Leoben, Austria, bakker@unileoben.ac.at (* presenting author)

Introduction

Diffusion of H_2O through minerals, such as quartz, that do not incorporate water at regular lattice positions is of major importance to understand fluid-rock interaction processes in deep rock, and to interpret fluid inclusion studies. The outcome of a variety of re-equilibration experiments with natural and synthetic fluid inclusions indicate that diffusion of H_2O plays an important role in these processes. Diffusion coefficients of H_2O in nominally anhydrous minerals were experimentally estimated from H_2O molecules (or part of these molecules) that replace oxygen at regular lattice positions in silicates, and which positions were detected in quenched samples after re-equilibration experiments.

Experiments

The properties of fluid inclusions in quartz can be relatively easily obtained from a variety of analytical techniques. Fluid inclusions can be regarded as constant volume containers inside a crystal lattice, which are more or less protected by the surrounding crystal from material exchange with rock pore volumes. Any change in fluid inclusion density and compositions is directly the result of diffusion processes. The exchange of fluid components in our experiments is provoked at high temperatures and pressures. Deoendent on experimental conditions, time, fluid inclusion size, and distance of fluid inclusions to the grain boundary, a variety of compositional changes are detected. similar effects are observed in assembalges of ynthetoc and natural fluid inclusions in quartz.

Conclusions

Concentration profiles based on fluid inclusion composition and density are not confirm diffusion coefficients obtained by altered isotopic compositions of quartz grains (i.e. the traditional technique to trace water in quartz). This illustrates that the mobility of H_2O in quartz must be a complex interaction of bulk diffusion and other processes suh as micro-crack enhanced or dislocation-enhanced diffusion. The reliability of natural fluid inclusions in metamorphic rock to determine rock-forming conditions can only be improved if these re-equilibration processes are fully understood.

Ice, but no fire: a new depositional age for the Rapitan Group, Canada

GEOFFREY J. BALDWIN[1*], ELIZABETH C. TURNER[1], AND BALZ S. KAMBER[2]

[1]Laurentian University, Department of Earth Sciences, Sudbury, ON, Canada, gj_baldwin@laurentian.ca (* presenting author), eturner@laurentian.ca

[2]Trinity College Dublin, Department of Geology, Dublin, Ireland, kamberbs@tcd.ie

The timing and causes of the glacial events associated with the 'Snowball Earth' hypothesis remain contentious. The earliest of these events, the Sturtian glaciation, has returned U-Pb zircon and Re-Os black shale ages from 740 Ma to as young as 660 Ma. Recently, strata correlated with the glaciogenic Rapitan Group of NW Canada have been dated at 716.47±0.24 Ma [1]. This supported a genetic correlation of the Sturtian glaciation and the Rapitan Group with the Franklin large igneous province (LIP), suggesting that the Sturtian glaciation may have been triggered by excessive CO_2 drawdown by weathering of this LIP – the 'fire and ice' model [1,2]. This model relies on penecontemporaneous emplacement of the LIP, its weathering, and Rapitan Group glacial onset at low latitudes. Here we present a new age for detrital zircon from the Rapitan Group itself. The sample was extracted from cross-bedded sandstone underlying the Rapitan iron formation by 75 m. A large number of zircon were pilot dated by LA-ICP-MS on double-sided tape and the youngest were then dated by high-precision ID-TIMS (see diagram). A coherent population of 8 grains defines a concordia age of 711.34±0.25 Ma. This is the new maximum age for deposition of the Rapitan Group and for the Sturtian glaciation in the region, and is consistent with Re-Os dates from shales overlying other Sturtian glacial deposits [3]. Significantly, it is a full 5 million years younger than the Franklin LIP, a span of time that is too long to support the 'fire and ice' model. The Rapitan Group may have been erroneously correlated with similar nearby strata. It is also possible that global 'Sturtian' glacial deposits were not the result of a single glacial episode.

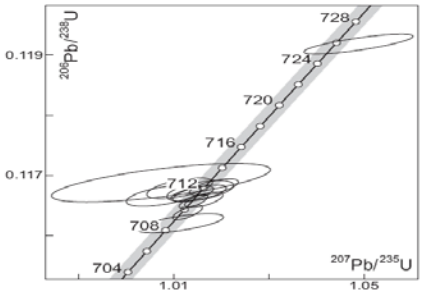

Figure 1: U-Pb concordia diagram for detrital zircon from the Rapitan Group, Canada. N=12, eight grains yielded a mean age of 711.34±0.25 Ma (MSWD = 2.0).

Reconstruction of *P-T* paths in polymetamorphic rocks of the Clearwater core complex, northern Idaho

JULIA A. BALDWIN [1*] AND VICTOR E. GUEVARA[1]

[1]Dept. of Geosciences, University of Montana, Missoula, MT, 59812, USA, jbaldwin@mso.umt.edu (* presenting author), victor.guevara@umontana.edu

Understanding where, when, why, and how metamorphic core complexes form in settings of continental shortening is important because these features are part of the rock record of deformation. Moreover, core complexes provide the most direct observational information about the relationship between the middle and uppermost crust in the late stages of orogenesis, so offer a valuable opportunity to investigate crustal coupling and mass transfer within continental crust.

In the northern U.S. Rockies, core complexes show a prolonged metamorphic history, lie inboard of the $^{87}Sr/^{86}Sr$ 0.706 line, and are spatially associated with major Cordilleran batholiths. Peak metamorphic conditions are amphibolite facies, with maximum crustal depths of around 25-35 km in the most deeply exhumed complexes. Metamorphosed footwall rocks include units within Proterozoic crystalline basement as well as the sediments of the overlying Mesoproterozoic Belt Supergroup. Widespread extension occurred 59-40 Ma, with several core complexes recording an initial rapid phase of extension at *c.* 49-48 Ma followed by more protracted exhumation. The focus of this paper is on characterization of polymetamorphism in the Clearwater metamorphic core complex (CMCC) located in northern Idaho, which contains a history of both Proterozoic and Cretaceous-Eocene tectonometamophic events.

Metamorphic events in rocks within the CMCC range from Paleoproterozoic basement formation, Mesoproterozoic crustal thickening, and Cretaceous convergence, magmatism, and final exhumation in the Eocene. The samples focused on in this study are pelitic and unusual Mg-Al-rich schists from both within the high grade core of the complex, as well as schists that lie west and east of the bounding detachments. Previous work has indentified three major metamorphic events in the area [1]. The first has recently been correlated with Mesoproterozoic (1.3 Ga) crustal thickening based on Lu-Hf garnet dating [2]. Rocks also show evidence for a 1.1 Ga event. Zircon rims indicate Cretaceous to Eocene metamorphism in pulses from 82-80, 74-72, 64, and 59-55 Ma [3]. The younger dates likely correspond to fluid migration during exhumation of the complex. Here we present results of pseudosection modeling and garnet compositional isopleth thermometry to place contrainsts on the complex polymetamorphic history of these rocks. The Cretaceous to Eocene history is best preserved in multi-stage garnet microstructures with diffuse high Ca – low Mn rims, rutile converting to ilmenite, pre-kinematic staurolite, and abundant andalusite and sillimanite after kyanite, particularly in rocks within Eocene shear zones.

Coping with Oxygen: Peroxy defects in Rocks and the survival of bacteria

MELIKE BALK[1*], PAUL MASON[1], ALFONS J.M. STAMS[2], FRIEDEMANN FREUND[3,4], AND LYNN ROTHSCHILD[3]

[1] Department of Earth Sciences, Utrecht University, (m.balk@uu.nl, presenting author* and p.mason@uu.nl), [2]Laboratory of Microbiology, Wageningen University (fons.stams@wur.nl) [3]NASA Ames Research Center, Moffett Field, CA, (Lynn.J.Rothschild@nasa.gov), [4]SETI Institute, Mountain View, CA (friedemann.t.freund@nasa.gov).

An oxygen-rich atmosphere appears to have been a prerequisite for complex life to evolve on Earth and possibly elsewhere in the Universe. The question is still shrouded in uncertainty how free oxygen became available on the early Earth. Here we study processes that introduce peroxy defects into silicate minerals which, upon weathering, result in oxygen formation in an initially anoxic subsurface environment. Reactive Oxygen Species (ROS) are precursors to molecular oxygen during this process. Due to their toxicity they may have strongly influenced the evolution of life. ROS are generated during hydrolysis of peroxy defects, which consist of pairs of oxygen anions. A second pathway for formation occurs during (bio) transformations of iron sulphide minerals. ROS are produced and consumed by intracellular and extracellular reactions of Fe, Mn, C, N, and S species. We propose that despite an overall reducing or neutral oxidation state of the macroenvironment and the absence of free O_2 in the atmosphere, microorganisms on the early Earth had to cope with ROS in their microenvironments. They were thus under evolutionary pressure to develop enzymatic and other defences against the potentially dangerous, even lethal effects of ROS and oxygen.

We have investigated how oxygen might be released through weathering and test microorganisms in contact with rock surfaces and iron sulphides. Our results show how early Life might have adapted to oxygen. Early microorganisms must have "trained" to detoxify ROS prior to the evolution of aerobic metabolism and oxygenic photosynthesis. A possible way out of this dilemma comes from a study of igneous and high-grade metamorphic rocks, whose minerals contain a small but significant fraction of oxygen anions in the valence state 1- , forming peroxy links of the type $O_3Si\text{-}OO\text{-}SiO_3$ [1, 2]. As water hydrolyzes the peroxy links hydrogen peroxide, H_2O_2, forms. As a result, microorganisms attached to mineral grains will be exposed to a constant trickle of ROS from the H_2O_2 production. Many different groups of microorganisms are able to grow or survive in the presence of ROS.

Impact of fungi and bacteria on the mobility of metals (Fe, Al) in podzolic soils

C. BALLAND-BOLOU-BI*, S. J. M. HOLMSTRÖM, N. G. HOLM

Stockholm University, Dept. of Geological Sciences, Stockholm, Sweden (*Clarissebolou-bi@geo.su.se)

Mineral weathering is a key process in soil leading to leaching and release of essential elements (Fe, Al), which sustain plant growth and determine the chemistry of soil solutions and exchange complex. Soil microorganisms (fungi and bacteria) play a major role in the availability of nutrients in soils. They participate in weathering of primary materials through the production of low-molecular organic molecules (siderophores and organic acids). Determination of their relative contribution and understanding their interaction with soil minerals through different mechanisms is a key step toward characterization of the mobility of metals and identification of the pedogenic processes in action.

Recent techniques of *in situ* dynamic sensor have been developed to assess bioavailable fractions of metal in soil according to different relevant time scales of environmental processes. Diffusive gradients in thin films (DGT) are one of these speciation analyses [1]. This technique allows to establish a permanent flux of labile metal through a gel and then to measure the labile concentration upon its deployment time (i.e. the labile fraction corresponds to free metals in solution and metals linked to inorganic and organic ligands). In order to identify different weathering agents implied on the mobility and speciation of metals (Fe and Al) in soil solutions both in field studies and laboratory experiments, we have deployed DGT and DET (Diffusive Equilibrium in Thin Film) in different horizons of a podzol (developed on granitic rocks) on Norunda Site (Sweden) in November 2011. In parallel, we lead several experiments of geological material (granite) bioweathering to investigate the impact of fungi and bacteria on the release of Fe and Al from granite. To characterize mechanisms of dissolution, we monitored low-molecular organic molecules produced by microorganisms, microbial biomass, pH, and free and labile iron and aluminium fraction released by combining DGT and DET techniques.

The comparison of the results between field studies and laboratory experiments will permit the improvement of our knowledge of the contribution of microorganisms on the bioavailability of metals in soils and also on the podzolisation process that remains still always debated.

(* presenting author)

Water bearing macrosystems that have been isolated from the surface, preserved on geological timescales (>10Ma) and capable of supporting life, are seemingly rare. The only study of its type is now established in the South African Precambrian Crystalline Shield [1, 2]. The Witwatersand Basin provides the case type study and a unique insight into the evolution of chemolithotrophic life, the ability of even the most nutrient poor environments to support life in extremis, and thus environments that may support life on other planets [2]. The stable isotopic composition of the water, showing a high degreee of water-rock interaction, allows the inference of isolation from surface waters and a long residence time. It is the in-situ buildup of radiogenic noble gases (e.g. ^{4}He, ^{21}Ne, ^{40}Ar, ^{136}Xe) that has provided the basis for quantifying how long this system may have been isolated from the surface [1]. An outstanding question is how rare are such systems?

We have determined the noble gas concentration and isotopic composition of 6 gas samples, co-produced with water, from deep exploratory boreholes in a producing mine in the Timmins region of the Canadian Precambrian Crystalline Shield. Neon isotopic compositions are similar to the Witwatersand study and used to validate the closed system assumption for the radiogenic noble gases [1]. Using a similar model to [1], modified for local conditions (2.8ppm U, 10.6ppm Th, 3.4% K and 1% porosity and 100% release efficiency), we calculate closed system noble gas ages of the free produced fluids to be between 650Ma to 1.5Ga. These are the oldest 'free water' yet found in a crustal system.

Multi-collector noble gas mass spectrometry provides an order of magnitude more precision in the isotope determination of some free fluids [3]. We also resolve in all samples a clear ^{129}Xe signal in excess of atmospheric values. We can discount mass fractionation mechanisms and need to identify the source of the ^{129}Xe enrichment, only ever observed before in mantle-derived terrestrial fluids. ^{3}He/^{4}He allows us to discount a significant magmatic fluid source. Similarly, U-fission Xe (e.g. $^{132\text{-}136}$Xe) are produced at a known rate with fission ^{129}I (^{129}I → ^{129}Xe, t½=15.7Ma). The excess U-fission ^{136}Xe precludes a simple U-fission source for the ^{129}I → ^{129}Xe.

The ^{129}Xe excess observed is nevertheless most likely due to a local source of ^{129}I. We are collecting data to resolve two possible sources: i) U-fission ^{129}I released at steady state into the porewater through an extreme CFF (Chemical Fractionation of Fission products) process. CFF is required to prevent the associated fission Xe products reaching the porefluid and in turn would impact our previous assumption of 100% release efficiency and require older ages yet; or ii) the possibility of organic rich sediments associated with the formation lithologies supplying either the ^{129}I or its decay product (^{129}Xe). The latter would require a fluid closure date related to the last major mineralising event at 2.670Ga.

While the age determinations undgergo refinement with the new Xe information, our results nevertheless suggest that ancient and isolated macrosystems that have the potential to support life [2] may yet be found in a substantial portion of the Earth's Precambrian Crystalline Shields.

Biotite Weathering in Watersheds of the Slavkov Forest, Czech Republic

Z. BALOGH-BRUNSTAD[1,2*], L. SACCONE[3,4], M.M. SMITS[5], C. BERNER[6], H. WALLANDER[6], T.J. MCMASTER[4], S.L.S. STIPP[1]

[4]H.H. Wills Physics Laboratory, University of Bristol, UK
[5]Environmental Biology, Hasselt University, Belgium
[6]Microbial Ecology, Lund University, Sweden

Introduction and Methods

Biotite is one of the primary sources of potassium and magnesium in soils and is easily weathered by microbes and plants to access these nutrients. It is shown that ectomycorrhizal fungi play a significant role in mineral dissolution and nutrient translocation to their host plant. Numerous controlled laboratory experiments have demonstrated physical and chemical interactions of ectomycorrhizal fungi with biotite, ranging in scale from individual grains to artificial mineral soils. However, whether ectomycorrhizal fungi have a significant contribution to soil mineral weathering under natural forest conditions, remains controversial.

In our study, mesh bags containing 1 wt% small biotite flakes and one large freshly cleaved flake in quartz sand, were buried in spruce forest soils for two years at three sites where the bedrocks were serpentinite (K limited), leucogranite (Mg limited) and amphibolite (no limitations). The 60 µm mesh size allowed fungal hyphae to grow in the bags, but excluded direct plant root contact with the minerals, allowing us to test the direct contribution of ectomycorrhizal fungi on biotite weathering under naturally occuring K and Mg limitations. Mineral surfaces were examined with scanning electron microscopy (SEM) and atomic force microscopy (AFM). The total ectomycorrhizal biomass was determined by Ergosterol analyses.

Results and Discussion

Microscopy documented 5% or less direct fungal attachment to basal planes of biotite from all sites, with the lowest occurrence found at the low Mg site. The ergosterol results support these observations, with the lowest colonization of the bags at the low Mg site. Potassium limitation does not influence ectomycorrhizal colonizations. Shallow etched channels, similar to hyphae in size and branching pattern, are seen by AFM and SEM. These channels show short, segmented sections, i.e. a pulsive growth pattern and at each "pulse," the channel deepens in the direction of growth. We propose that this morphology reflects both chemical dissolution and physical force at the hyphal-mineral interface. However, abiotic processes, such as wear from sand grains rolling over biotite surfaces can produce similar patterns that are nearly indistinguishable from channels formed by hyphal activity.

Our observations from these field experiments support laboratory results, i.e., that fungal hyphae exercise both chemical dissolution and physical force at the hyphal-mineral interface, but abiotic processes cannot be excluded as an explanation for the formation of shallow channels on the soft biotite surfaces.

Aragonite – calcite seas and the evolution of biocalcification

UWE BALTHASAR[1*] AND MAGGIE CUSACK[1]

[1]University of Glasgow, School of Geographical and Earth Sciences, Glasgow, UK, uwe.balthasar@glasgow.ac.uk (* presenting author), maggie.cusack@glasgow.ac.uk

The influence of aragonite-calcite sea conditions on the evolution of biocalcification remain poorly understood. While selection for the polymorph favored by the aragonite-calcite sea status is relatively strong for organisms that evolved shells for the first time [1], there is no statistically significant correlation between shifts in the aragonitic/calcitic proportions in calcareous skeletons through time and sea chemistry [2]. However, case studies suggest that changes in aragonite/calcite sea conditions can influence the mineralogy of individual calcifying lineages [3].

A particularly intriguing group in this context is trimerellids, the only known group of aragonitic brachiopods [4]. With shells up to 20cm wide, trimerellids were also the most prolific calcifiers amongst brachiopods of the Ordovician/Silurian calcite seas. The success of trimerellids as measured by their large shell size and cosmopolitan distribution in the Ordovician/Silurian palaeo-tropics suggests that the innovation of aragonite during a calcite sea interval was advantageous for this group.

This success is best explained by considering the role of temperature on $CaCO_3$ polymorph formation. While the switch between aragonite and calcite sea conditions is commonly attributed to the ratio of Mg/Ca or pCO_2 [5, 6], it is often ignored that Mg/Ca controls the formation of aragonite and calcite as a function of temperature [7], with warmer temperatures favoring aragonite. When combining the values of marine Mg/Ca through time [5] with the Mg/Ca – temperature curve that separates aragonite from calcite precipitation fields [7] it becomes apparent that aragonite was the favored polymorph in warm tropical surface waters even during calcite sea intervals (Fig. 1).

Based on the available data [5, 7], water temperatures above 25° C favored the formation of aragonite even during calcite sea intervals (Fig. 1). The conventional view of aragonite/calcite sea conditions as a globally homogenous model needs to be reconsidered in the light of latitudinal surface water temperature differences.

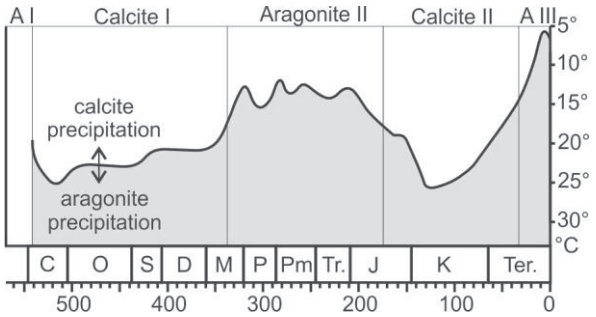

Figure 1: temperature separating the marine aragonite/calcite precipitation fields through time (from [4]; based on [5] and [7]).

A transferable classical polarizable model for the water molecule

ANDRÁS BARANYAI[1*] AND PÉTER T. KISS[2]

[1]Eötvös University, Institute of Chemistry, Budapest, Hungary bajtony@chem.elte.hu (* presenting author)

[2]Eötvös University, Institute of Chemistry, Budapest, Hungary peter.kiss.20@gmail.com

The model

We developed a new model for the water molecule, which contains only three Gaussian charges. Using the gas-phase geometry, the dipole moment of the molecule matches, the quadrupole moment closely approximates the experimental values. Two positive charges are on the hydrogen atoms, while the negative charge is connected by a harmonic spring to its gas-phase position. This position is on the main axis of the molecule between the oxygen and the hydrogen atoms. The polarized state is established by the equality of the electrostatic forces and the spring force of the negative charge. In each time step the position of the massless negative charge is determined by iteration.Using the technique of Ewald summation, we derived expression for the energy, the forces, and the pressure for Gaussian charges. The dispersion interactions were fitted [1].

Tests of the new model

The model was tested and provided good results for the properties of gas-phase clusters up to 6 molecules, ambient water and hexagonal ice [1]. We calculated the properties of ice polymorphs under high pressure as well. In moderatly dense phases the closest O-O distances are very close to the same distances in hexagonal ice. In compressed phases, however, the number of neighboring molecules in the second shell is larger than in hexagonal ice. To use a repulsion suitable for hexagonal ice gives low density for the compressed ice phases. We calculated the "compressing force" for each particle and connected a variable "size" to this force. With this approach we obtained agreement from water clusters to ice VII up to 25 GPa [2]. Relying on earlier studies, we devised a reasonable form for an electric field dependent polarizability of the molecules. At low fields the polarizability starts from the experimental gas-phase value towards a treshold at high fields. The decline of this function was determined by the calculated dielectric constant of ambient water [3]. The model was tested for liquid-vapor behavior. The surface structure of the model was analysed. Its surface tension provides superior estimates of the experimental value than nonpolarizable models [4]. The algorithm of the program code is given for the model. Due to different numerical speeding up methods, it is only 2.6 times slower than the code of the well-known TIP4P nonpolarizable model [5].

Abstract

Iron oxides have been shown to promote the preservation of 1/5th of the total organic carbon pool in marine sediments (1). These iron-organic matter phases are formed within the oxic layer of marine sediments through oxidation of dissolved iron(II) produced during weathering and diagenetic recycling (2). However, it remains unclear what type of interaction (adsorption of organic matter onto the surface of oxides or co-precipitation to form iron-organic complexes) is formed between iron and organic matter in these systems. In this work, iron oxides were synthesized by oxidizing a solution of Fe(II) in seawater at constant, near circumneutral pH to closely mimic natural environmental conditions. Synchrotron X-ray absorption techniques (XANES and EXAFS) were used to probe the local environment of iron using beamline X26A at the Brookhaven National Laboratory. We determined that iron oxides precipitated in the presence of organic matter have a shifted iron Kα edge with respect to organic free iron oxide minerals, demonstrating that iron-OM co-precipitates are likely a prevalent form of iron in sedimentary environments. Using this shift in Kα edge the approximate contribution from organic free iron oxides and organic rich mononuclear iron compounds of our synthetic Fe(III)-OM precipitates were determined using linear combination fitting.

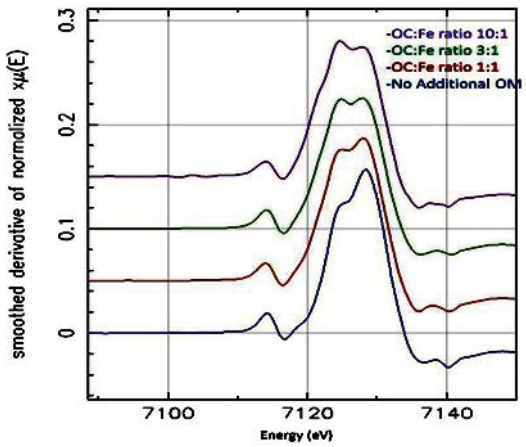

Figure 1: The first derivatives of stacked normalized iron Kα edge XANES spectra with OC:Fe ratios varying from 10:1 to 1:1.

Introduction

Exposure to asbestos fibers is well known to be associated with respiratory diseases such, mesotheliomas and lung cancer. *FB* (**Figure 1**) are the result of a coating process, taking place in the host organism, of a variety of fibers such as asbestos (crocidolite, amosite, chrysotile) and phyllosilicate fibers (talc, mica, kaolinite), coal dust, oxalate, and fiberglass. This coating was generally accepted to be a protective mechanism produced by macrophages to segregate the cytotoxic fibers from the organic tissues [1]. However, more recently, other authors suggested that the coating material may enhance the cytotoxic properties of the asbestos fibers by increasing the production of free radicals [2,3,4,5,6]. In spite of the large attention devoted to this subject, the exact nature of the coating, along with the biological effect of *FB*, is still not clear. This is mainly due to the difficulty of sampling large enough amounts of *FB* using reliable isolation procedures, and to their microscopic dimensions (2-5 μm diameter, 20-90 μm length). The use of state of the art synchrotron radiation microprobe techniques gave the first direct characterization of single *FB*.

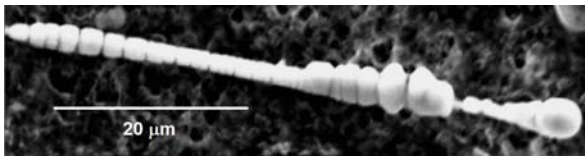

Figure 1: SEM image of a *FB* collected from human lung tissue.

Results and Conclusion

Human lung tissue rich in *FB*, owing to professional exposure, were collected from two subjects who were affected by lung cancer. μXRF high resolution elemental maps of *FB* (2 μm pixel size) were acquired on ID18F at ESRF, and μXANES spectra were recorded at selected points at the Fe edge on ID21. μXRF revealed that the external coating is mainly composed of Fe, Cu, Zn, and As (plus Ge and Ba in one subject) distributed in different areas of the *FB*, while μXANES gave the first direct confirmation that iron is mainly present as ferritine.

Fe atom exchange between aqueous Fe^{2+} and hematite

MICHELLE BARGER[1*], KEVIN ROSSO[2], AND MICHELLE SCHERER[1]

[1]Civil and Environmental Engineering, University of Iowa, Iowa City, IA 52242(*correspondence: michelle-barger@uiowa.edu)
[2]Chemical and Materials Science Division, Pacific Northwest National Laboratory, Richland, Washington 99352

Recent work has revealed that Fe oxides are dynamic phases that will undergo significant Fe cycling in the presence of aqueous Fe(II) [1]. Complete exchange of Fe atoms between aqueous Fe(II) and goethite has been shown [2] and extensive exchange has also been observed for ferrihydrite and lepidocrocite [3]. Bulk electrical conduction linking oxidative adsorption of Fe(II) and reductive dissolution of the Fe(III) oxide at spatially separated sites has been suggested as a potential mechanism to explain the extensive exchange observed in the presence of Fe(II) [2; 4]. Interestingly, bulk electrical conduction linked to growth and dissolution has only been directly demonstrated in hematite, yet, ^{55}Fe isotope data indicate little exchange occurred between aqueous Fe(II) and hematite [3].

Here we are investigating atom exchange between aqueous isotope specific ^{57}Fe(II) and isotopically normal hematite to determine if exchange occurs between aqueous Fe(II) and hematite. Our working hypothesis is that the reaction of aqueous Fe(II) with hematite will result in significant Fe atom exchange and recyrstallization of hematite particles and that the rate of exchange will be influenced by particle size.

Unravelling the crustal architecture of Cape Verde; the xenolith record

ABIGAIL K. BARKER[1*], DAVID NILSSON[1], VALENTIN R. TROLL[1], THOR H. HANSTEEN[2] AND ANDREAS KLÜGEL[3]

[1]CEMPEG, Department of Earth Sciences, Uppsala University, Uppsala, Sweden abigail.barker@geo.uu.se (* presenting author)
[2]IFM-GEOMAR, Dynamik des Ozeanbodens, Kiel, Germany
[3]Department of Earth Sciences, University of Bremen, Bremen, Germany

The Cape Verde submarine plateau was extensively sampled during the Meteor M80/3 research cruise in January 2010. The suite of sampled lavas are found to host a range of xenoliths. These xenoliths provide a spectrum of lithologies available to interact with magmas during transport through the lithospheric mantle and crust. Exploring the depths of origin of such xenoliths will complement the information we derive from the host lavas and thus the 3-D geochemical framework of magma-crust interaction in the Cape Verde magmatic plumbing systems. This will allow the development of a model for the crustal architecture beneath the Cape Verde oceanic plateau.

The host lavas are nephelinites containing clinopyroxene, nosean, nepheline, ± apatite, ± sanidine phenocrysts. The crustal xenoliths are mostly mafic plutonic assemblages with one sedimentary xenolith occurring. The mafic plutonic xenoliths are holocrystalline, and fine to medium grained. They contain plagioclase, clinopyroxene, olivine and/or amphibole. The sedimentary xenolith contains rounded grains of quartz, together with minor clay minerals, biotite and alkali feldspar.

Mafic plutonic xenoliths have developed reaction zones on contact with the host magma. The reaction zones are approximatley 50 to 100 microns and are observed petrographically by crystallisation of fine grained sericite, epidote and chlorite. Element mapping highlights the increase of Na and K and decrease in Ca and Al in the reaction zone compared to plagioclase of the xenolith.

REE profiles of clinopyroxenes in the host lavas are LREE enriched whereas clinopyoxenes from the plutonic xenoliths are LREE depleted. Modelling of REE melt compositions indicates the plutonic xenoliths are derived from MORB ocean crust opposed to intrusives of the Cape Verde plateau.

Mineral chemistry of the clinopyroxenes in the host lavas and xenoliths have been used to determine crystallization pressures. Thermobarometry indicates that clinopyroxenes in the host lavas formed at depths of 17 to 46 km[1], whereas those in the xenoliths formed at 5 to 15 km. This places the depth of origin of the plutonic xenoliths above the Cape Verde Moho and in the oceanic crust.

The xenoliths thus trace magma-crust interaction to the MORB oceanic crust and overlying sediments located beneath the Cape Verde submarine plateau. The spatial distribution and vertical representation provided by crustal xenoliths will help to develop a better idea of the 3-D architecture of the oceanic crust beneath the Cape Verde plateau.

[4]National Energy Technology Laboratory, Pittsburg, PA brian.strazisar@netl.doe.gov

The saline Arbuckle aquifer in south-central Kansas has been proposed for a pilot scale injection of CO_2 [1]. This paper presents characterization of Arbuckle mineralogy and hydrogeochemistry along with experimental flow cell data and geochemical modelling of CO_2 injection. Two wells (KGS 1-32 and 1-28) have been drilled to the basement to provide rock core and brine data for a site specific determination of the storage potential of the Arbuckle. Thin section and XRD data reveal dominant mineralogy in the injection zone to be dolomite with sporadic cherty nodules. Chert appears to replace dolomicrite and euhedral dolomite as well as infilling porosity. Porosity values range between 1.2 and 11.8% within the injection zone. Drill stem test water samples were collected from 8 depths (3677, 4182, 4335, 4520, 4876, 4927, 5036, 5183 ft) to describe the changing brine chemistry with depth. Sulfate peaks at 4876' and 4927' may be indicative of microbial action at these depths. Chemical analysis show a hyper saline brine (~50,000 - 190,000 TDS) dominated by Cl, Na and Ca. Elemental ratios of Cl:Br, Na:Cl and Ca:Sr are what is expected of a typical saline aquifer system [2]. Major and trace elemental chemistry suggest the brine originated from evaporated seawater that has been affected by digenetic processes.

Laboratory flow experiments carried out at the National Energy Technology Laboratory show increases in Ca, Mg, Na and Cl while Fe, S, P and SO_4 decrease within the first 15 hours while hours 15 through 24 show a reverse trend for these elements. Flow experiments at supercritical temperatures and pressures allow determination of the extent of mineral carbonation, mineral dissolution reactions and help constrain reaction rates determined through geochemical modelling [3].

A textural and mineralogical assessment of NWA 3118

G. C. BARLET[1*], D. W. DAVIS[1], D. MOSER[2], K. TAIT[1,3], I. BARKER[2] AND B. C. HYDE[3]

[1]Department of Geology, University of Toronto, Toronto, Canada barlet@geology.utoronto.ca
[2]Department of Earth Sciences, University of Western Ontario, London, Canada
[3]Department of Natural History, Royal Ontario Museum, Toronto, Canada

Northwest Africa (NWA) 3118 is a reduced CV3 chondrite, with large, irregularly shaped Calcium-Aluminum-rich Inclusions (CAIs) and Amoeboid Olivine Aggregates (AOAs) as well as dark inclusions [1]. Previous work by Ivanova [2,3,4] on NWA 3118 showed remarkable features such as compound CAIs with variable degrees of internal melting as well as unusual Zr-Y-Sc-rich mineral inclusion. NWA 3118, a relatively new addition to the list of chondrites, still contains numerous evidences about the early solar system. Initial textural observations were made by optical microscopy. EDS mapping and BSE imaging of uncoated slabs was carried out in variable pressure mode by FEG-SEM. In complement, we investigated the mineralogy of CAIs and AOAs using Raman Spectroscopy.

The surface distribution of chondritic components appears heterogeneous on our slabs where some areas are overpopulated by large inclusions, while other areas are composed of widespread small inclusions, and the rest is a mixture of both. Amorphous (fluffy) CAIs and AOAs are relatively common in NWA 3118 and appear very similar when observed optically. In some cases their shapes are controlled by compression between adjacent chondrules, although there does not seem to be any consistent axis of strain. Silicate chondrules themselves are rarely spherical and some of them appear to have responded to local strain, suggesting that they were partially molten when NWA 3118 was accreted.

Our specimen contains singular assemblages of fine-grained and coarse-grained amorphous CAIs. We also report the presence of compact (spherical) CAIs surrounded by Wark-Lovering rims embedded in fluffy CAIs. The largest compact CAI (400 micron) is associated with two significantly smaller distorted compact CAIs (50 micron) near the edge of its amorphous host.

Because amorphous CAIs and AOAs are nearly indistinguishable in texture, we presume that they were produced by similar physical processes in different reservoirs, or in the same reservoir with an evolving bulk chemistry. The presence of amorphous CAIs with different grain sizes supports the idea that the heat transfer and/or other factors that control crystal size (e.g. degree of undercooling) in the forming region were not uniform. In particular, the presence of compact CAIs included in amorphous CAIs suggests a variable non-uniform heat source where dusty CAI material may have been melted to form compact CAIs which subsequently accreted more dust in a process similar to that suggested for chondrules [5].

Links between tectonics and life, 4.0 to 2.3 Ga and the rise of oxygen

M.E. BARLEY[1*],

[1] School of Earth and Environment, The University of Western Australia, Crawley, Western Australia, 6009, Australia (correspondence: mark.barley@uwa.edu.au)

Earth is the only planet in our solar system with a bimodal topographic distribution crucial for the evolution of complex life. The tectonic records of the Archean to Paleoproterozoic (4.0 to 2.3 Ga) terranes indicate a link between evolving global tectonics with the formation of stable continents, increased subaerial volcanism and increased orogenic mountain building and the rise of atmospheric oxygen on Earth ~2.4 billion years ago. The first 2 stable cratons formed between 3.0 and 2.9 Ga after the first unambiguous evidence for plate tectonics. The Neoarchean record started at 2.8 Ga involving the possible break of a single pre-existing continent and the most prodigious period of generation and preservation of juvenile continental crust during a period of mantle plume breakout (2.72 to 2.65 Ga). During this period many cratons formed and aggregated into larger cratons and continents. Lower sea levels between 2.65 and 2.55 Ga were followed by a second (~2.51 to 2.45 Ga) period of plume breakout. Although oxygenic photosynthetic bacteria are thought to have evolved by 2.7 Ga or 2.5 Ga, the irreversible rise of atmospheric oxygen appears to have occured between 2.48 and 2.32 Ga suggesting a dynamic linkage and interaction of both sources and sinks of oxygen. Increased subaerial volcanism [1] and reduced temperature of magmatism (less komatiites) after 2.65 Ga helped cyanobacteria and also resulted in a decline of methane helping oxygen strat to rise [2]. There is growing evidence the long time the rise took involves interaction between cyanobacteria and oxygen using acid rock drainage bacteria from 2.48 Ga [3] as well as the rise of iron in the ocean using oxygen to form the bigest banded iron formations (BIFs). The 2.4 Ga break in tectonics and decline of BIFs helped the cyanobacteria and volcanic gasses with the rise of oxygen.

Chlorine isotope geochemistry of Icelandic geothermal waters

JAIME D. BARNES[1] AND ANDRI STEFÁNSSON[2]

[1]Department of Geological Sciences, University of Texas, Austin, Texas, USA jdbarnes@jsg.utexas.edu (* presenting author)

[2]Institute of Earth Sciences, University of Iceland, Reykajavik, Iceland, as@hi.is

The chlorine isotope composition of several geothermal systems in Iceland were determined in order to evaluate possible chlorine stable isotope fractionation in geothermal systems. The geothermal systems studied exhibit a range of temperatures (~38°C to >300°C) and pH (6 to 9.5). Chlorine concentrations range from ~5 to ~200 ppm. δ^{37}Cl values for all samples are near 0‰ (range = -0.3 to +0.3‰; error = +/- 0.2‰).

The source for the chlorine in the analyzed systems is commonly hypothesized to be from magmatic degassing or from leaching of host basalt during water-rock interaction. The δ^{37}Cl values are consistent with either of these hypotheses based on the near 0‰ value for the upper mantle and MORB glasses [1].

No large isotopic shifts due to fractionation are observed in these samples. These results are in agreement with previous experimental work on chlorine isotope fractionation between coexisting vapor and liquid in the system H2O–NaCl at 400°C and 450°C which show $\Delta^{37}Cl_{vapor-liquid}$ = 0 +/- 0.2‰ [2]. However, large Cl isotope fractionation has been observed in a few high-temperature (>100°C) and highly acidic volcanic fumaroles in Central America. ^{37}Cl preferentially partitions into the vapor phase as HCl resulting in extreme positive δ^{37}Cl values (~ +4 to +12‰) in acidic geothermal systems [3]. Further work will focus on acidic Icelandic geothermal systems in which Cl^- is hosted as HCl in order to explore the full range of δ^{37}Cl values in geothermal systems.

These results show that Cl stable isotopes act as a conservative tracer in neutral to slightly basic geothermal sytems regardless of phase separation; thereby, making Cl isotopes an excellent tracer of chloride sources in neutral systems.

The Composition of the Stillwater and Bushveld Parental Magmas.

SARAH-JANE BARNES [1]* AND PHILIPPE PAGE[2]

[1] Universite du Quebec a Chicoutimi, Canada sjbarnes@uqac.ca
[2] Universite du Quebec a Chicoutimi, Canada ppage@uqac.ca

The Bushveld and Stillwater Complexes contain most of the world's platinum-group element resources and it has long been recognized that their cumulate stratigraphies show similarites, which suggests that the magmas they formed from were similar with respect to major element compositions. At both localities a magma rich in SiO_2 and MgO is needed to produced the orthopyroxene rich lower parts of the intrusions. Chill margins with the composition of Mg-rich basaltic andesite are present at both localities (the B-1 and Gp-3 chills). To produce the gabbroic middle zones of the intrusions, melts close to tholetiitic basalt composition are required. Chills with these compositions are found at both intrusions (B-2 and Gp-1 chills). Recent studies on Bushveld have provided information on the trace element content of the Bushveld magmas and cumulates indicating that the magmas were strongly enriched in LILE and LREE (Fig. 1). We have determined the trace element content of the equivalent magmas from Stillwater and they are poorer in LILE and LREE. The Mg-rich andesite (Gp-3) are closer to boninite compositions than the Busheld B-1 rocks. The tholeiitic basalt (Gp-1) show some similarities to arc tholeiites.

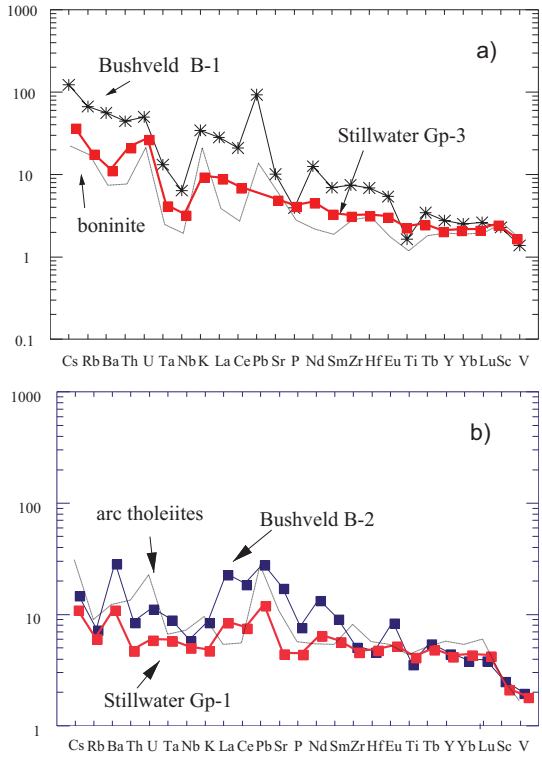

Fig. 1 Mantle normalized incompatible element plot of the marginal rocks of the Bushveld and Stillwater compared with modern magmas

Lead Isotopic bias during the *Chaîne Opératoire* of Non Ferrous metal: Implications for Provenance Studies

S. BARON[1*], C.G. TAMAS[2] AND B. CAUUET[3]

[1]CNRS, Toulouse, France, sbaron@univ-tlse2.fr (* presenting author)
[2]University Babes-Bolyai, calingtamas@yahoo.fr
[3]CNRS, Toulouse, France, cauuetb@aol.com

Introduction

The rise of the high resolution mass spectrometers (MC-ICP-MS) during the last ten years allows the analyses of traditional and non traditional isotopes to be more accurate, precise, relevant and consequently subtly interpretable [*e.g.* 1, 2]. The lead isotopic tracing, from mines/ore bodies to archaeological materials, constitutes the main tool of metal provenance studies. Despite the use of high-resolution isotopic measurements, the identification of the geographical ores source is difficult because of several factors. The most important factor is inherent to the ores themselves: *i)* the ores could have lead isotopic heterogeneity in a same ore body and *ii)* numerous different geographical mining districts could have same lead isotopic compositions. Furthermore, the ores are disconnected of any geological, archaeological and historical significance in respect with the metal provenance study. When the archaeological materials are well documented by mining archaeology and history, the provenance studies (coupled with high resolution measurements) are improved [3]. Another factor, rarely taken into account, is the possible lead isotopic bias during the metallurgical processes. Because the isotopic tracing is directly operated from ores to object at global scale, the consequence is that the *chaîne opératoire* is not taken into account. But, during the *chaîne opératoire*, numerous human operations occurred. Some archaeological experiments conducted on ores reduction have measured isotopic bias between ores / metal of slags and metal of slags / slags silicated matrix at furnace scale [4]. Through two regional studies, conducted on materials well documented by mining archaeology and history, we found isotopic bias due to the local *chaîne opératoire*. These results corroborate the previous experimental ones.

Results and discussions

We will present here the results from two *chaîne opératoire* well documented by mining archaeology: *i)* the lead-silver one in France for medieval time and ii) the gold-silver one in Romania for roman time. We will demonstrate here that the addings during the metallurgical processes produce lead isotopic bias. According the high-resolution isotopic measurement available today, it is necessary to take into account these biases in order to refine the tracing and understand the *chaîne opératoire* in its historical context. This approach will allow the understanding of regional management of ore sources in ancient times. It constitutes the first step before the beginning of a metal diffusion at global scale.

Mercury stable isotopes in fish tissue as indicators of photochemical transformations

GIDEON BARTOV[1*], THOMAS M. JOHNSON[1]

[1]University of Illinois Urbana-Champaign, Urbana, USA, (*gbartov2@illinois.edu)

During the 1950s and 1960s, the U.S Department of Energy (DOE) plant Y-12, near Oak Ridge, TN, was using Hg in the production of thermonuclear weapons. During normal plant operations, large amounts of Hg were discharged into the East Fork Poplar Creek (EFPC) and its floodplain [1]. Current research aims to better understand Hg transformations that control its mobility and bioavailability.

Hg isotopes have the potential to identify and perhaps quantify certain biogeochemical reactions. Photo-reduction and -demethylation have been shown to fractionate the odd isotopes of Hg (^{199}Hg and ^{201}Hg), independent of their mass, due to the magnetic isotope effect [2]. Fish are assumed to be good integrators of bioavailable Hg over space and time and do not change the mass independent fractionation signature of the odd Hg isotopes. As a result, it is possible to use fish as indicators of photochemical reactions occurring in the water column. According to Bergquist and Blum [2], photoreduction of $Hg(II)_{(aq)}$ creates a slope, on a Δ^{199}Hg vs. Δ^{201}Hg graph, of 1.00±0.02, methyl-Hg (MeHg) photoreduction has a slope of 1.36±0.02, and fish tissue plots on a 1.28±0.03.

Our study aims to detect and quantify Hg chemical transformations in the EFPC. Frozen fish tissues received from Oak Ridge National Laboratory were digested and analyzed on a Nu Instruments MC-ICP-MS using the Mead and Johnson [3] double-spike technique. The ^{202}Hg/^{198}Hg ratio (reported as δ^{202}Hg) was measured with a precision of ~0.11‰ relative to the NIST SRM 3133 Hg standard. Odd isotope deviations were measured with a precision of ~0.04‰ and are reported as Δ^{199}Hg and Δ^{201}Hg deviations from theoretical mass dependent fractionation values.

The δ^{202}Hg of the fish shows a weak increase increasing distance downstream from Y-12, from -0.57±0.08‰ (n=4) upstream to -0.29±0.15‰ (n=4) downstream. The odd isotope deviations also show a slight positive trend with increasing distance downstream from Y-12 (shifting Δ^{201}Hg from -0.05±0.04‰ to 0.05±0.04‰ and Δ^{199}Hg from -0.04±0.07‰ to 0.09±0.05‰). The slope of the data is 1.3, consistent with the slope obtained for photochemical demethylation by Bergquist and Blum [2]. Based on equations given by Bergquist and Blum [2], we can calculate, to first order, the amount of photoreduction of MeHg in the water between 4-11% using the Δ^{201}Hg values.

Fish are a good proxy for the extent of photoreduction of Hg in the water column; however, it would be beneficial to look directly at the Hg present in the water, the reactant pool. Therefore, water samples from the EFPC have been obtained and will be analyzed.

Bottom Water Changes in the South Pacific Over the Last 30 ka Documented by Nd Isotopes

CHANDRANATH BASAK[1, 2]*, KATHARINA PAHNKE [1,2]

[1]Max Planck Institute for Marine Microbiology, Bremen, Germany *(cbasak@mpi-bremen.de)

[2]Institute for Chemistry and Biology of the Marine Environment (ICBM), Oldenburg, Germany

North Atlantic Deep water (NADW) and the Antarctic Bottom water (AABW) are the two central supporting pillars that control deep ocean ventilation and influence atmoshperic CO_2 concentrations on glacial-interglacial timescales. While much is known about past NADW changes, very little is known about variations in AABW formation and export from the Southern Ocean. Available paleo-records point at enhanced northward advection of southern sourced deep water during times of reduced NADW formation [1]. It is, however, not clear whether the observed presence of AABW in the North Atlantic is due to increased southern sourced deep water production or related to reduced NADW formation. In this study we used paleo seawater Nd isotope ratios to address the AABW formation history in the Pacific Southern Ocean for the last 30 ka.

Our study site is located in the eastern Pacific sector of the Southern Ocean [PS58/271-1; 61.24°S, 116.05°W, 5214m water depth; [2]]. Currently this site is bathed by AABW with contributions from Circumpolar Deep Water and Pacific Deep Water, and is located at the Polar Front. The Ross Sea is the nearest deep water formation area and the prsent-day northern limit of 'pure' Ross Sea bottom water (RSBW; defined by high salinity and density) reaches just south of our site. Thus, during times of enhanced deep water formation in the Ross Sea, RSBW would be expected to have reached the study site. Since RSBW carries the characteristic Nd isotope signal of Ross Sea sediments (ε_{Nd} = -7; [3]), any northward expansion of RSBW should be recorded in the sediments at our core site. The Late Holocene ε_{Nd} value (ε_{Nd} = - 6.2) at our study site is consistent with the influence of RSBW and CDW/PDW at the core site. The downcore ε_{Nd} record shows that the study site was bathed by a water mass with an Nd isotopic composition of (ε_{Nd} =) ~ -5.5 during the last glacial maximum (LGM). The ε_{Nd} value of the water mass gradaully started to change towards more Pacific deep water-like values (ε_{Nd} = -3) with the initiation of deglaciation around 18 ka BP. Strong Pacific deep water influence is observed at around 15.3 ka, followed by a gradaul decrease to the Late Holocene value (ε_{Nd} = -6.2). The time of maximum ε_{Nd} around 15.3 ka coincides with warming in the Southern Hemisphere and corresponding cooling and shut down of NADW in the Northern Hemispere. Our data do not support increased RSBW/AABW formation at this time, rather, we observe enhanced influence of Pacific deep water. If this holds true for the entire Southern Ocean, the observed presence of AABW in the deep North Atlantic has to be explained by reduced NADW production.

Toward an understanding of metal uptake in a methanogenic archaeon isolated from the Rancho La Brea Tar Pits

JENNA L. BASS[1], ELIZABETH L. EDWARDS[1], ALEXIS LLOYD[1], SARA J. WEAVER[1] AND JOHN S. MAGYAR[1*]

[1]Department of Chemistry, Barnard College, New York, NY 10027, USA jmagyar@barnard.edu (* presenting author)

Recalcitrant petroleum sources, such as heavy oil, oil sands, and asphalts, are an increasingly important part of the global petroleum supply. In situ conversion of these materials to methane would have significant environmental and economic advantages over current mining and extraction methods, but significant fundamental research on anaerobic methanogenic petroleum degradation is required before such approaches will become practical. Understanding the bioinorganic chemistry of such processes is essential to an overall understanding of methanogenesis, which requires a series of metallocofactors. Of these, several key proteins are nickel-binding proteins, including the hydrogenases. We are investigating mechanisms of nickel uptake in *Methanocorpusculum labreanum*, a methanogen isolated from natural asphalt sediments in the La Brea Tar Pits, Los Angeles. We have isolated a gene for a putative metalloregulatory protein from genomic DNA, cloned it into *E. coli*, and overexpressed and purified the resulting protein. Using a variety of spectroscopic methods, including UV-vis-NIR absorption, fluorescence, and circular dichroism spectroscopies, we are characterizing the coordination chemistry and structure of this protein. We have identified the presence of both flavins and iron-sulfur clusters, and work is currently underway to elucidate the structure and binding of these cofactors and the role they may play in regulating cellular nickel uptake.

Microbial uranium reduction monitoring: Linking isotopic fractionation factors with microbial metabolism

ANIRBAN BASU*, THOMAS M. JOHNSON, ROBERT SANFORD, AND CRAIG C. LUNDSTROM

Department of Geology, University of Illinois at Urbana-Champaign, Urbana, IL, USA, abasu3@illinois.edu (* presenting author), tmjohnsn@illinois.edu, rsanford@illinois.edu, lundstro@illinois.edu

Microbial reduction of soluble and mobile U(VI) to sparingly soluble U(IV) is a promising remediation strategy for uranium-contaminated aquifers. A wide range of microorganisms with diverse metabolic pathways can reduce U(VI) to U(IV). Microbial U(VI) reduction fractionates U isotopes; heavier isotopes partition in the solid U(IV) products. The remaining U(VI) pool becomes isotopically lighter with progressive reaction. The isotopic enrichment is quantified by measuring $^{238}U/^{235}U$ ratio in the remaining unreacted pool of U(VI) and the magnitude of the isotopic enrichment is expressed by the isotopic fractionation factor ε ($\varepsilon=1000*(\alpha-1)$; $\alpha = (^{238}U/^{235}U)_{Product}/(^{238}U/^{235}U)_{Reactant}$). The isotopic enrichment is related to the extent of reduction by the fractionation factor ε. $^{238}U/^{235}U$ ratios can be used to detect and possibly quantify U(VI) reduction, if the ε for the relevant microbial reductions are known.

Here we report ε values for U(VI) reduction by two strains of *Geobacter sulfurreducens* (PCA and Criddle), *Anaeromyxobacter dehalogenans* strain FRCW, *A. dehalogenans* strain FRC-R5, and *Desulfitobacterium* Viet1. For each bacterial species, we measured the ε values in duplicate batch incubation experiments with U(VI) and 0.5 mM electron-donor at 30 °C.

All strains tested in this study induced significant isotopic fractionation during U(VI) reduction. The ε yielded by *Geobacter sulfurreducens* strains PCA and Criddle were 0.68‰ and 0.95‰, respectively. The ε values for *A. dehalogenans* strain FRCW, *A. dehalogenans* strain FRC-R5, and *Desulfitobacterium* Viet1 were 0.75‰, 0.98‰, and 0.84‰, respectively. The results of this study indicate that the ε does vary with microbial metabolism. We observed an increasing trend in ε with decreasing cell-specific reduction rate. Our results suggest that cell-specific reduction rates are good indicators of the magnitude of microbial U isotopic fractionation. The ε tends to reach highest values (~1‰) under nutrient limited electron-donor poor conditions. Our results shed light on the fundamental relationship between metabolism and isotopic fractionation and will be useful to detect and possibly quantify U(VI) reductions in the sites undergoing active bioremediation.

Progress in detrital garnet Sm-Nd geochronology: the second point on the isochron

E.F. BAXTER , K.A. ECCLES, N.C. SULLIVAN

Boston University, Department of Earth Sciences, Boston, MA, 02215 U.S.A, (*correspondence: efb@bu.edu)

Detrital minerals in the sedimentary record provide valuable information about the tectonic evolution of the Earth. Detrital garnets also preserve a chemical record of tectonometamorphic processes, conditions and provenance [1] that may not necessarily be recorded by other commonly dated detrital minerals. Detrital garnets could therefore form a valuable and complimentary tool in detrital analysis of ancient tectonic processes and provenance. Here, we describe recent advances beyond previous attempts to date detrital garnets [2,3] and illuminate the current possibilities and limitations.

Two challenges must be overcome. First, is the sample size limitation which is solved through use of NdO^+ TIMS analysis with Ta_2O_5 activator [3,4]. This small sample capability provides an opportunity for geochronology on single >500 um grains or equivalent multi-grain separates. Second, a detrital garnet grain is no longer associated with the parent rock from which it crystallized. Thus there is no obvious second point to constrain an isochron. Here, detrital garnets may be crushed and treated with acids (including HF) to partially dissolve and analyze mineral inclusions which should in most cases adequately represent the original garnet host assemblage. But, well established methods for conventional garnet geochronology demonstrate that the garnet's inclusions often fall off the garnet-matrix isochron [5], and thus these inclusions are typically removed and discarded. Fortunately, in the detrital garnet application, the magnitude of the "age effect" related to the use of inclusions as the second point on the isochron (rather than the matrix) is small; generally less than a few million years which is an acceptable tolerance for most detrital geochronologic studies. Only if inherited zircons, which themselves can have high Sm/Nd ratios, represent a dominant part of the inclusion population could the detrital garnet age be skewed more significantly.

Test garnets extracted from New England (USA) sediments have been dated with this approach, yielding Acadian ages (as expected) with age uncertainty as low as ±4 Myrs on single grains as small as 3mg (or about 1.5mm diameter). $^{147}Sm/^{144}Nd$ ratios as high as 2.4 in cleansed garnet reflect success in separating inclusions from garnet via partial dissolution. Our data show a correlation with apparent isochron age and spread in $^{147}Sm/^{144}Nd$. The larger the spread between the two points in the isochron, the younger and more accurate the age. With our test samples, we have found that $^{147}Sm/^{144}Nd$ spread greater than 0.5 is necessary to produce accurate ages. Samples which yield less spread are too old, reflecting incomplete separation of garnet from inherited inclusions.

[2]University of Calgary, Geoscience, Canada
[3]McMaster University, Geography and Earth Sciences, Canada
[4]Mongolian University of Science and Technology, Hydrogeology and Environmental Geology, Mongolia
[5]Korea Environment Institute, South Korea

In Ulaanbaatar City (UB), Mongolia, significant population growth (currently, ~1.2 million) and rapid industrialization over the last two decades resulted in diverse environmental problems including a shortage and contamination of the water supply. Municipal water supply in UB depends on groundwater withdrawn from an alluvial aquifer located along the Tuul River. There are also many private wells completed in variable depths. Groundwater in UB has become increasingly polluted because of a deficient municipal sewer system, illegal waste dumping, air and soil pollution, and deforestation of surrounding areas. To our knowledge, there is no detailed survey that has assessed the status of groundwater quality in UB. Therefore, we have performed a hydrogeochemical survey including hydrochemical and multiple isotopic (i.e., $\delta^{13}C$ of dissolved inorganic carbon, $\delta^{15}N$ and $\delta^{18}O$ of nitrate, and $\delta^{34}S$ and $\delta^{18}O$ of sulfate) measurements on 45 groundwater, 4 surface water and 2 spring water samples collected in July 2011. The obtained data were interpreted in relation to land use patterns, which include the urban center, peripheral residential areas with dense traditional homes, grasslands, and forests.

Our results show the occurrence of three major hydrochemical types: 1) Ca-HCO_3 type, 2) Ca(-Na)-HCO_3-Cl(-NO_3) type, and 3) Ca-Na-HCO_3 type. The spatial distribution of different water types is controlled by land use. Types 1 and 3 occur under forest and grassland areas and are representative of unpolluted or less-contaminated groundwater. On the other hand, type 2 occurs predominantly in urbanized areas and shows progressive enrichments of groundwater with Cl+NO_3 (and NO_2)+SO_4 with increasing TDS, due to anthropogenic impact from latrines and domestic sewage. Nitrate contamination especially in the city center and peripheral residential areas is pervasive and severe resulting in NO_3^- concentrations of up to ~290 mg/L. The $\delta^{15}N$ and $\delta^{18}O$ values of nitrate suggest that in the city center and peripheral residential areas, latrines and domestic sewage are major sources of the severe nitrate contamination. Therefore, better management of latrines and sewage systems is urgently needed in UB. Our study also shows that groundwater contamination in UB is linked to the progressive population growth and city expansion.

Intensifying weathering and land-use in Iron Age Central Africa

GERMAIN BAYON[1]*, BERNARD DENNIELOU[1], JOËL ETOUBLEAU[1], EMMANUEL PONZEVERA[1], SAMUEL TOUCANNE[1], SYLVAIN BERMELL[1]

[1]IFREMER, Géosciences Marines, Plouzané, France gbayon@ifremer.fr (* presenting author)

A major vegetation change occurred in Central Africa during the third millennium before present, when mature evergreen trees were abruptly replaced by savannas and secondary grasslands [1-3]. The consensus is that the forest disturbance was caused by a regional climate change [1-3]. However, this episode of forest clearance occurred contemporaneously with the migration of Bantu-speaking peoples from near the modern Nigeria-Cameroon border [4-7]. The so-called Bantu expansion led to diffusion of agriculture and iron smelting technology across Central Africa, with potential impacts on the environment [10]. Whether the Bantu farmers played an active role in the Central African deforestation event remains an open question.

Here we present major element (Al/K ratios) and radiogenic isotope (Nd, Hf) records from a marine sediment core recovered in the Gulf of Guinea, that permit the reconstruction of chemical weathering intensity in Central Africa for about the last 40,000 years. The data indicate a pulse of intensified weathering centered around 2,500 years ago, contemporaneous with the rainforest crisis. Evidence that this weathering event departs significantly from the long-term weathering fluctuations related to the Late Quaternary climate suggests that it was not triggered by natural climatic factors solely. Instead, we propose that the settlement of Bantu-speaking farmers in Central Africa at that time had a more pronounced environmental impact than initially thought.

Rock micro-structure controls regolith thickness

E. BAZILEVSKAYA[1]*, M. LEBEDEVA[1], G. ROTHER[2], M. PAVICH[3], D. PARKINSON[4], D. COLE[5] AND S.L. BRANTLEY[1]

As feldspar transforms to clay, a zone of residual weathered material, regolith, forms on ridges of diabase and granite in the Piedmont Province, Virginia. In spite of similar erosion rates and the fact that Ca-rich plagioclase in diabase is expected to dissolve 10x faster, weathering has advanced 20x deeper into the granite compared to the diabase. This result runs counter to conventional wisdom that would predict a deeper weathering profile on the diabase. We explained this enigma by studying the nano- to micro-structural features of these two rocks in plagioclase reaction zone. Nano-pores (1 nm < d < ~5 μm) and micro-pores (> 3 μm) were studied by neutron scattering (NS) and micro-computed tomography (μ-CT), respectively. We found that granite has a larger connected micron-sized pore network than diabase as well as abundant micro-fractures around oxidizing biotite. In contrast, the plagioclase reaction zone in diabase has some regions of low porosity due to smectite and calcite precipitation. Therefore, we concluded that the regolith is 20x thinner on diabase because it supports only minimal fluid advection, while advective transport in granite is significant.

We explored this hypothesis with numerical modelling of plagioclase dissolution in diabase and granite. For diabase, the diffusion-only model yields shallow regolith with a thin reaction front -- as observed in the field. However, we could not model a deeper and thicker reaction front in granite with diffusion only. With advection in the numerical model, the reaction front in granite is wide and the regolith is deep, as observed.

Our results show that the difference in regolith thicknesses in the Piedmont is largely explained by different regimes of reactive fluid transport. Minimal advection creates shallow regolith and a thin reaction front in the more massive diabase. In contrast, significant advection occurred in the relatively fractured granite, producing deep regolith and a thick reaction front. At the grain-scale, infiltration of advecting fluid is controlled by texture (e.g., grain size distribution, porosity) and reaction-induced permeability. The parent lithology is an important factor in this latter permeability because oxidation of biotite at depth apparently accelerated pervasive fluid infiltration into the granite. If micro-structure is important in controlling the factor of 20x, then it is possible that felsic rocks such as granites generally develop thicker regolith profiles than diabase, regardless of age or location, under comparable geomorphological regimes. Such observations may help predict and explain regolith thickness in localities in many places around the globe.

Identifying Key Controls on the Behavior of an Acidic-U(VI) Plume at the Savannah River Site using Reactive Transport Modeling

S.A. BEA[1*], H. WAINWRIGHT[1], N. SPYCHER[1], S. HUBBARD[1], AND J. DAVIS[1]

[1]Lawrence Berkeley National Lab., Berkeley, CA, 94720 USA, sabea@lbl.gov (*presenting author)

Acidic waste solutions containing low level radioactivity from numerous isotopes were discharged to a series of unlined seepage basins at the F-Area of the Savannah River Site, South Carolina, from 1955 through 1989. Although the site has gone through many years of active remediation, the groundwater remains acidic, and the concentrations of U(VI) and other radionuclides are still significant. Monitored Natural Attenuation (MNA) is a desired closure strategy for the site, based on the premise that clean background groundwater will eventually neutralize the groundwater acidity, causing an increase in pH and driving natural immobilization of U(VI) through sorption. The development of the understanding of the long-term pH and U(VI) sorption behavior at the site is critical to assess MNA and in-situ treatment over the long term.

We use reactive transport (RT) models and uncertainty quantification (UQ) to explore key controls on the U(VI)-plume evolution and long-term mobility at this site through considering U(VI) adsorption by sediments and key hydrodynamic processes. Two-dimensional RT simulations through the saturated and vadose zones were conducted by considering the dissolution and precipitation of Al and Fe minerals, as well as H^+ and U(VI) surface complexation. Simulations indicate that mineral dissolution and precipitation together with sorption reactions on goethite and kaolinite (primary minerals present with quartz) could buffer pH at the site for long periods of time.

UQ techniques were applied with RT modeling in order to: (1) identify the complex physical and geochemical processes that control the migration of the acidic-U(VI) plume in the pH range where it is highly mobile, (2) evaluate those physical and geochemical parameters that are most controlling, and 3) attempt to predict the future plume evolution constrained by historical chemical and hydrological data. UQ-RT results show that model results are most sensitive to the reactive surface area available for sorption, discharge rates, the relative rates of H^+ influx and kaolinite dissolution. The plume behaviour also appears to be sensitive to parameters controlling the amount of residual U(VI) in the vadose zone, which acts as a buffering zone in the modeled system.

Iron isotope fractionation during femtosecond laser ablation of magnetite determined by aerosol size sorting experiments

[3] Univ. Wisconsin, Dept. of Civil and Environmental Engineering, Madison WI, USA, jjschauer@wisc.edu

Aerosol particles generated from femtosecond laser ablation (fs-LA; 198nm laser manufactured by Photon Machines) of natural magnetite were size sorted using a Micro-Orifice Uniform-Deposit Impactor (MOUDI). The MOUDI separates particles by size based on aerodynamic properites using 10 stages. Aerosols were collected using fluences of 1, 2, and 4 J/cm^2 and there is a positive correlation between total Fe collected per laser shot; 25, 50, and 100 picograms of Fe per laser shot were harvested from the impactor, respectively. The aerosol size distribution of the fs-LA generated particles were determined by analyzing Fe concentration for each stage of the impactor using ^{57}Fe isotope dilition mass spectrometry (~10^5 laser shots) or spectroscopically via the ferrozine technique (~10^6 laser shots). The size distribution of aerosol particles done at different fluences are the same; all are unimodal with a peak at an aerodynamic size between 180 to 320 nm.

Sized aerosol particles have been analyzed for their Fe isotope composition. The smallest sized particles have δ^{56}Fe values that are less than the magnetite substrate by 0.5‰, whereas larger sized particles (≥180–320 nm stage) have δ^{56}Fe values that were up to +0.7‰ greater than the magnetite substrate. There are no differences in isotope compositions as a function of fluence. In all experiments, the integrated Fe isotope composition of all the stages matches that of the magnetite substrate. This isotopic mass balance highlights that although the process of fs-LA produces Fe isotope fractionation, if the generated aerosol is quantitatively delivered and ionized, one can obtain accurate Fe isotope measurements. Indeed, for sample-standard comparisons, accuracy of Fe isotope compositions will hinge on having similar transport efficiencies spatially in the ablation cell. For example, if 12% of the particles ≥ 180–320 nm in aerodynamic size are not transported to the ICP source, and these particles consist of 70% of the total Fe mass with δ^{56}Fe values that are 0.7‰ greater than the bulk substrate, the measured Fe isotope composition would be inaccurate by -0.1‰. This can easily be monitored, however, by comparing Fe yields derived by total ion signal. Using the above example, there would be a ~9% decrease in the total Fe ion signal.

The correlation between Fe isotope composition and particle size may result from condensation wherein the first condensed particles from fs-LA generated vapor have low δ^{56}Fe values. As condensation continued and some particles coarsened, they inherited higher δ^{56}Fe values from the isotopically heavy vapor.

Clay-rock alteration experiments at 80°C in closed and open conditions: application to the waste storage

CATHERINE BEAUCAIRE[1*], EMMANUEL TERTRE[2], ERIC FERRAGE[2], BERNARD GRENUT[1], STEPHANE PRONIER[2] AND BENOIT MADÉ[3]

[1]CEA, DEN/DANS/DPC/SECR/L3MR, Gif-sur-Yvette, France, catherine.beaucaire@cea.fr

[2]Université de Poitiers-CNRS, IC2MP UMR 7285, Poitiers, France, emmanuel.tertre@univ-poitiers.fr

[3]ANDRA, Chatenay-Malabry, France, benoit.made@andra.fr

In the framework of radioactive waste storage in geological formations, many investigations were carried out to characterize chemical properties of pore water at the field temperature (*e.g.*, 20°C). However, few studies were devoted to the modifications that temperature could induce on the chemical composition of pore water in the host-rock. Among the chemical parameters which are sensitive to temperature, the pH and $CO_{2(g)}$ partial pressure (*i.e.*, $p_{CO2(g)}$) are likely the most sensitive. These latter parameters could also strongly impact the mobility of radionuclides in geosphere. Under thermal gradient, many reactions would occur such as minerals dissolution-recrystallisation or organic matter degradation. The knowledge of geothermal systems in sedimentary contexts tends to prove that whatever the mineral or/and organic contribution, $p_{CO2(g)}$ is likely constrained by a mineralogical buffer combining carbonate mineral (calcite, dolomite), quartz or chalcedony and alumina-silicate phases (kaolinite, illite or Mg-chlorite) [1]. Hydrothermal alteration experiments were carried out with Callovo-Oxfordian clay-rock with the aim of characterizing the ultimate step of thermal alteration at 80°C, which is the temperature expected in the waste storage.

The experiments were performed in both open and closed systems where initial $p_{CO2(g)}$ values were fixed (*e.g.*, $p_{CO2(g)}$=0.4 atm.). High solid/solution ratios (1 to 3 kg/L) are chosen in order to favour neoformation of secondary mineral phases. Aqueous and gas phases were regularly extracted at temperature and fully analyzed. The evolution of clay mineralogy was also characterized using X-ray diffraction profile modeling of experimental patterns and Transmission Electron Microscopy. Then, results obtained for solution as well as for solids were interpreted and discussed in term of thermodynamic equilibrium achievement.

After 15 months of alteration in closed conditions at 80°C, the $p_{CO2(g)}$ is stabilized at 1 atm. and final solution is equilibrated with respect to quartz, kaolinite, calcite and ordered-dolomite. Modeling of experimental X-ray diffraction patterns [2] evidenced a slight increase of the illitic layers content in mixed-layer minerals (*i.e.*, 5%). However, it is not possible to conclude to illite neoformation. Consequently, in absence of equilibrium with a secondary Al-Si mineral phase which would participate to the complete mineralogical buffer, the constrain on $CO_{2(g)}$ is not evidenced in these experimental conditions. Other experiments devoted for determining reaction pathways are currently in progress.

kcochran@notes.cc.sunysb.edu

It is not clear if the strontium (Sr) isotope budget of the modern ocean is at steady state [1]. It has been hypothesized that submarine groundwater discharge (SGD) is an important Sr source to the ocean [2], but few data exist for Sr in coastal groundwater or in the geochemically-dynamic subterranean estuary (STE). We examined Sr concentrations and isotope ratios from 9 globally-distributed coastal sites, and examined the behavior of Sr in the STE.

Dissolved Sr generally exhibited conservative mixing behavior in the STE, although large differences were observed in the meteoric groundwater endmember among sites (0.1 – 24 μM Sr). Differences in groundwater Sr concentrations and isotope ratios ($^{87/86}$Sr = 0.707-0.710) reflected aquifer lithology characteristics. In part, because groundwater Sr concentrations are orders of magnitude higher in less-radiogenic carbonate and volcanic island aquifers, the SGD endmember Sr ratio must be lower than modern seawater (i.e., less than 0.70916). A simple lithological model was used to estimate a global average groundwater endmember of 2.9 μM Sr with $^{87/86}$Sr = 0.7089, representing a meteoric-SGD-driven Sr input to the ocean of 0.7-2.8 × 10^{10} mol Sr a^{-1}. Meteoric SGD therefore accounts for 2-8% of the oceanic Sr isotope budget, comparable to other known source terms, but insufficient to balance the remaining budget.

Sr isotope exchange was observed in the STE at five of the sites studied, invariably favored the meteoric groundwater endmember signature, and reached up to 40% exchange at salinity 10. Using reported estimates for brackish SGD, the estimated volume discharge at salinity 10 (7-11 × 10^{15} L a^{-1}) was used to evaluate the impact of isotope exchange in the STE on the brackish SGD Sr flux. A moderate estimate of 25% isotope exchange in the STE gives a resultant SGD Sr endmember isotope composition of 0.7091. The brackish SGD Sr flux accounts for 12-25% of the marine Sr isotope budget, and does not appear sufficient to balance some 40% of the remainder.

Substantial uncertainties remain for estimating the SGD source of Sr to the global ocean, such as the volume flux of meteoric SGD, and lacking measurements of groundwater Sr isotope composition in major SGD regions such as Papua New Guinea, the South America west coast, and West Africa. Nevertheless, the combined sources of meteoric SGD and isotope exchange in the STE are a major component of the modern oceanic Sr isotope budget, and represent a Sr source to the ocean that may have contributed to documented fluctuations in the oceanic $^{87/86}$Sr ratio over geologic time.

A major problem for the interpretation of the composition of ancient marine carbonates is the variable response of different elements to diagenesis and post-depositional fluid flow. We have studied this issue in Ediacaran dolostones, limestones and marlstones from members D1, D3 and D4 of the Doushantuo Formation (635-551 Ma) from the slope facies Panmen section (Songtao, Guizhou) on the Yangtze Platform. The carbonate rocks display a strong, but variable influence of secondary processes as indicated by $\delta^{18}O$ (-5 to -14) and $^{87}Sr/^{86}Sr$ (0.723 to 0.710) data in comparison to data of stratigraphically correlated samples from shallow platform settings [1]. Decreasing $^{87}Sr/^{86}Sr$ from bottom to top of the section and very low abundances of feldspar, illite and chlorite in some of these samples suggest that the radiogenic Sr in the carbonates was not introduced by closed-system diagenetic redistribution from silicates within the rock, but by open-system fluid flow and associated recrystallization of carbonates. In the D3 member, the overprint by fluid flow is indicated by a weak correlation of $\delta^{18}O$ with $^{87}Sr/^{86}Sr$ and correlation of $\delta^{18}O$ with $\delta^{13}C_{carb}$. Modeling of fluid-rock interaction shows that high and variable Sr abundances in water rich fluids (low-C/O) are consistent with the data trends in the D3 member, and may account for 1 to 2 ‰ of the variation in $\delta^{13}C_{carb}$. In spite of these secondary modifications, some carbonate rocks at different positions in the section display seawater signals in their acetic acid leachates, such as high Y/Ho and positive or negative Ce anomalies. Relatively high abundances of Th, REE and Pb in the acetic acid leachates and correlations of Th with Fe abundances, suggest that these elements were redistributed by fluid flow. They may have been originally hosted in Fe oxyhydroxide phases in the rock, released upon reduction and dissolution of Fe phases and incorporated into recrystallized carbonates. Further constraints were obtained from leaching experiments on cap dolostones of the section using stepwise digestion in 10% HAc, 6 M HCl and conc. HF-HNO_3. These results indicate the presence of HCl soluble Fe rich phases, presumably oxides or oxyhydroxides. The REE patterns of the HCl fraction are bell shaped and differ considerably from the patterns of acetic acid leachates. The data suggest that in many samples, fluid mobile elements, but also REE, Th and Fe have been redistributed into recrystallized carbonates. This is raising questions about the scale of postdepositional element redistribution in such sections.

Quantum-mechanical calculations on actinide sorption and reduction of sulfides and oxides

U. BECKER[1]* AND D. RENOCK[2]

[1] Dept. of Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI., USA, ubecker@umich.edu (* presenting author)

[2] Dept. of Earth Sciences, Dartmouth College, Hanover, NH., USA, Devon.J.Renock@Dartmouth.edu

The results of several recent studies are challenging the way actinide geochemists consider redox processes in the near surface environment. Such studies include: the complex chemistry of electron and spin transitions between $U^{6+} \leftrightarrow U^{5+} \leftrightarrow U^{4+}$ aqueous complexes and solids, spatially separated redox processes linked over millimeter distances by complex networks of bacterial nanowires combined with pyrite, simultaneous oxidative growth and reductive dissolution on a single hematite crystal driven by potential differences between crystal faces, sulfide oxidation mechanisms that are rate-limited by the transition from high spin O_2 to low spin O.

In order to shed light on the electron transfer between reductants (*e.g.*, hydrogen sulfides, Fe^{2+}, hydroquinones as an organic/microbial analogue), oxidants (different actinyl complexes), catalytic mineral surfaces (periodic slabs and nano-clusters of hematite, pyrite, and mackinawite, and galena), and polarizing anions (*e.g.*, carbonate, sulfate).

An example calculation is the co-adsorption of a uranyl cation and a hydroquinone on the opposite sides of a pyrite nano-cube. The interaction of the hydroquinone with the uranyl complex through the pyrite nanoparticle can be quantified/visualized in different ways: (i) by the synergistic energy of the co-adsorption of uranyl and hydroquinone on pyrite, (ii) by the amount of electron transfer to the uranyl, and (iii) by visualization of the charge distribution in different adsorbate configurations.

During the co-adsorption/reduction process, the hydroquinone becomes positive (sum of Mulliken charges = 1.12) and the uranyl with an initial charge of +2 becomes almost neutral (+0.08), indicating electron transfer of about two elemental charges towards the uranyl. This is an indication that a neutral UO_2 unit is formed, which can serve as a nucleus of UO_2 formation. In contrast, if no hydroquinone is present, only about half an elemental charge is transferred from the pyrite nanoparticle. This is an example how the hydroquinone can be used as an analogue for electron shuttling by metal-reducing bacteria through the pyrite towards the uranyl.

Another example is the co-adsorption of hydroquinone and uranyl on a mackinawite nanoparticle. While the π orbitals of the quinone interact with the postitive Fe cations, the uranyl-O comes within bond distance with the Fe on the right. Electrons can be transferred within the same orbital of the entire system (e.g, the HOMO stretches over the entire system). Interestingly, even though mackinawite is a low-spin system as a bulk mineral, the co-attack by quinone and uranyl spin-polarizes the Fe atoms along the path in a down-up-up-down pattern. This is kinetically important to accommodate the spin transition on the right from U^{6+} (no spin) to U^{4+} (two unpaired spins).

Archaean cratonic mobilism and growth on a subductionless, stagnant lid Earth

BÉDARD, J.H.[1*], Harris, L.B.[2], THURSTON, P.[3]

[3]Laurentian University, Sudbury, Canada

Igneous rocks with geochemical signatures similar to those of Phanerozoic continental or oceanic arcs are rare in the Archaean and proposed Archaean ophiolites, Atlantic-style passive margins, overprinting thrust and fold belts, blueschists, ultra high-pressure rocks, paired metamorphic belts, orogenic andesites, and subduction-zone mélanges that typify Phanerozoic orogens are rare to absent. The archetypal Archaean granite-greenstone dome-and-keel architecture has no modern analogue. Most Archaean lavas have geochemical signatures that imply evolution by assimilation-fractional crystallization, rather than the source-metasomatic signatures of Phanerozoic arcs; and trace element models imply that the felsic contaminants were generated by anatexis of typical Archaean tholeiites. Mass balance calculations imply that melting of subducted crust or fractionation of basalt cannot generate requisite volumes of TTG in the available time, and a basal/delaminated oceanic plateau melting model is preferred.

Despite the absence of evidence for Archaean subduction, many Archaean cratons have shortening fabrics and cratons contain terranes with contrasting histories that were somehow assembled. What could be a plausible driving force for compression and terrane accretion on a subductionless Earth? Cratonic mobilism in response to mantle convection currents offers a possible solution to this paradox. Once a proto-craton develops a stiff mantle keel, it would become subject to pressure from mantle currents and would drift. Immature cratons or oceanic plateaux lack deep keels and so would be static. So, contrary to conventional wisdom, we consider that Archaean cratons are not immobile nucleii along whose margins 'mobile belts' form by subduction-zone accretion. Instead, we propose that Archaean cratons were active tectonic agents, accreting basaltic plateaux, other proto-cratons, and heterogeneous mantle domains as they migrated. Overridden oceanic plateau lithosphere would form subcretion complexes where the underthrust basalt would melt to generate syntectonic pulses of tonalite-trondhjemite-granodiorite (TTG), so contributing to craton growth and stabilisation. Garnet pyroxenite restites from anatexis would founder into the mantle and trigger new pulses of tholeiitic magmatism. The non-cratonic Earth would have been covered by a mosaic of shield volcanoes, with eruption and basal attrition being in a quasi steady-state in a stagnant lid régime, suggesting that mantle convection may have been layered in the Archaean.

The Neoproterozoic Franklin Large Igneous Province, geochemical and isotopic evidence for changing sources, and linkages between intrusive and extrusive components

[7]University of Bristol, UK

The Neoproterozoic (ca.716 Ma) Franklin Large Igneous Province formed during the breakup of Rodinia. The Natkusiak continental flood basalts (≤1 km thick, preserved as 2 lobes in a syncline) are the extrusive phase of the Franklin event, and erupted onto a shallow-water continental platform. An underlying fluvial sandstone, the Kuujjua Fm., pinches out towards the NE, suggesting pre-eruptive thermal doming, possibly associated with arrival of a mantle plume. The lowermost extrusive unit (ca 50-100 m thick) is a primitive basalt (7-11 wt% MgO), and is tentatively interpreted as agglutinate (welded fire fountain deposits) erupted from multiple vents. The unit is characterized by LREE-LILE-enrichment, high L/HREE, high $^{87/86}Sr_i$ (up to 0.70791), intermediate εNd (4.0-8.1) and εHf (0.03-6.7), high $^{208/204}Pb$ (up to 39.136), high $^{207/204}Pb$ (up to 15.686), and high $^{206/204}Pb$ (up to18.978) ratios; indicating either an enriched source, extensive crustal contamination, or influx of enriched fluids from the footwall. A hiatus in eruptive activity is marked by deposition of red-weathering volcaniclastic rocks that contain matrix-supported conglomerates (lahars or damburst deposits?) that fill palaeovalleys. Two differentiation cycles of laterally extensive basaltic (10-6% MgO) sheet flows were then deposited above the basal lavas and volcaniclastics. Both cycles show upward shifts in phenocryst populations, decreases in Mg#, Cr and Ni, and increases in incompatible element concentrations, consistent with up-section fractional crystallization. Only cycle 1 sheet flow basalts are exposed in the SW. These have higher εNd (7.7-9.6), lower $^{87/86}Sr_i$ (0.70251-0.70605), higher εHf (4.1-9.7), lower $^{208/204}Pb$ (36.196-37.623), lower $^{206/204}Pb$ (16.147-17. 787), and lower $^{207/204}Pb$ (15.383-15.605) than basal basalts. The cycle 1 sheet flow basalts in the NE have trace element and isotopic trends that differ from those in the SW (c.150km separation), indicating regional-scale isotopic heterogeneity in the source and/or contaminants of these lavas. Alternatively, isotopic heterogeneities may have been enhanced during ascent through the crust in a compartmentalized feeder system.

The plumbing system that fed the lavas is dominated by sills, with localized fault-guided dykes. Two magma populations have been identified: Younger diabasic sills with trace element signatures matching the sheet flow lavas, and older sills (based on cross-cutting relationships), commonly with olivine-enriched bases, that match the basal basalts. Field, geochemical and isotopic evidence imply that steep, dyke-like feeders were sites of preferential wall rock assimilation and allowed melt to ascend between sills. On the scale of the entire magmatic system, the secular decrease in incompatible trace element concentrations, L/HREE ratios, and radiogenic isotope signatures could be interpreted as a decrease in the degree of host contamination with time. Changing magma composition could also reflect a shift from a fertile mantle source to a less enriched source, possibly associated with upwelling of asthenospheric mantle during the separation of Siberia from Laurentia.

Reference materials mapping: spatial geochemical heterogeneity characterization

L.PAUL BÉDARD[1*], GABRIELLE ROCHEFORT[2], ALEXANDRE NÉRON[3], AND KIM H. ESBENSEN[4]

[1]Sciences de la Terre, Université du Québec à Chicoutimi, Chicoutimi, QC, Canada PBedard@uqac.ca (* presenting author)
[2]Sciences de la Terre, Université du Québec à Chicoutimi, Chicoutimi, QC, Canada gabrielle.rochefort@uqac.ca
[3]Sciences de la Terre, Université du Québec à Chicoutimi, Chicoutimi, QC, Canada alexandre.neron@uqac.ca
[4]Geological Survey of Denmark and Greenland, Copenhagen, Denmark, ke@geus.dk

Reference materials (RM) are mandatory to produce high quality analytical results, and therefore must be well characterized with respect to heterogeneity. Microbeam techniques use very small sample masses, which can make representativity a difficult goal to achieve. Characterization of RM has mainly been done by computing statistics on numerous replicate determinations (microbeam and bulk samples; mg to g). Such studies do not take into account the systematic spatial relationships between determinations and may hence not necesarily arrive at a representative heterogeneity estimate. In the case of glasses (NIST-600s, GSD-1, etc.) and some pressed pellets (MASS-1, MACS-1 and MASS-3), anomalous "hot pots" can sometimes be larger than beam size, and can be clustered or segregated along a spatial trend. Such information is critical to determine optimal beam size or for locating optimal transects for calibration. Improved heterogeneity characterisations will lead to improved constraints on precision and accuracy of RM in general and specifically for microbeam RM.

A set of systematic experiments has been carried out to map RM with LA-ICP-MS and microXRF, to determine concentration variations in the widest possible field of view regimen. The first step is instrumental optimization of mapping to control instrumental drift. MicroXRF mapping of pulverized RM (precious metal bearing: WMS-1, CHR-Pt+, MASS-1 and MASS-3) were used to delineate precious metals nuggets, which are indeed present in many instances. This has been used to demonstrate that large sample masses are often necessary for many sulfide RM. Precipitated materials (such as MASS-1) are devoid of nuggets while most powdered RM showed nuggets. LA-ICP-MS mapping of glasses typically used to calibrate analysis, e.g. NIST-600 series, also show heterogeneities, especially for precious metals. Elemental maps have been computed to show visually heterogeneities and their locations. Variographic analysis has been undertaken to visualize variability as a function of the spatial scales.

Spatial information is an important contribution in characterizing many RM (glass and powders). Such information was previously difficult or expensive to acquire. Now spatially resolved geochemical data for RM are rapidly becomming easily accessible; this type of characterisation is the next step in RM characterization.

Volatile transfer from magma sources in the Taupo Volcanic Zone

FLORENCE BÉGUÉ[1], CHAD DEERING[2*], DARREN GRAVLEY[1], BEN KENNEDY[1] AND ISABELLE CHAMBEFORT[3]

[1]University of Canterbury, Christchurch, New Zealand, florence.begue@pg.canterbury.ac.nz darren.gravley@canterbury.ac.nz ben.kennedy@canterbury.ac.nz
[2]University of Wisconsin-Oshkosh, Oshkosh, USA, deeringc@uwosh.edu (* presenting author)
[3]GNS Sciences, Wairakei Research Centre, Taupo, New Zealand, i.chambefort@gns.cri.nz

The Taupo Volcanic Zone (TVZ) is a rifted arc where dominantly silicic magmatism and volcanism has evolved intimately with tectonic. Two distinct rhyolite magma types (dry-reducing and wet-oxidizing) have erupted from the central TVZ over the past ~550kyrs [1]. We measured major, trace, and volatile element concentrations (including B isotopes) in quartz-hosted melt inclusions from several large, rhyolitic eruptions representing these distinct types in an effort to: 1) determine if the magma was vapour saturated, and 2) identify disparities in the volatile contributions to the overlying hydrothermal systems. Dry magma in the upper crust may not be volatile saturated and, therefore, would contribute very little to the overlying hydrothermal system.

Melt inclusions from the dry type Ohakuri and Mamaku eruptions (~240 ka) have high chlorine values ranging from 0.25 to 0.36wt%, and show a positive correlation between chlorine, fluorine, Rb/Sr ratio and other incompatible elements, suggesting that no vapour phase was exsolved prior to eruption. In comparison, volatile data from the wet type Kaharoa eruption (~1314AD) show vapour saturation and exsolution of a volatile phase during crystallisation [2].

The combination of boron and boron isotopes is an effective tracer of the volatile contribution from slab-derived fluids. Measured B and $\delta^{11}B$ in these two different types of systems, reveal distinct signatures. The isotopic composition of the Kaharoa is homogeneous, with $\delta^{11}B$ of + 4‰, and boron contents range from 20-30 ppm. Because the Kaharoa was saturated, the boron preferentially partitions into the fluid phase ($D_B^{fluid/melt} >> 1$), which requires that a much higher bulk content of boron existed prior to eruption. The Mamaku and Ohakuri melts, on the other hand, have homogeneous boron contents around 15 ppm, but isotopic ratios ranging from – 3 to + 3‰. These two different signatures can be linked to variable contributions of fluid from the subducting slab, and we attribute this to a decrease in slab-derived fluid flux across the TVZ.

Geochemical heterogeneities and the generation of wet vs. dry rhyolites in the TVZ can be directly linked to the input of slab-derived fluids. As such, boron could potentially be a very useful tracer for volatile transfer processes where magmas are saturated. Our methodology can determine if a magmatic system is volatile saturated, and hence, could help identify areas in the upper crust where there is a maximum potential for heat transfer to the overlying geothermal system.

Great Oxidation Event: How quickly did it come and go?

A. BEKKER[1*], N. PLANAVSKY[2], C. SCOTT[3], C. PARTIN[1], B. RASMUSSEN[4]

[1]Department of Geological Sciences, University of Manitoba, Winnipeg, MB, R3T 2N2 Canada, bekker@cc.umanitoba.ca (* presenting author)
[2]Department of Earth Sciences, University of California, Riverside, CA 92521, USA, planavsky@gmail.com

[4]Department of Applied Geology, Curtin University, Kent Street, Bentley WA 6102, Australia, B.Rasmussen@curtin.edu.au

The loss of mass-independent fractionation of sulfur isotopes (MIF-S) defining the first appearance of oxygen in the atmosphere as a stable component, the so-called Great Oxidation Event (GOE), has been recently constrained between ~2.4 and 2.32 Ga. However, the texture of the pO_2 secular changes in the Late Archean to the Paleoproterozoic remains controversial and highly debated. Some authors favor a gradual rise in atmospheric oxygen starting at ca. 2.7 or 2.5 Ga and a peak at 2.1-2.0 Ga at the end of the Lomagundi positive carbon isotope excursion in seawater composition. Combining geological and geochemical constraints, we will discuss the history of atmospheric and oceanic redox conditions in the early Paleoproterozoic.

Detrital pyrite and uraninite in shallow-marine and terrestrial deposits persists until the loss of MIF-S at ca. 2.32 Ga, when sulfate evaporites first appear in the shallow-water marine record. This change indicates a rapid increase in the seawater sulfate content, at least 10 fold, to >>2 millimole level, associated with oxidation of the atmosphere-ocean system. Consistent with this rapid change, concentrations of redox-sensitive elements (e.g., Mo, Re, and U) in the ca. 2.32 Ga and younger GOE black shales are dramatically higher from those in the pre-GOE black shales. Although surface oxidation likely continued during the Lomagundi excursion, which was tied to high burial rates of organic carbon and high flux of oxygen to surface environments, evidence for this progressive rise is currently unrecognized, with the potential exception of the concentration of redox-sensitive elements in black shales.

The end of the Lomagundi excursion is associated with a sharp collapse in the surface oxidation state as reflected by an abrupt fall in seawater sulfate content, disappearance of sulfate evaporites from the rock record, and drop in concentrations of redox-sensitive elements in black shales. The surface oxidation state returned to the intermediate state between those before and during the GOE. In association with this collapse, methane flux from the ocean to the atmopshere and atmospheric methane concentrations increased, contributing to climatic stability during the Boring Billion. The end of the Lomagundi excursion at ca. 2.1-2.0 Ga and associated negative excursion in carbon isotope values of organic carbon in shales, the so-called Francevillian Event, thus reflects the collapse rather than a peak in the oxidation state of the atmosphere-ocean system.

Land use changes and mercury transfers to aquatic systems in the Brazilian Amazon

Bélanger[1*], Emilie; Lucotte[1], Marc; Oestreicher[1], Jordan; Moingt[1], Matthieu; Rozon, Christine[1]; Davidson[1,2], Robert; Grégoire[1], Benjamin,.

robertdavids@gmail.com

In the Tapajos River region of the Brazilian Amazon, mercury (Hg) contamination has become a problem to human health trough fish consumption. Hg present in the water system rises into the trophic chain and affects riparian communities. Studies have shown that recent deforestation contributes to soil mercury release trough terrigenous organic matter fluxes to the aquatic environment. Changes in sedimentation patterns have also been observed, suggesting a large-scale modification of the natural organic matter dynamics in the drainage basins. Local small-scale farmers use slash-and-burn agricultural practices, which consist in slashing and burning a patch of forest to benefit from the soil fertility enrichment caused by fire. After one or two years, soil fertility drops and another patch is slashed and burned. This dynamics creates a mosaic of different land uses: agricultural lands, pastures, secondary forest fallows and forested areas. The aim of this study was to investigate the movements of organic matter and its associated Hg in the watershed and to relate it to land use characteristics. Three watersheds were characterized by geographical system analysis and sampled for vegetation (20 species), soils (33 cores), suspended particulate matter (6 stations) and sediment cores (3, one in each aquatic system). All samples were analyzed for total Hg, lignin biomarkers, C, N and Pb^{210} datation was performed on sediment cores. TOM signatures were elaborated for the different land uses and followed from the terrestrial environments to the aquatic systems. Our results show an increase of TOM and mercury concentrations in recent sediments, with maximum values ranging up to 310 ng/g, concomitant to land use changes and altered watershed characteristics. These findings on the newly colonized watersheds of the Amazon can help to establish the dynamic portrait of Hg movements, leading to the development of conservation measures adapted to this environment.

Introduction

Planting fast growing trees on abandoned agricultural land (afforestation) is done all over the world as a means to satisfy increasing wood demand. However, similar to modern agriculture, increased nutrient uptake due to fast growth and nutrient export from harvest could lead to a decrease in soil nutrient availability and the increased use of fertilizer to maintain soil productivity. Recent research suggests that some tree species, notably late succession conifers, release acid exudates from their roots which attack the crystal lattice of minerals. This releases substantial amounts of base nutrients (Ca, Mg, K) which could sustain productivity over several rotations without fertilization. A sequential extraction/leaching procedure with diluted salt and weak acid solutions was therefore used to evaluate if available and structural base nutrients and other major cations (Na, Al, Fe) in soils were being depleted along a soil productivity (and age) gradient of hybrid *Populus*, a fast growing early succession deciduous tree genera used worldwide in an intensive plantation context, relative to abandoned agricultural fields.

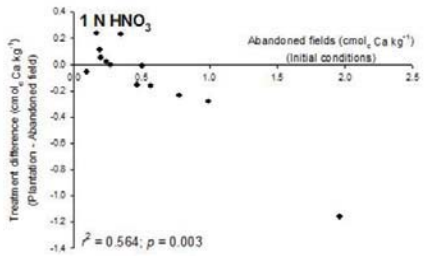

Figure 1. Relationship between abandoned fields and treatment difference for soil Ca following 1 N HNO_3 extraction.

Results and Conclusion

Soil structural Ca and Mg were lower under *Populus* at about half of the sites. The results suggest a greater capacity of the trees to promote soil mineral weathering than plants in abandoned fields. However, this ability appears to be linked to the initial chemical and mineralogical composition of the soils: the divergence between land use types was larger at sites with greater soil cation exchange capacity (more clay) and (or) structural Ca and Mg (more easily weathered Ca and Mg containing minerals) (Fig. 1). This means that fast growing *Populus* may only be capable of augmenting soil mineral weathering where soils are vulnerable to acid exudates. Hybrid *Populus* are not able to promote base nutrient release from minerals on coarse textured acidic soils where soil productivity is a real concern.

High-iron chamosite in bituminous coals in Xuanwei County, China: a possible contributing factor to a high lung cancer rate

HARVEY E. BELKIN[1*], AND JAMES C. HOWER[2]

[1]U.S. Geological Survey, Reston, USA, hbelkin@usgs.gov (* presenting author)
[2]University of Kentucky Center for Applied Energy Research, Lexington, USA, james.hower@uky.edu

Certain communes in Xuanwei County, eastern Yunnan Province, have some of the highest rates of lung cancer mortality in China. Nationwide, age-adjusted mortality rates (per 100,000) are 6.8 and 3.2 for Chinese males and females, respectively [1]. With rates for Yunnan Province 4.3 and 1.5. In Xuanwei County, the rates are 27.7 for males and 25.3 for females and in the three communes with the highest mortality, the rates are males 118.0 and females 125.6 [1]. This exceptionally high rate and the similarity between the male and female rates is unusual as the females in this locality are essentially non-smokers. Previous workers attributed the high incidence of Xuanwei County lung cancer to domestic combustion of locally mined coal in houses with non-vented stoves [2]; however, this practice occurs in many Provinces without the effect of a high lung cancer rate. Generation of polycyclic aromatic hydrocarbons (PAHs) by coal combustion was first thought to be the disease etiology [1]. Additional work on coal mineralogy and combustion models suggested that small (<10 μm) to nanometer-sized quartz played a significant role in the disease etiology and that the combined influence of silica-volatile (PAHs) interaction was more hazardous and causal than either component alone [3].

We have examined 12 smoky bituminous coals from mines in communes with various degrees of age-adjusted lung cancer death rate as well as smokeless anthracite coals from mines southwest of Xuanwei City. We find no significant relationship between overall coal characteristics and the lung cancer rate with the exception of the iron content of the coal (expressed as Fe_2O_3 on an ash-basis). The abundance of very iron-rich chamosite [(Fe/(Fe+Mg)) > 0.85] is the source of this iron enrichment (iron sulfides and oxides are rare).

Although iron is critical for normal cell function, because of its ability to reduce oxygen, iron is the most potent inducer of free radicals in most biological systems. Recent work on the cause of coal workers' pneumoconiosis suggests a strong correlation with the bioavailable iron content of coal [4]. We suggest that during domestic coal combustion, chamosite is thermally decomposed and may supply minute iron oxides to the coal smoke. Although our statistical basis is small (n = 12) the presence of this high-iron phase may add to the combined influence of PAHs and silica and should be considered as a potential contributing factor to the high lung cancer rate.

The Effects of Dissolved Chloride on the $Fe^{3+}/\sum Fe$ of Rhyodacitic Melt

AARON S. BELL*[1], JAMES WEBSTER[2], & M. DARBY DYAR[3]

[1]American Museum of Natural History, New York, NY, USA, abell@amnh.org
[2]American Museum of Natural History, New York, NY, USA, jdw@amnh.org
[3]Mount Holyoke College South Hadley, MA, USA , mdyar@mounthoyoke.edu

We have conducted a series of experiments designed to evaluate intrinsic effects of the dissolved chlorine on the equilibrium $Fe^{3+}/\sum Fe$ in hydrous, chloride-rich rhyodacite liquids. Experiments were conducted at series of controlled fO_2 in an IHPV at 950°C and 130 MPa. The $Fe^{3+}/\sum Fe$ values of the run-product glasses were measured with synchrotron μ-XANES spectroscopy on beamline 13ID-D at the Advanced Photon Source, Argonne National Laboratory.

Data from experiments indicate that the addition of dissolved chloride increases the equilibrium $Fe^{3+}/\sum Fe$ of the melt relative to values predicted by several popular algorithms that equate $Fe^{3+}/\sum Fe$ with fO_2 and bulk melt composition. The deviation of the observed $Fe^{3+}/\sum Fe$ values from their predicted "equilibrium" values suggests that the interaction of dissolved chloride with Fe in the melt alters the activity-composition relationships for FeO and $FeO_{1.5}$ in the melt. Calculated G^{ex} associated with the $FeO_{1.5}$ and FeO components of the melt systematically vary as a function of the imposed experimental fO_2.

Data from these experiments imply that hydrous Fe-poor melts with intermediate silica and fairly modest chloride contents (i.e., ≤ 0.75 wt%) may display rather oxidized $Fe^{3+}/\sum Fe$ values despite possessing a relatively reduced equilibrium fO_2. The data further suggest that any empirical or thermodynamic model of the $Fe^{3+}/\sum Fe$ in silicate liquids must include terms to account for the non-ideal behaviour of $\gamma FeO_{1.5}/\gamma FeO$ that is associated with the presence of dissolved chlorine in the melt.

Jack Hills zircons record a thermal event coincident with the hypothesized Late Heavy Bombardment

Introduction

The Late Heavy Bombardment (LHB) is a hypothesized period of intense bombardment of the inner solar system at ca. 3.9 Ga, inferred from disturbed lunar ages. Major thermal effects to the Earth's crust are expected from LHB-impact scenarios, but unambiguous terrestrial evidence of this event is unknown, probably owing to the sparse geologic record from this period. However, detrital zircons from Jack Hills, Western Australia span the period 4.3-3.0 Ga, including the time period of the LHB, and may record evidence for this event.

Results and Discussion

We investigated the trace element chemistry of the Jack Hills detrital zircon record for the period 4.0 – 3.8 Ga in search of apparent changes in thermal conditions consistent with the LHB. The Ti-in-zircon temperature (T^{xlln}) distribution is well established for Hadean detrital grains, clustering about an average value of ~680°C – likely indicating near water-saturated granitic melting conditions. The average T^{xlln} does not change appreciably through the period 4.0-3.8 Ga, but between 3.91-3.84 Ga, there is a notable group of low-Ti zircons with apparent T^{xlln} extending well below the granite solidus. Further investigation revealed that this period contains two groups of zircons with clearly distinguishable trace element signatures. Group I resembles the Hadean Jack Hills zircons in Ti, Hf, Ce, U, and Th/U, whereas Group II contains lower Ti, Ce, and Th/U along with higher Hf and U. Group II also displays a high degree of U-Pb concordance compared to the 4.0-3.8 Ga Jack Hills zircons as a whole, despite their high U contents. We interpret Group II as originating from the solid-state recrystallization of originally magmatic (perhaps even Group I-like) zircon during a thermal event ca. 3.9 Ga. This thermal excursion is also seen in epitaxial growths on Hadean zircon cores found in previous studies.

Conclusion

A group of Jack Hills zircons at ca. 3.9 Ga appear recrystallized, and likely record a significant thermal event in the source terrane. Although an endogenic cause for this thermal event cannot be definitively ruled out, these observations may constitute the first terrestrial evidence for the LHB.

Anaerobic, nitrate-dependent U(IV) oxidation has considerable relevance to the bioremediation of uranium-contaminated aquifers and also represents a novel bacterial metabolic capability of fundamental scientific interest. A favored process for U bioremediation is *in situ* reductive immobilization, a process by which anaerobic bacteria reduce water-soluble U(VI) complexes to poorly soluble U(IV) phases. The discovery that *Thiobacillus denitrificans* [1] and other bacteria can anaerobically re-oxidize, and thus, re-mobilize, uranium in groundwater highlights a process that could compromise the efficiency of this bioremediation approach. While microbial U(VI) reduction has been the subject of extensive research, far less is known about anaerobic U(IV) re-oxidation.

We will discuss our efforts to identify the genes/proteins that are key to nitrate-dependent U(IV) oxidation in *T. denitrificans*. These efforts included: (a) detailed analysis of the *T. denitrificans* genome [2], (b) whole-genome transcriptional analyses of *T. denitrificans* with high-density, oligonucleotide microarrays [3], (c) proteomic studies of membrane-associated, *c*-type cytochromes in *T. denitrificans* [4], and (d) development of a genetic system in *T. denitrificans* [5].

We identified two diheme, *c*-type cytochromes critical to anaerobic U(IV) oxidation in *T. denitrificans* (putatively c_4 and c_5 cytochromes, Tbd_0187 and Tbd_0146, respectively). Insertion mutations in each of the two genes encoding these cytochromes resulted in a greater than 50% decrease in nitrate-dependent U(IV) oxidation activity, and complementation *in trans* restored activity to wild-type levels. Sucrose-density-gradient ultracentrifugation confirmed that both cytochromes are membrane associated. Sequence-based evidence links the Tbd_0187 protein to the high midpoint reduction potentials that would be required to catalyze U(IV) oxidation. Insertion mutations in other membrane-associated *c*-type cytochromes in *T. denitrificans* did not diminish U(IV) oxidation. To date, Tbd_0146 and Tbd_0187 are the only genes identified as being associated with anaerobic U(IV) oxidation.

We are also investigating nitrate-dependent Fe(II) oxidation in *T. denitrificans*, a process that we observed to accelerate U(IV) oxidation. Notably, the two cytochromes involved in U(IV) oxidation in *T. denitrificans* do not appear to be involved in Fe(II) oxidation. Random transposon mutagenesis studies to further investigate Fe(II) oxidation in *T. denitrificans* are ongoing.

Stable Isotope and Isotopomeric Constraints on N_2O Production in Wastewater Treatment Plants

F. BELLUCCI[1*], M. GONZALEZ-MELER[2], N.C. STURCHIO[2], J.K. BÖHLKE[3], N. E. OSTROM[4], AND J. KOZAK[5]

[5]Metropolitan Water Reclamation District of Greater Chicago, Chicago, IL, USA, joseph.kozak@mwrd.org

Wastewater treatment plants (WWTPs) constitute a substantial source of N_2O to the atmosphere, with a wide range of estimated emission factors, varying from 0.3 to 140 g N_2O/person/yr [1]. The majority of N_2O emissions occur in the aerobic reactors, where both incomplete nitrification and denitrification might contribute to the overall N_2O emissions. To better constrain production mechanisms and overall N_2O fluxes, we measured N and O isotope ratios of NH_4^+, NO_2^-/NO_3^-, and N_2O, and isotopomer ratios (N isotope site preference) of N_2O at two large-scale activated-sludge WWTPs in Chicago.

The average N2O concentration in the off-gas from the aerobic reactors was 34 and 56 ppmv for plants 1 and 2, respectively. At both plants the isotopic distribution of the major aqueous N-species (NO_3^- and NH_4^+) within the aerobic reactor can be approximated with a Rayleigh-type fractionation model determined by nitrification of ammonium along the wastewater flow path, accompanied by denitrification of about 5 % of the NO_3^- produced, with constant fractionation factors of about -15 ‰ and -20 ‰ for NH_4^+ nitrification and NO_3^- denitrification, respectively. The N isotope site preference in N_2O, averaging +2.7 ‰ and +3.9 ‰ at the two plants, suggests that N_2O was mainly produced by incomplete denitrification [2] in the portions of the tanks where dissolved oxygen was between 0.2 and 2.5 mg/L (fig. 1).

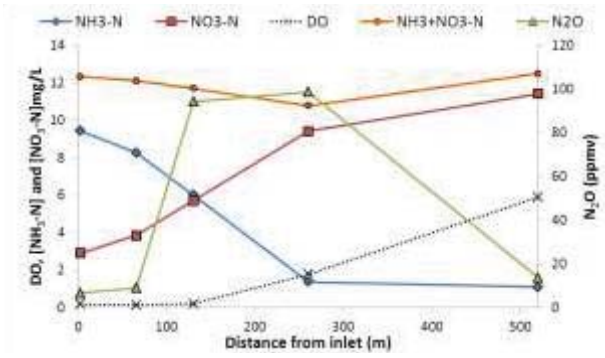

Figure 1. Average concentrations of dissolved oxygen (DO), N aqueous species, and off-gas N_2O along the wastewater flow path in a single tank of the aerobic reactor at plant 1.

The early formation of the continental crust: constraints from zircon Hf-isotope data

E.A. BELOUSOVA[1], W.L. GRIFFIN[1], Y.A. KOSTITSYN[2], N.J. PEARSON[1], G. BEGG[3] AND S.Y. O'REILLY[1]

A worldwide database of >16,000 U–Pb and Hf-isotope analyses of zircon, largely from detrital sources, has been interogated to analyse the processes of crustal evolution on a global scale, and to test existing models for the growth of continental crust through time. At any timeslice, most zircons have ε_{Hf} well below the Depleted Mantle (DM) growth curve, reflecting later reworking of originally juvenile material. To quantitatively estimate the proportion of juvenile material added to the crust at any given time during its evolution, it is necessary to correct for this effect. "Crustal" model ages are calculated assuming the zircon-bearing magmas were generated from the average continental crust ($^{176}Lu/^{177}Hf = 0.015$); zircons with non-juvenile Hf are projected back to the DM growth curve using this ratio. Juvenile magmas are defined as having $\varepsilon_{Hf} \geq 0.75$ times the ε_{Hf} of the DM at the time of genesis. The distribution of corrected model ages can then be used to model the true crustal growth rate over the 4.56 Ga of Earth's history. The modelling shows that there was little episodicity in the production of new crust, as opposed to peaks in magmatic ages. The distribution of age-Hf isotope data from zircons worldwide implies that at least 60% of the existing continental crust separated from the mantle before 2.5 Ga, and has been variably reworked since then. However, taking into consideration new evidence coming from geophysical data, and correcting for the geographical biases in database, the formation of most continental crust still earlier in Earth's history (at least 70% before 2.5 Ga) is even more probable. Thus, crustal reworking has dominated over net juvenile additions to the continental crust, at least since the end of the Archean. Moreover, the juvenile proportion of newly formed crust in any timeslice decreases stepwise through time: it is about 70% in the 4.0–2.2 Ga time interval, about 50% in the 1.8–0.6 Ga time interval, and possibly less than 50% after 0.6 Ga. These changes may be related to the formation of supercontinents.

Applications of the Arctic sea ice proxy IP_{25}: Quantitative versus qualitative considerations

SIMON BELT[1*], PATRICIA CABEDO SANZ[1], ALBA NAVARRO RODRIGUEZ[1], JOCHEN KNIES[2], KATRINE HUSUM[3], AND JACQUES GIRAUDEAU[4]

[3]University of Tromsø, Tromsø, Norway, katrine.husum@uit.no
[4]Université Bordeaux, Bordeaux, France, J.Giraudeau@epoc.u-bordeaux.fr

Background

The presence of the sea ice diatom biomarker IP_{25} in Arctic marine sediments has been used in previous studies as a proxy for past spring sea ice occurrence and as an indicator of wider palaeoenvironmental conditions for different regions of the Arctic over various timescales [e.g. 1, 2]. Recent attempts have also been made to make the interpretations of the IP_{25} data more quantitative by comparison of IP_{25} (and other biomarker) concentrations with known sea ice conditions (3). However, the extent to which such calibrations can be extrapolated for longer timescales and for different Arctic regions remains unclear.

Current work

This presentation will focus on recent results, with particular emphasis on the importance of accurate analytical methods for the quantification of IP_{25} in marine sedments and a consideration of the factors that likely influence whether IP_{25}-based interpretations can be considered as qualitative or quantitative. Recent case studies to illustrate these points will be taken from different geological epochs (including modern times, the Holocene and the Younger Dryas) and from a diverse range of Arctic and sub-Arctic regions including the Canadian Arctic and the Nordic Seas. The outcomes of these analyses not only provide important information on past Arctic sea ice conditions, but also help identify areas of research that still require attention.

Geochemical proxies for changes in dust sources in Negev desert loess

MICHAL BEN-ISRAEL[1,2*], YIGAL EREL[1], YEHOUDA ENZEL[1], RIVKA AMIT[2]

[1]Hebrew University of Jerusalem, Institute of Earth Sciences, Israel, michal.benisrael@mail.huji.ac.il (* presenting author)
[2]Geological Survey of Israel, Jerusalem, Israel

The loess of the Negev desert of Israel, was deposited mainly during the late Pleistocene [1, 2]. It is characterized by a bimodal grain-size distribution with modes between 2-8 micrometer (fine silt) and 50-60 micrometer (coarse silt) that represent two different sources of dust, one distal and one proximal [3].

Here we investigate the carbonate-free samples of the two size fractions and search for a geochemical signature of the distal and proximal sources of the loess in three OSL-dated primary loess sequences along a climatic transect: Hura village (~250 mm/yr) and Ramat Beka (~150 mm/yr) in the northern Negev and Mt. Harif (~100 mm/yr) in the central Negev. The fractions are separated and analyzed for major and trace elements and for Sr and Nd isotopic composition. Preliminary results show differences between the fine and coarse fractions that agree with the observation of two different sources contributing to loess in the Negev. Sr-Nd isotopic ratios of both silt fractions suggest contribution from several distal (e.g. Sahara, Arabia) and local proximal sources (e.g. Sinai deserts, Nile delta sediments, and the Sinai-Negev sand dunes). Moreover, changes in loess sources over time were detected in shifts in Sr and Nd isotopic values of the fine fractions, these shifts acure at ~60-70 kyr in Mt. Harif and Ramat Beka sites and at ~20 kyr at Hura site.

These results support the formation model of primary desert loess by eolian abrasion of sand dunes and suggest that the loess chemical and isotopic composition reflect changes of dust sources over time.

Adsorption of purified Aldrich humic acid (PAHA) onto α-Al_2O_3 is studied by batch experiments at different pH, ionic strength and coverage ratios R (mg of PAHA by m² of mineral surface). After equilibration, samples are centrifuged and the concentration of PAHA in the supernatants is measured. The amount of adsorbed PAHA per m² of mineral surface is decreasing with increasing pH. At constant pH value, the amount of adsorbed PAHA increases with initial PAHA concentration until a constant pH-dependant value is reached.

UV/Visible specific parameters such as specific absorbance $SUVA_{254}$, ratio of absorbance values E_2/E_3 and width of the electron-transfer absorbance band Δ_{ET} are calculated for supernatant PAHA fractions of adsorption experiments at pH 6.8, to have an insight on the evolution of PAHA characteristics with varying coverage ratio. No modification is observed compared to original compound for $R \geq 20$ mg_{PAHA}/g. Below this ratio, aromaticity decreases with initial PAHA concentration. Size-exclusion chromatography - organic carbon detection measurements on these supernatants also show a preferential adsorption of more aromatic and higher size fractions.

Spectrophotometric titrations were done to estimate changes of reactivity of supernatants from adsorption experiments made at pH ≈ 6.8 and different PAHA concentrations. Evolutions of UV/Visible spectra with varying pH were treated to obtain titration curves that are interpreted within the NICA-Donnan framework. Protonation parameters of non-sorbed PAHA fractions are compared to those obtained for the PAHA before contact with the oxide. The amount of low-affinity type of sites and the value of their median affinity constant decrease after adsorption. From PAHA concentration in the supernatant and mass balance calculations, "titration curves" are obtained and fitted for the adsorbed fractions for the first time. These changes in reactivity to our opinion could explain the difficulty to model the behavior of ternary systems composed of pollutants/HS/mineral since additivity is not respected.

Figure 1: LC-OCD chromatograms of PAHA and of supernatants from adsorption experiments at 0.1M and pH ≈ 6.8 (R in mgPAHA/g α-Al_2O_3).

Stabilization and Assembly of Mineral Clusters Guided by Enamel Proteins.

PING-AN FANG[1], HENRY C. MARGOLIS[2], JAMES F. CONWAY[1], JAMES P. SIMMER[3], ELIA BENIASH[1*]

[1]University of Pittsburgh, Pittsburgh, PA, USA;

*-presenting author ebeniash@pitt.edu

Dental enamel, being the most mineralized vertebrate tissue, is extremely well preserved in the paleontological record and thus a favorite subject for studies of vertebrate evolution, archeology and paleoclimate. Enamel is a structurally complex hierarchical nanomaterial. Although, mature enamel is 95% carbonate apaptite it starts as a network of nanocrystaline arrays suspended in a protein matrix, with the mineral phase comprising only 10% of its volume. Despite these differences in composition, the mineral organization in nascient and mature enamel is identical. While the organic matrix is believed to regulate mineral formation, the basic mechanisms of enamel mineralization are poorly understood. Here we present our recent studies of calcium phosphate mineralization *in vitro* in the presence of the major enamel matrix protein, amelogenin. These experiments were carried out on carbon-coated electron microscopy (EM) grids, and studied in conventional and cryo-EM. We found that amelogenin induces formation of parallel arrays of apatitic crystallites that are structurally similar to the basic building blocks of enamel, enamel rods. Importantly, these structures only formed when monomeric, rather than preassembled, amelogenin was introduced to the mineralization solutions. These results suggest that the mineralization occurs not on the preformed organic matrix as in other systems but instead via cooperative interactions between forming crystals and assembling proteins.[*1*] Our cryo-EM studies show that amelogeinin undergoes stepwise assembly via oligomers that then organize into higher order structures. Our results indicate that amelogenin oligomers stabilize calcium phosphate prenucleation clusters and organize them into linear chains. Subsequently, the clusters fuse together to form needle-shaped mineral particles which further organize into parallel arrays.[*2*] We find that the mechanism of enamel formation is very different from the templated mineralization that is observed in other biomineralization systems. Specifically our results indicate that amelogenin oligomers can stabilize prenucleation clusters and organize them into mesostructures prior to their crystallization. This mechanism in which protein assemblies fully control organization of the initial mineral phase enables formation of intricate structures that cannot be obtained via classical crystallization from supersaturated solutions. These studies supported by NIH grants R01DE016376 (to H.C.M.), R01DE016703 (to E.B.) and PA grant SAP 4100031302 (to J.F.C.)

Fluid inclusions give chemical, physical, biological, and climatic insights into acid saline lake and groundwater systems

KATHLEEN COUNTER BENISON
Dept. of Earth and Atmospheric Sciences, Central Michigan University, Mt. Pleasant, Michigan, 48859 USA, benis1kc@cmich.edu

Acid saline lakes and associated shallow groundwaters represent amongst the Earth's most extreme aqueous chemistries. Modern lakes and groundwaters in Western Australia and Chile have pHs as low as 1.5, total dissolved solids as high as 32%, unusually high concentrations of Al, Si, and Fe, and many other atypical chemical characteristics. Permian lake environments in the U.S. midcontinent had even more extreme water compositions.

Fluid inclusions in halite and gypsum from modern and Permian acid saline lakes record specific physical, chemical, and biological conditions of these environments. Primary inclusions in these chemical sediments trap shallow lake water, air bubbles, crystals of other minerals, and microorganisms. Isolated fluid inclusions in early diagenetic phases of halite are remnants of shallow groundwaters and yield their chemical compositions.

A variety of traditional methods, including petrography, freezing/melting microthermometry and laser Raman spectroscopy, and innovative variations, such as homogenization of artificially-nucleated vapor bubbles and UV-vis petrography, produce data detailing environmental conditions. Other traditionally used methods, such as laser ablation ICP-MS, are not effective due to the nature of the inclusions. Making synthetic solutions that match the complexity of natural acid saline inclusions is another challenge. Ongoing efforts include the analyses of modern and Permian air and documentation of microorganisms and organic compounds within these fluid inclusions (Fig. 1).

Equilibrium core formation loses it's lustre: High pressure & temperature partitioning of gold

NEIL BENNETT[1*] & JAMES BRENAN[1]

[1]The University of Toronto, Toronto, Canada, bennett@geology.utoronto.ca (* presenting author)

Experiments to determine the distribution of highly siderophile elements (HSE) between core-forming metal and the magma ocean suggest that the primitive upper mantle (PUM) should be highly depleted in most of these constituents relative to what is observed. This is not the case for Au. We have measured Au solubility at 2GPa and 1800-2315°C, at ~IW-IW+2.5, under both C-bearing and C-free conditions. Metal-silicate partition coefficients ($D_{Met/Sil}$) were then calculated using the relation of [1]. After combination with the low temperature results of [2], the following temperature dependence for $D_{Met/Sil}$ was found:

$$D_{Met/Sil} = 1.14(0.07)*10^4/T\,(\mathrm{K}) - 1.41(0.34)$$

$D_{Met/Sil}$ is essentially independent of fO_2 and the results from previous studies at 0.1MPa-23GPa [2], [3] agree well with our 2GPa data. Temperature therefore appears to be the primary factor controlling the affinity of Au for Fe-metal. Os isotope systematics and concentrations of the other HSEs in the PUM are best explained by a late veneer of LL-chondrite, comprising 0.5% of the bulk silicate earth [4]. $D_{Met/Sil}$ values for Au limit metal-silicate equilibration to ~2450°C if an over-abundance of Au in the PUM is to be avoided, placing the base of the magma ocean at ~400km. This is much shallower than the >800km depth required by the convergence of Ni-Co partitioning [5]. Low $D_{Met/Sil}$ values at high temperature also predict Au/Ir ratios much greater than estimated for the PUM. Metal-silicate equilibrium therefore appears unable to account for the Au content of the PUM. One solution to this discrepancy may be incomplete equilibration between the magma-ocean and the accreting cores of large, differentiated planetesimals [6]. In this scenario, Au may be transported to the Earth's proto-core deprived of communication with molten-silicate, thus imbuing the core with a Au content greater than predicted by metal-silicate partitioning.

Expanding early Earth frontiers: A new Eoarchean-Hadean(?) terrane in Southwestern Greenland

VICKIE C. BENNETT[1*], ALLEN P. NUTMAN[2], JOE HIESS[3] AND CLARK R.L. FRIEND[4]

[1]Australian National University, Canberra, Australia, vickie.bennett@anu.edu.au. (* presenting author)

[4]45 Stanway Road, Headington, Oxford, UK

The strongest controls on early Earth processes and environments are obtained through direct study of the rock record, which currently, with few exceptions, terminates at ca. 3.9 Ga. Although rare >4.0 Ga zircons and their inclusion suites preserved in Western Australian Mesoarchean metasediments provide a wealth of information about early Earth history and conditions, they are an incomplete and likely restricted record of early processes.

Here we present new geochemical observations from metagabbros and associated felsic rocks from a previously unstudied region of SW Greenland. Minimum age constraints on the metagabbros are provided by U-Pb zircon (SHRIMP) ages of cross-cutting granitoids; a dated tonalite has a dominant population of euhedral, oscillatory-zoned magmatic zircons with an age of 3889±5 Ma. Two adjacent relatively older gabbros yielded populations of small, oval zircons with only ca. 2.97 Ga ages, which are interpreted to have formed in a recognized regional metamorphic event. This event is not recorded at either Isua or on Akilia, demonstrating that this is a distinct block of ancient crust, rather than contiguous with previously documented Eoarchean domains. Initial εHf values of the ca. 3.89 Ga zircons are within error of estimated chondritic compositions, with no evidence for early Lu/Hf fractionation. This is in accord with Lu-Hf data from zircon populations extracted from >3.7 rocks worldwide.

Measured Hf isotopic compositions of the metagabbro Mesoarchean metamorphic zircons determined by LA-MC-ICPMS range from εHf= -79 to -83; initial compositions calculated at the metamorphic age are highly negative (-13 to -16). Two-stage chondritic mantle model ages calculated using plausible $^{176}Lu/^{177}Hf$ ratios for the pre-zircon first stage are >4.0 Ga. For example, using $^{176}Lu/^{177}Hf$ =0.018 as typifies Isua metabasaltic rocks, yields chondritic model ages of ca. 4.3 Ga. In contrast, similar-aged metamorphic zircons from a nearby Mesoarchean metasedimentary rock have positive initial εHf values =+8 with DM model ages equal to zircon crystallization age. The ancient Hf model ages combined with the minimum 3.89 Ga age provided by cross-cutting tonalites point to a ≥4.0 Ga age for the metagabbros. Continued investigations of these potential Hadean rocks are in progress.

The majority of rocks analysed from SW Greenland Eoarchean terranes have ^{142}Nd isotopic anomalies when compared with modern terrestrial rocks, with the magnitude of ^{142}Nd generally increasing with crystallization age as shown by Bennett et al, (*Science*, 2007). In the absence of igneous zircons in the ≥3.89 Ga metagabbros, ^{142}Nd compositions may provide confirmation of the Hadean age suggested by Hf isotopic modelling. These recently recognised earliest Eoarchean and possibly Hadean suites are a significant new laboratory for testing models of early Earth formation and evolution.

The mechanism of metal-silicate segregation is key to constraining core formation processes in the early Earth. Experiments performed at conditions of core formation in terrestrial planets have generally found metallic melts to be immobile in a solid silicate matrix. This implies that a liquid silicate 'Magma Ocean' was required for efficient differentiation to occur. There is some doubt as to the applicability of this model to other planetary bodies, particularly those with smaller radii, which may not have been heated to silicate melting temperatures. Recent experimental work has found that deformation can enhance permeability of melt through a solid silicate system without the need to melt the surrounding silicate. We have conducted a series of deformation experiments in the rotational Paris-Edinburgh Cell (roPEC), which allows controlled deformation at simultaneous high pressures and temperatures over a large range of strain rates. Textural analysis confirms melt is interconnected at a grain scale. This implies core formation could have taken place earlier and more rapidly than previously believed, affecting inferred geochemistry of the core and mantle. We use 3D reconstructions of the sample interior from Computed Axial Tomography scans to characterise melt network geometry in order to constrain melt migration rates and permeability.

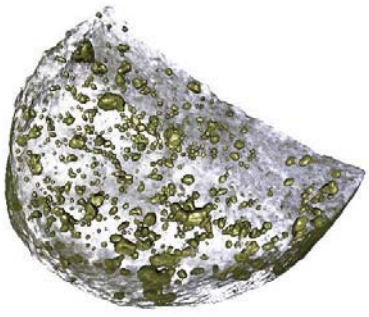

Figure 1: Preliminary tomographic reconstruction of undeformed sample. Sample diameter is 2mm. High density Fe_3S shown in gold, grey-transparent areas are olivine.

Petrogenesis of voluminous silicic magma in northeast Iceland

SYLVIA E. BERG[1, 2*], VALENTIN R. TROLL[2], MORTEN S. RIISHUUS[1] AND STEFFI BURCHARDT[2]

[1]Nordic Volcanological Center, Reykjavik, Iceland sylvia@hi.is (*presenting author)
[2]Dept. of Earth Science, CEMPEG, Uppsala University, Sweden

Neogene silicic volcanic complexes in the greater Borgarfjörður eystri area, NE-Iceland, are the focus of a petrological and geochemical investigation. The region contains the second-most voluminous occurrence of silicic rocks in Iceland, including caldera structures, inclined sheet swarms, extensive ignimbrite sheets, sub-volcanic rhyolites and silicic lava flows. Despite the relevance of these rocks to understand the generation of evolved magmas in Iceland, the area is geologically poorly studied [c.f. 1, 2, 3].

The voluminous occurrence of evolved rocks in Iceland (10-12 %) is very unusual for an ocean island or a mid-oceanic ridge, with a typical signal of magmatic bimodality, often called "Bunsen-Daly" compositional gap [e.g. 4, 5, 6]. The Bunsen-Daly Gap is a long-standing and fundamental issue in petrology and difficult to reconcile with continuous fractional crystallization as a dominant process in magmatic differentiation [7]. This implies that partial melting of hydrothermally altered crust may play a significant role. Our aim is to contribute to a solution to this issue by unravelling the origin, timing and evolution of voluminous evolved rhyolites in NE-Iceland.

We use a combined petrological, textural, experimental and in-situ isotope approach on a comprehensive sample suite of intrusive and extrusive rocks, ranging from basaltic to silicic compositions. We are performing major, trace element and Sr-Nd-Hf-Pb-He-O isotope geochemistry, as well as U-Pb geochronology and Ar/Ar geochronology on rocks and mineral separates. Zircon oxygen isotope analysis will be performed in conjuction with zircon U-Pb geochronology for further assessment of the role of processes such as partial melting of hydrated country rock and/or fractional crystallization in generating Icelandic rhyolites. In addition, high pressure-temperature partial melting experiments aim to reproduce and further constrain natural processes. Using the combined data set we intend to produce a comprehensive and quantitative analysis of rhyolite petrogenesis, and of the temporal, structural and geochemical evolution of silicic volcanism in NE-Iceland. The chosen field area serves as a good analogue for active central volcanoes in Iceland, such as Askja and Krafla, where interaction of basaltic and more evolved magma has led to explosive eruptions.

Petrology of two pre-orogenic granites, Damara Orogen, Namibia

CHRISTIAN BERGEMANN[1*], STEFAN JUNG[1], JASPER BERNDT[2] AND ANDREAS STRACKE[2]

[1] Mineralogisch-Petrographisches Institut, Universität Hamburg, Germany (*), christian_bergemann@yahoo.de

[2] Institut für Mineralogie, Universität Münster, Germany

The Damara Orogen sensu strictu of Namibia was formed during the late Archean/early Proterozoic Pan-African orogenic event. It is characterised by medium p/high T regional metamorphism and large-scale granitoid intrusion. The two plutons investigated in this study are part of the Damaran Northern Central Zone within the Okombahe district and can readily be distinguished by field criteria. LA-ICP-MS U-Pb geochronology on zircon yielded similar ages of 576±6 Ma and 571±5 Ma. This is the earliest date of granite intrusion discovered in the Central Damara Orogen. Both plutons consist of granodiorite and granite that are metaluminous to slightly peraluminous. Both rock types have high calculated zircon saturation temperatures up to 890°C, show only limited fractionation and exhibit no signs of shallow crustal contamination. Chemical and isotope data overlap almost completely in which the granodiorites and granites are characterized by a range in K_2O (3.1-5.9 wt.%) and moderate to high HFSE and LREE abundances (up to 620 ppm Zr and 250 ppm Ce) and a strong enrichment of LREE over HREE (La/Yb: 19-49) with variable negative Eu anomalies (Eu/Eu*: 0.82-0.19). Initial Sr and Nd isotopic compositions vary over a narrow range (init $^{87}Sr/^{86}Sr$: 0.704 - 0.706; init. ε Nd: -1.9 to -3.9). Relatively young Nd model ages (T_{DM}: 1.2-1.4 Ga) and 1.7 Ga-old restitic zircon suggest a derivation from a juvenile source rock of probably meta-igneous composition. As the intrusion ages precede the minimum age of high-grade regional metamorphism, crustal heating as the cause of granite formation can be ruled out. Previous studies have shown that the meta-igneous basement of the Damara orogen has an average heat production of 6.8 HGU (1 HGU=10^{-13} cal/cm^3*sec; Haack et al. 1983). This value is significantly higher than that of average continental crust (2.14 HGU; Rudnick & Gao 2004) hence, a major contribution from pre-existing continental crust is possible. In addition, intrusion of large scale mafic bodies in the lower crust could also potentially provide some extra heat for crustal melting, however, seismic refraction studies gave no evidence for the existence of large volumes of mafic rocks in the lower crust (Green 1983). We therefore suggest that emplacement of numerous sill-like intrusions (Petford & Gallagher 2001) may have provided the necessary heat for melt generation.

Mercury (Hg) is an active redox-sensitive metal with a complex biogeochemical cycle that displays a wide range of stable Hg isotopic fractionation. In addition to mass-dependent fractionation (MDF), Hg isotopes also display large (up to 10‰) mass-independent fractionation (MIF). The large MIF in Hg isotopes is commonly expressed only for the odd isotopes (^{199}Hg, ^{201}Hg). To date, the large MIF in the odd Hg isotopes is thought to occur during kinetic photochemical reactions due to the magnetic isotope effect. In the first photochemical experiments (Bergquist and Blum, 2007), Hg(II) species were photo-reduced to Hg(0) in the presence of fulvic acid. It was found that the odd isotopes were preferentially enriched in the reactant in the aqueous reservoir. In these experiments, the Hg/DOM ratios were such that Hg was likely bound to carboxylic ligands. However, subsequent experiments show that the sign and ratio of MIF can be changed during photo-reduction in the presence of different organic ligands or in presence of UVC. In particular, Zheng et al. (2010) demonstrated that photoreduction of Hg bound to reduced S containing ligands results in the odd isotopes being depleted in the reactant in the aqueous phase.

The chemistry of the atmosphere and ocean changed drastically in the Precambrian due to the evolution of life and rise of oxygen. The large changes in the redox conditions and the sulfur cycle of the surface Earth along with changes in UV penenetration likely had large impacts on the biogeochemical cycle of Hg and on the Hg isotope system. It is also likely that the nature of the organic ligands binding Hg changed dramatically in response to evolution of different groups of organisms. The goal of this research was to study Hg isotopes preserved in the sedimentary and metasedimentary geologic record where major changes in either UV shielding or major changes in the nature of DOC may have occurred. Preliminary Hg isotope analyses show that the younger samples mostly show negative MIF with $\Delta^{199}Hg/\Delta^{201}Hg$ close to 1 whereas the older samples have positive MIF with $\Delta^{199}Hg/\Delta^{201}Hg$ greater than 2. The timing of the shift is consistent with the first major glaciation and suggestion of an organic fractal haze, which would have blocked higher energy UV. The timing is also consistant with a change in S isotopes that is thought to occur because of an increase in sulfate and sulfate reducing bacteria. Both possible explanations will be discussed in the context of experimental constraints. These are preliminary results, but they reveal the potential of Hg isotopes to add to our understanding of the eveolution of life and chemistry of the early Earth.

CO_2-rich fluids in the mantle: a comparative fluid inclusion study

MÁRTA BERKESI[1], CSABA SZABÓ[1*], TIBOR GUZMICS[1], ZSANETT PINTÉR[1], RÉKA KÁLDOS[1], JEAN DUBESSY[2], MUNJAE PARK[3] AND GYÖRGY CZUPPON[4]

Negative crystal shaped fluid inclusions enclosed in spinel lherzolites from five different locations all around the world were the subject of a detailed fluid inclusion study. Samples were studied from: the Central Pannonian Basin (Hungary), Cameroon Volcanic Line (Cameroon), Jeju Island (S-Korea), Rio Grande Rift (New-Mexico, USA) and from Mt. Quincan (Australia). As a result, CO_2-rich fluids within the fluid inclusions could be studied and compared.

High resolution Raman spectroscopy at different temperatures revealed that fluids in inclusions are heterogeneous and contain small amounts of other species. We show that nitrogen (N_2) can be present in the dense fluid and is more common than was previously thought. H_2O is present in almost all of the inclusions, and was identified by the combination of stepwise heating experiments and Raman spectroscopy [1]. Our results show that, although H_2O is a minor component in mantle fluids, its relative amount varies between different locations, which has not been previously recognized.

Sulfur in the fluid at room temperature can be present either as H_2S or as SO_2, however these species never occur together at the same location. In addition, following fluid inclusion exposure by the FIB-SEM (Focused Ion Beam-Scanning Electron Microscopy) technique, a complexity of S-bearing solid phases has also been identified: sulfides and sulfates were also found within the fluid inclusion cavity. OH-bearing solids are also found in some cases within the fluid inclusions.

Combination of Raman spectroscopy and the FIB-SEM technique proved the presence of carbonates and quartz that are interpreted to be a reaction product of the trapped CO_2 and the host pyroxene. In addition, a common feature found on the inclusion walls is a thin glass film at a submicron scale that documents the ability of mantle fluids to dissolve and transport trace elements and cause cryptic metasomatism as has previously been inferred [2].

We can conclude that, similar to the solid phases involved in the construction of the subcontinental lithospheric mantle, the coexisting fluid can also be heterogeneous in the mantle, although the dominant component in each case is CO_2.

Investigating the role of microbial processes in the weathering of rock-derived graphitic carbons

SABRINA BERLENDIS [1 *], OLIVIER BEYSSAC[1], KARIM BENZERARA[1], FERIEL SKOURI-PANET[1], CELINE FERARD[1]

During erosion and chemical weathering, organic carbon contained in (meta)sedimentary rocks may be oxidized or recycled. Recent studies in the Himalaya[1] and Andes[2] orogenic systems have demonstrated that the fate of these carbonaceous phases is highly dependent on their graphitization degree: in such large-scale systems only graphite is finally preserved whereas poorly graphitic compounds are oxidized. This oxidation which happens in the bedrock or during fluvial transport is assisted, and most likely driven, by microbial processes. The present study investigates the effect of inorganic compounds commonly found in shale and coal (metals, sulphur and nitrogen compounds) on the bio-alteration of carbonaceous material by microbial populations. For that purpose, we sampled several carbon-bearing rocks which experienced varying metamorphic grades and have therefore various structural organizations for carbons (from kerogen/coal to graphite) following a strict protocol to minimize contamination. The sample set includes carboniferous coals (Graissessac and Briançon basins, France) and black shales as well as graphitic schists (Western Alps, France). The mineralogy and structure of organic carbon have been characterized by various techniques (XRD, Raman and IR, SEM). The high-grade metamorphic rocks contain highly crystalline carbonaceous phases (graphite) and a low mineral diversity (chlorite, muscovite and quartz). In addition, sulfate minerals such as jarosite and gypsum were detected in slightly less graphitized schist rock. By contrast, the coals contain turbostratic carbons and a wide variety of minerals (montmorillonite, feldspar, illite and kaolinite). Back to the lab, enrichment cultures were set up under both oxic and anoxic conditions using the rock-derived carbonaceous material as the sole carbon source. The effect of various inorganic electron donors and acceptors added in combination are tested. Microscopy and biomolecular studies show a low biomass content in microbial enrichments, but we have detected in some of them thin filamentous bacteria and short rod cells that are embedded in a biofilm deeply-incrusted inside carbonaceous particles and other minerals. The metabolic functions of enriched microbial populations are currently assessed by microscopy, hybridization techniques and spectroscopy techniques. Their possible influences on the alteration of rock-derived graphitic carbons will be discussed.

9f. Innovative geochemical approaches to understanding geothermal systems

The halogen composition of seven geothermal fields and eight hot spring areas in the Taupo Volcanic Zone (TVZ), North Island New Zealand, were studied in order to constrain the origin of the geothermal fluids and to identify the effect of physico-chemical processes on the isotopic composition of these fluids. A set of 74 samples from well brines and hot springs were analyzed for Cl, Br, Li, $\delta^{37}Cl$, $\delta^{18}O$ and δD. In particular, this study offers a first approach to the application of the Cl/Br systematics in geothermal fluids to constrain the behaviour of stable chlorine isotopes.

The determination of the Cl/Br ratios in the set of samples analyzed, allowed the initial characterization of geothermal fields and hot spring areas in the TVZ. The highest Cl/Br ratios were found at Mokai (1,664), Orakeikorako (1,611), Rotokawa (1,478) and White Island (1,373). The chlorine isotopic composition of all the samples ranged from -0.97 to 0.67‰. With the exception of some samples from Orakeikorako and Rotokawa, most samples with high Cl/Br ratios had positive $\delta^{37}Cl$ values, the geothermal field Mokai was the most enriched in $\delta^{37}Cl$ (0.03 to 0.38‰). The sample from Broadlands Ohaaki had a negative $\delta^{37}Cl$ value (-0.57‰) and a Cl/Br ratio of 870. In the hot springs the Cl/Br ratios also correlate well with the $\delta^{37}Cl$ values. Waikite has the highest $\delta^{37}Cl$ values (0.47 to 0.67‰), followed by Taupo, White Island, Tokaanu and Waimangu.

The data suggest that in the central part of the TVZ, there is a deep fluid of magmatic origin with a Cl/Br ratio of at least 1,200, a positive $\delta^{37}Cl$ signature around 0.5‰, a Cl concentration above 3,200 ppm and a Li content of more than 29 ppm. Fluids with similar characteristics were found at Tokaanu, White Island, Mokai, Wairakei, Tauhara and Ngatamariki. A second fluid is characterized by negative $\delta^{37}Cl$ values (-0.02 to -0.97‰), Cl/Br ratios below 1,200 and Li concentrations around 10 ppm. The influence of this second fluid is more dominant towards the E and NE of the TVZ in hot spring areas and geothermal systems like Rotorua, Waiotapu, Rotokawa and Kawerau.

How citrate slows magnesite growth: a high temperature AFM study

ULF-NIKLAS BERNINGER[1*], QUENTIN GAUTIER[2], GUNTRAM JORDAN[1] AND JACQUES SCHOTT[2]

[1] Ludwig-Maximilians-Universität, Department für Geo- und Umweltwissenschaften, Munich, Germany,
ulf-niklas.berninger@campus.lmu.de (*presenting author)

quentin.gautier@get.obs-mip.fr

Preliminary work and experimental methods

Magnesite shows a high stability in natural enviroments and hence is of scientific interest due to its potential for long-term CO_2 sequestration. In a recent study we were investigating the inhibition of carboxylic ligands on magnesite growth and found out that among the investigated ligands citrate caused the highest degree of inhibition [1]. Besides the effect of complexation of Mg^{2+} in aqueous solution, a prominent surface effect of citrate was detected. This surface effect of citrate on magnesite growth at elevated temperatures, however, is still insufficiently understood.

In the present study, hydrothermal atomic force microscopy (HAFM) was used to investigate magnesite growth on the (104) surface as a function of citrate concentrations (0.1-10 mmol/kgw) and saturation state. Experiments were conducted at pressures up to 4 bars, temperatures of 100 °C and 120 °C and alkaline conditions (pH 7.5-8.5).

Results and outlook

HAFM experiments showed that spiral growth is the dominant growth mechanism over a wide range of saturation state in ligand-free solutions as well as in the presence of citrate. Accordingly, the determined growth rates follow an exponential dependency on supersaturation and are in close agreement with previous mixed-flow reactor experiments [1][2]. Furthermore, HAFM observations revealed that citrate interacts with steps on the (104) surface of magnesite producing growth islands elongated along the trajectory of the c-axis. This pronounced morphological change was taking place without an effect on obtuse step kinematics but with a reduced advancement rate of acute steps. These observations indicate specific blocking of acute kinks by citrate. For the rotation frequence of spirals and thus the growth rate, acute step advancement is essential. The rate of step generation via spiral growth in the presence of 1 mmol/kgw citrate was thereby decreased by a factor of more than 3.

Overall, this study confirms the control exerted by acute steps on magnesite growth rates. Therefore, numerical molecular simulations should preferentially focus on stereochemical effects between organic molecules and acute steps and kinks. This could help to better understand and predict the role of organic additives on magnesite growth.

Controls on the Carbonation of Steel Slag

ELEANOR J. BERRYMAN[1*], ANTHONY E. WILLIAMS-JONES[1], ARTASCHES A. MIGDISOV[1], SIEGER VAN DER LAAN[2]

[1]McGill University, Montreal, Canada, berryman.eleanor@gmail.com(* presenting author)
[2]Tata Steel RD&T, IJmuiden, The Netherlands

Goals and Methodology

Mineral carbonation provides a robust method for permanent sequestration of CO_2 that is environmentally inert. Larnite (Ca_2SiO_4), the major constituent of steel slag, reacts readily with aqueous CO_2 [1]. Consequently, its carbonation offers an exciting opportunity to reduce CO_2 emissions at source [2]. A potential added benefit is that this treatment may render steel slag suitable for recycling. This study investigates the impact of temperature, fluid flux and reaction gradient on the dissolution and carbonation of steel slag, and is part of a larger study designed to determine the conditions under which conversion of larnite, and other calcium silicates, to calcite is optimized.

The experiments were conducted on 2 – 3 mm diameter steel slag grains supplied by Tata Steel RD&T. A CO_2-saturated aqueous fluid was pumped through a steel flow-through reactor containing these grains at a temperature between 120°C to 200°C; the fluid pressure was 250 bar. Fluid flux was varied between 0.8 and 6 mL/min/cm^2. The duration of experiments ranged from 3 to 7 days.

Results

The steel slag grains reacted with the CO_2-saturated aqueous fluid to form phosphorus-bearing Ca-carbonate phases. At high fluid flux, these phases dissolved at the edges of grains, leaving behind a porous aluminium and iron oxide rind. Increasing temperature increased the rate of this reaction. At low fluid flux, carbonates precipitated on the slag grain surface inhibiting further reaction. In contrast, at intermediate fluid flux, dissolution of the primary Ca-bearing minerals was balanced by precipitation of carbonate phases, thereby optimising carbonation of the steel slag.

Conclusions

These results of this study show that carbonation of steel slag by aqueous CO_2 is feasible using relatively large grains and that it can be optimised by varying fluid flux. Experiments of the type described above will contribute to the eventual global reduction of industrial CO_2 emissions.

guillaume.berthe@cea.fr (*presenting author)

Introduction

In the case of a CO_2 storage in geological media, the understanding of the behavior of the caprock encountering an acid fluid is crucial. A set of twenty "dynamic" through-diffusion experiments was performed to investigate the changes in chemical and physical properties of a caprock-type argillite.

Methods

The "dynamic" through-diffusion setup enables, during the CO_2 attack, (i) a monitoring of the ion concentrations in the upstream and the downstream reservoirs and, (ii) an estimate of the transport property change, using HTO, HDO, ^{36}Cl and Br^- as tracers [1]. The impact of several parameters on the caprock behavior was studied, such as the amount of carbonate minerals, the sample thickness, the upstream volume, the presence or not of calcite-filled fracture and the bedding plane orientation regarding the diffusion.

Results and Discussion

The results showed that the extent of the reaction front, lowering the caprock confinement properties, would be more related to the initial rock transport properties and the calcite texture than the amount of carbonate minerals.

This large set of experimental data acquired, allowed us to identify from the chemistry-transport modeling some key parameters, such as the kinetic rate equations used for describing the dissolution/precipitation reactions (Figure 1).

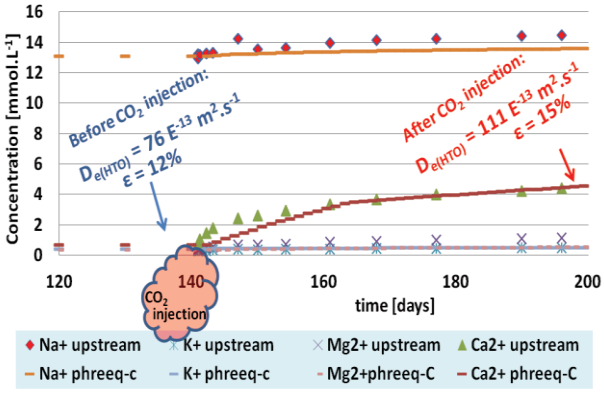

Figure 1: Comparison of experimental concentrations measured in the upstream reservoir with the simulated ones obtained by means of PHREEQC using rate equations from [2].

Can we use ice sheet reconstructions to constrain meltwater for deglacial simulations?

INGO BETHKE[12]*, CAMILLE LI[12] AND KERIM H. NISANCIOGLU[12]

[1]Bjerknes Centre for Climate Research, Bergen, Norway, ingo.bethke@bjerknes.uib.no (* presenting author)
[2]Uni Research, Bergen, Norway

Abstract

Freshwater pulses from melting ice sheets are thought to be important for driving climate variability. This study investigates challenges in simulating and understanding deglacial climate evolution within this framework, with emphasis on uncertainties in the ocean overturning sensitivity to meltwater inputs. The response of the model used in this study to a single Northern Hemisphere (NH) meltwater pulse is familiar: a weakening of the overturning circulation, an expansion of NH sea ice cover and a meridional temperature seesaw. Nonlinear processes are vital in shaping this response, and are found to have a decisive influence when more complex scenarios with a history of pulses are involved. For this study, a meltwater history for the last deglaciation (21-9 ka) was computed from the ICE-5G ice sheet reconstruction, and the meltwater was routed into the ocean through idealized ice sheet drainages. Forced with this meltwater history, model configurations with different freshwater sensitivities produce a range of outcomes for the deglaciation. Theses outcomes are determined by the thresholds for collapse and resumption of the overturning circulation, as well as the dependence of the sensitivity on the changing background climate. For all sensitivity configurations, there is a mismatch between the simulated deglaciation and proxy records, indicating that uncertainties in the meltwater scenario play an important role as well. This study illustrates that current uncertainties in model sensitivity to freshwater and meltwater reconstructions are limiting in efforts to forward-model deglacial climate variability using data-constrained meltwater forcing scenarios.

Strata-specific bacterial diversity in aquifers of the Thuringian Basin/Germany

A. BEYER[1;2*], M. LONSCHINSKI[2], E. KOTHE[1], G. BÜCHEL[2],

[1] Friedrich Schiller University, Institute of Microbiology-Microbial Phytopathology, Jena, Germany
andrea-beyer@uni-jena.de (*presenting author)

[2] Friedrich Schiller University, Institute of Applied Geology, Jena, Germany
georg.buechel@uni-jena.de
martin.lonschinski@uni-jena.de

The INFLUINS (Integrated fluid dynamics in sedimentary basins) project investigates coupled dynamics of near surface and deep flow patterns of fluids, transported materials and component substances in the Thuringian Basin. The extensive basin landscape is located in eastern Germany and belongs to the Triassic period of Bunter sandstone (Buntsandstein), shell limestone (Muschelkalk) and Keuper, which crop out at the surface. Older sediments and Permian (Zechstein) can be found at the edges of the basin. With microbial investigations, we are analyzing the bacterial diversity of ground- and mineral water at different locations to see whether there are special patterns in bacterial distributions originating from the different rock strata. This will facilitate understanding fluid movement in the Thuringian Basin. We determined bacterial diversity from water samples out of two natural springs and ten groundwater wells by cultivation and subsequent morphological, physiological and molecular identification. To elucidate differences to other rock strata, we compared these samples to two brine springs (4.62 M and 1.03 M salt content), located in Permian aquifers. First results show that the largest proportions were found to be members of Bacilli and γ- proteobacteria, including the genera *Pseudomonas* and *Bacillus*. Next steps will be a comparison of cultivation-dependent and cultivation-independent methods to gain further information on bacterial strains which where uncultivable or suppressed by other bacteria strains.

Trends in Solute fluxes across a 3.8 km elevation transection from Narayani river system in central Himalaya

M.P. BHATT, J. HARTMANN

KlimaCampus, University of Hamburg, Hamburg, Germany, maya.bhatt@zmaw.de

Chemical weathering is an integral part of the rock and carbon cycles and rates vary largely. To study the variability of chemical weathering rates and controls within a mountainuous system, the hydrochemistry along the Narayani basin in central Himalaya region has been sampled including glacial meltwater samples of the upstream Langtang glacier.

Cation composition of the water was dominated by carbonate and silicate dissolution. Preliminary results based on samples of the first months show that concentration of measured chemical parameters such as the sum of base cations, dissolved silica and alkalinity decreased exponentially with elevation (from 169 m to 3989 m). Contribution of sea-salt appeared negligible to the total mass of solute along the drainage network except for the lowermost elevation site. The export of sea-salt corrected sulfate at the outlet point of the Narayani river suggests pyrite dissolution as its main source. Thus the oxidation of sulfide minerals might regulate significantly the dissolution of minerals within the basin. Export of nitrate from the Narayani basin appeared many fold higher than observed fluxes in the Langtang sub-basin, located upstream in the upper Himalaya.

First results suggest that area specific cationic and silica weathering fluxes were comparable with previous reports from the region but appeared to be increased at lower latitudes if compared to the upper Himalayan section of the basin and the world average. Human influence, primarily agricultural activities, may have increased the rate to some extent. Preliminary results of the weathering advance rate of the basin, at the terminus of the Himalaya, also appeared increased compared to large river systems of the world [1, 2, 3]. Influence of controlling factors like relief, physical erosion rates, temperature and precipitation will be discussed.

Section Heading

Introduction This study aims to monitor the electron exchange interactions between the Fe(II,III) center and the different functional groups of cysteine (carboxylic, amine and thiol) with time using X-ray absorption spectroscopy. We present the XANES spectra of Fe(II,III)-cysteine complexes at all relevant absorption edges (Fe L-edge and C, N,O and S K-edges) collected at different times (0,2,10 and 12 months) after the initial synthesis of the complexes as well as the Fe K-edge EXAFS of Fe(II,III)-cysteine complexes, also as a function of time. The experimental results are compared with multiplet and quantum mechanical simulations, providing a detailed picture of the iron-ligand structure, co-ordination, and electron shuttling capabilities of the complex.

Results and Conclusion

The Fe L-edge XANES of Fe(III)-cysteine indicates an initial reduction of Fe(III) caused by an internal electron transfer reaction either from N of $-NH_2$ or S of -SH, both of which show oxidation in their respective spectral features. The N K-edge of Fe(II) cysteine at all time scales did not show much variation and is identical to the N spectrum of cysteine. The N of Fe(III) cysteine showed oxidation of N (to nitrate, a +5 oxidation state of N) at time scales 0, 10 and 12 months; however, at time=2 months the N spectral features resemble that of N in cysteine. The O K-edge spectra for Fe(II) cysteine shows a change in spectral pattern with passage of time whereas that for Fe(III) cysteine does not change much after the time of initial synthesis and had characteristics similar to that of O in cysteine. Oxidation of Fe(II) in Fe(II)-cysteine with time was accompanied by a simultaneous reduction of the C as revealed by the C K-edge features of Fe(II) cysteine. This is reflected in a reduction of the C which involves an electron exchange of the C within the unsaturated –COOH of cysteine. In contrast, the C K-edge features for Fe(III) cysteine show no variation with time. The S K-edge of Fe(II) cysteine show S oxidation states intermediate between sulfoxide and sulfate. Overall, spectral characteristics of Fe(II,III)-cysteine complexes suggest thiol/disulfide exchange, H-atom transfer, or electron transfer between Fe and cysteine. Our studies of the Fe(II,III)-cysteine system provide a mechanistic understanding of the electron shuttling that occurs between a redox active metal and a redox active ligand. In this particular case, cysteine represents an organic molecule with functionalities (O-, S-, N- functional groups) and a C backbone that may mimic the functional groups present in organic matter from terrestrial and aquatic environments.

High resolution rare earth element (REE) study on mussel shells, a proxy for the geochemical cycling at the coastal region?

NANXI BIAN[1*], PAMELA A. MARTIN [2], ALBERT COLMAN[1] AND CATHERINE PFISTER[3]

[1]Department of Geophysical Sciences, the University of Chicago, Chicago, IL, USA, nanxibian@uchicago.edu
[2]Department of Earth and Environmental Sciences, IUPUI, Indianapolis, IN, USA
[3]Department of Ecology and Evolution, University of Chicago, Chicago, IL, USA

Trace and minor element variations in biogenic calcium carbonate shells have been widely applied in reconstruction of past environmental conditions [1,2,3]. Successively deposited biogenic calcareous shells, such as mussel shells, may have the potential to provide high resolution records of temporally resolved variability to investigate changes in climatic configurations and/or geochemical cycling where instrumental records are non-existent. In our previous work, we developed a high precision analytical method, using laser ablation coupled with sector field inductively coupled plasma mass spectrometry (LA-ICP-MS), to obtain high resolution time series of a suite of element/Ca ratios for mussel shells [4]. Here, we investigate the potential of one species of mussels, *Mytilus californianus*, to provide high-resolution records of coastal geochemical changes.

Mussel shell samples used in this study are from Tatoosh Island, Washington, USA, a coastal upwelling region where 11 years of instrumental records are avaialble to calibrate shell chemistry on modern shells. Age models of the shells are anchored by stable isotope analysis on seasonally resolved micromilled shell material. An anti-correlated relationship between rare earth element (REE)/Ca and $\delta^{18}O$ is apparent upon comparison of the two records. A reliable shell age model is then constructed by combining both high resolution REE/Ca records and the seasonally resolved $\delta^{18}O$ records. Multi-Taper Method (MTM) spectral analysis was applied to identify significant quasi-periodic variability in shell REE/Ca records [5]. An intra-annual (3-5 cycles/year) periodic component has been identified in both modern and midden shells; similar periodic variability was also observed in the high resolution instrumental data for evironmental parameters, such as upwelling and temperature. Calculated Ce anormalies (Ce*), a proxy for redox state in the water column, show similar ranges of variations in modern and acient shells. Our results indicate REE/Ca ratios in mussel shells have the potential to serve as a proxy for the geochemical cycling at this coastal area and could possiblly offer hints for explaining the recent and dramatic pH declines at this location [6].

Molecular structure and acidity

BARRY BICKMORE[1]*, JOSHUA MAURER[1], AND KENDRICK SHEPHERD[1]

[1]Brigham Young University, Geological Sciences, Provo, UT, USA barry_bickmore@byu.edu (*presenting author), josh3996@gmail.com, kenear@gmail.com

Surface complexation models (SCMs) are often capable of fitting the same macroscopic data (e.g., titration data) by employing substantially different assumptions about molecular-scale reactions. This has been addressed by constraining SCMs with 1) more macroscopic data and information about molecular-scale processes obtained from 2) advanced spectroscopic techniques, 3) molecular modeling studies, and 4) quantitative structure-activity relationships (QSARs) like MUSIC [1]. All of these are reasonable, but even given the first three options, QSARs would still be necessary to provide a conceptual framework for interpreting the other types of results.

A problem with QSARs is that they assume only certain aspects of the molecular structure determine a particular type of reactivity. Sometimes, however, other structural features are important, but were roughly constant in the calibration set. E.g., MUSIC is calibrated on a certain set of (hydr)oxo-monomers, and assumes only the metal-oxygen bond valences and coordination numbers are important for determining functional group acidities. The model is then applied to the acidities of oxide surface functional groups, which are much more difficult to experimentally determine.

Are the MUSIC predictions always accurate for oxide surface functional group acidity, or are some important structural features missing from the model? Our previous work [2] used an expanded calibration set of solution monomers to show that in addition to bond valence and coordination number, the electronegativity of the metal atoms is also necessary to accurately predict acidity, but we provided no compelling structural explanation.

We are now assembling a complete potential energy model, based largely on the Bond-Valence Model (BVM), to guide development of QSARs based on the BVM. Our model combines the predictions of the VSEPR model of molecular geometry with the BVM, using the concept of bond valence vectors [3], along with van der Waals and electrostatic potentials to describe non-bonded interactions. So far, we have been able to show that changes in Me-H van der Waals potential energies due to structural relaxation are likely to be important for determining acidity in our calibration set of oxyacids, and that this effect is highly correlated with the electronegativity of the metal atoms. Thus, we have found a way to explain our previous results in structural terms, and a way to determine how an acidity QSAR based on bond valence, coordination number, and acidity might be successfully transferred to oxided surfaces. This kind of theoretical guidance for creating and transferring QSARs is essential for systems like mineral-water interfaces, where it is often difficult to check the veracity of model results at the molecular scale.

Very fast silicic magma genesis in caldera and rift environments based on isotope zoning in zircons, experiments, and thermal modeling

BINDEMAN IN[1]*, LUNDSTROM C.[2], SCHMITT AK[3], SIMAKIN[4] A., SELIGMAN A.[1] AND DREW D[1]

[1]Geol Sci, Univ of Oregon, Eugene, USA, bindeman@uoregon.edu (*presenting), [2]University of Illinois, Urbana-Champaign, IL, USA, [3]Earth Space Sci, UCLA, Los Angeles, CA, USA, [4]Inst Physics Earth, Moscow, Russia

Large-volume sub-liquidus silicic rocks are erupted in caldera environments with short repose time. Modern in situ isotopic methods have recently permitted analysis of isotopic and trace elemental abundances on micron to smaller scale and demonstrate strong crystalline heterogeneity. We review recent discoveries of isotopically (O, U-Pb) zircons in large volume ignimbrites (Snake River Plain, Kamchatka, and Iceland).

We report results from a long-duration isotope exchange experiment with natural zircon and rutile that was held for 4 months at 850°C and 0.3 kbars in a silica-rich solution doped with ^{18}O, ^{2}H, ^{7}Li and ^{10}B. The length-scales of in-diffusion were examined by depth profiling using time-of-flight (TOF) and Cameca 1270 high-sensitivity dynamic SIMS. Rutile and zircon developed ~2 μm and ≤0.13μm Fickian profiles, respectively, suggesting that rutile diffusion coefficients were at ~400 times greater than zircon's, and both are consistent with the wet diffusion coefficients for zircons and rutiles reported by Watson and Cherniak (1997) and Moore et al (1998). These results are relevant for interpreting timescales of magma evolution, in particular those related to controversial sharp intra-crystal zircon oxygen isotopic gradients. We instead consider sharp boundaries to be related to rapid episodes of solution-reprecipitation that outpace diffusive exchange, and generate concave-up zircon crystal size distributions (CSDs). Isotopic profiles in natural zircons will translate into 100-1000 yrs residence and characterize 100-1000 km^3 volumes of near-liquidus magmas.

Given diffusive-equilibration and recrystallization timescales, these new results call for very fast magma segregation from diverse in $\delta^{18}O$ hydrothermally-altered protoliths, occuring rapidly at shallow depths. As oxygen is a major component of silicates and oxides, isotopic variation of several permil reflect tens of percent of mass addition. Isotopic diversity in zircons spanning 2-7‰ $\delta^{18}O$ characterize near-liquidus magmas of 100-1000km^3 volume. Coexisting high, normal and low-$\delta^{18}O$ zircons indicate contributions from diverse protoliths, and convective mixing on 10^2-10^3 yr. timescales comparable to mineral-diffusive, solution-reprecipitation, and crystal size distribution timescales. Modeled convective rates of silicic magmas are fast enough to homogenize ~1000 km^3 magma over 10^4 yr. timescales.

Numerical experiments demonstrate the feasibility of rapid (10m/yr) convective melting rate which may translate into >10km^3/yr magma production rates over spatial dimensions of typical calderas. We suggest that neither conductive cooling nor hydrothermal refrigeration are capable of dissipating heat sufficiently fast to prevent catastrophic melting.

Evidence for a mid-crustal channel flow during the Sveconorwegian orogeny of Baltica ?

B. BINGEN [1*], G. VIOLA [1,2], K. YI [3] AND A.K. ENGVIK [1]

[1]Geological Survey of Norway, 7491 Trondheim, Norway, bernard.bingen@ngu.no (* presenting author)
[2]Norwegian University of Science and Technology, 7491 Trondheim, Norway, giulio.viola@ngu.no
[3]Korea Basic Science Institute, 363-883 Chungbuk, South Korea, kyi@kbsi.re.kr

New structural, petrological and SIMS U-Pb zircon data from SE Norway suggest that a mid-crustal channel flow may have developed during the main Sveconorwegian orogenic phase at the margin of Baltica. The 500 km wide Sveconorwegian orogen is interpreted as the product of a hot and long-lived, polyphase, bivergent orogeny, resulting from the collision of Baltica with another major plate (Amazonia, Laurentia) at the end of the Mesoproterozoic. The Sveconorwegian orogen is built on Mesoproterozoic crust that youngs toward the west. The orogeny followed a voluminous 1200-1130 Ma bimodal, within-plate magmatism in the west, more extensive than previously assumed. High-pressure (HP) metamorphic rocks are only recorded in the east of the orogen. These three observations suggest a warm lithosphere at the onset of orogeny, increasingly warmer toward the west. At around 1080 Ma, Bamble and Kongsberg were thrusted westwards on top of Telemark marking the onset of collisional tectonics. The main orogenic phase started at c. 1050 Ma. In the Idefjorden terrane, HP granulite-facies mafic boudins and kyanite gneisses locally record conditions of c. 930 °C - 1.3 GPa at c. 1050 Ma. This was followed by widespread LP amphibolite-facies partial melting. Leucosomes associated with top-to-the-west regional kinematics and resulting from muscovite-, biotite- and amphibole-dehydration melting of orthogneiss and paragneiss, range in age from 1039 ± 17 to 997 ± 16 Ma, as provided by low-U zircon rims. This partial melting episode was coeval with metamorphism along the Vardefjell shear zone bounding the Idefjorden terrane in the west, and coeval with widespread syn-collisional granitic plutonism and LP amphibolite- to granulite-facies metamorphism in the west of the orogen in Rogaland-Vest Agder. The reported long-lived high-grade conditions suggest development of a mid-crustal west-directed (?) channel flow activated after c. 1040 Ma, probably associated with a slowly eroding orogenic plateau. Lack of foreland basins to the east of the orogen is consistent with west directed flow. In this model, the low-grade Telemark supracrustals may belong to a shallow orogenic lid, covering a large area in the centre the orogen and characterized by deposition of immature sediments in grabens (Eidsborg Fm <1118 Ma, Kalhovde Fm <1065 Ma). At c. 980 Ma, the Sveconorwegian orogeny propagated eastwards in the footwall of the arcuate, southeast-verging, "Mylonite Zone" back-thrust, leading to eclogite-facies metamorphism in the Eastern Segment. Convergence was followed by gravitational collapse after c. 970 Ma. High-grade LP conditions were maintained in Rogaland-Vest Agder until c. 930 Ma and were associated with voluminous post-collisional plutonism, including anorthosites.

Isotopic fractionation between Cr^{3+} species in aqueous solutions

JEAN LOUIS BIRCK[1*], TU-HAN LUU[1,2], AND ROXANE JOURDAIN[1,3]

[1]IPGP, Paris, France, birck@ipgp.fr (*presenting author)
[2] luu@ipgp.fr
[3]roxanejourdain@gmail.com

When chromium is oxidized from the 3+ to the 6+ state, the 6+ species displays a δCr_{53-52} of up to 7 permil ($^{o}/_{oo}$) relative to the 3+ state [1-3]. Here we show that large fractionation predicted by theory [4] within the same oxidation state (3+) can also be evidenced. Cations are present in different species which result from the interaction with the anions present in the solution. Chromium has the property similar to only a few other elements (e.g. Os) that coexisting species do not re-equilibrate immediately when the medium changes (e.g. by dilution or by addition of an acid). In contrast to most cations which interact instantaneously with the aqueous solvent, Cr^{3+} requires several days at room temperature in HCl solution for the different species to reach equilibrium.

Procedure

This property which is usually a drawback for a clean separation of Cr from other elements [5] can be used for identification purposes as described in the following. A chromium III standard solution was made in HCl 6N to produce easily measurable amounts of chlorocomplexes and was left for several days to reach equilibrium. A chromatographic separation [5] was achieved in less than 30mn to avoid significant kinetic isotopic effects. The isotopic ratios of the different hydrated chlorocomplexes as well as the Cl free hydrated $[Cr(H_2O)_6]^{3+}$ cation were measured by high precicion MC-ICPMS at medium mass resolution (ca 4000) with a precision of $0.05^{o}/_{oo}$.

Results and conclusion

The $[Cr(H_2O)_6]^{3+}$ species shows an excess in δCr_{53-52} of 2.37 ± 0.05 $^{o}/_{oo}$ relative to the starting Cr solution. $[CrCl(H_2O)_5]^{2+}$ displays a deficit in δCr_{53-52} of -0.03 ± 0.05 $^{o}/_{oo}$. The higher complexes $[CrCl_x(H_2O)_{(6-x)}]^{(3-x)+}$ x>1 which have not yet been resolved in the chemical separation display alltogether a deficit of δCr_{53-52}: -0.39 ± 0.05 $^{o}/_{oo}$. HBr and H_2SO_4 media have also been investigated; they yield negative values for $[Cr(H_2O)_6]^{3+}$ which are interpreted as being dominated by kinetic effects during the hydrolysis of the anion-chromium complexes.

The results for the HCl media are in a first order agreement with the theoretical estimates of Schauble et al. [1]. Whether the significant fractionation that may occur in solutions within the Cr^{3+} oxidation state has an impact in natural samples has to be investigated.

The solubility of amorphous aluminous silica between 100 - 350°C: Implications for scaling in geothermal power stations

JULIA. K. BJÖRKE [1, 2 *]; BRUCE. W. MOUNTAIN [2]; TERRY. M. SEWARD[1]

[1]Victoria University, Wellington, New Zealand, j.bjorke@gns.cri.nz (*presenting author), terry.seward@vuw.ac.nz
[2]GNS Science, Wairakei Research Centre, Taupo, New Zealand, b.mountain@gns.cri.nz

Scaling is a common problem in geothermal power plants. In particular it occurs from brines where minerals become saturated and precipitate. To prevent scaling, geochemists use thermodynamic modelling to apply treatment methods, such as adjusting temperature or pH. Amorphous aluminous silica scaling has been reported in many geothermal power plants such as in New Zealand, Philippines, Salton Sea, Japan and Iceland [1]. Currently, the sole study on the solubility of amorphous aluminous silica was carried out by Gallup 1998 [2]. These were simple batch experiments in which there was no control on pH or Al concentration. A general reaction can be written for the precipitation of this phase as:

$$xH_4SiO_4 + yAl(OH)_4^- + yH^+ = xSiO_2.yAlO_{1.5} + (2x + 2.5y)H_2O.$$

Unlike amorphous silica precipitation, this reaction is pH and Al concentration dependent over a wide region of pH. Unfortunately, there have been no well-controlled experiments to determine thermodynamic data for this reaction.

Preliminary calculations, using the data of Gallup 1998 [2], were used to estimate the solubility of amorphous aluminous silica and compare it with the solubility of pure silica. These show that scaling, caused by amorphous aluminous silica, can occur at temperatures up to 50°C higher than for pure silica, based on the chemistry of a cooling, flashed Ohaaki brine.

Four samples of amorphous aluminous silica scale were collected from Wairakei and Ohaaki geothermal power plants. XRD, XRF and SEM analyses were carried out on the samples and to verify that Al was not present as a distinct Al phase from the amorphous silica. Results from the XRD analyses showed amorphous material with quartz peaks in all samples. XRF results show concentrations of SiO_2 ranging from 73.89-76.70%, Al_2O_3 from 8.38-10.46%, K_2O from 2.13-3.05%, Na_2O from 1.72-2.15%, CaO from 1.08-2.13% and MgO from 0.06-1.99%. Other oxides were less than 1% of the total sample. XRD results and EDX mapping by SEM verified that Al is present within the silica and is not in a distinct phase. Al concentration is zoned and correlates with increases in alkali concentration.

Experiments are planned to investigate the solubility of amorphous aluminous silica in the temperature range 100 - 350°C. These will be conducted at saturated vapor pressure and with varying pH using a continuous flow-through system and batch reactors.

Oxygen consumption by granite samples under sterile glacial melt water conditions

EVA BJÖRKMAN[1], DAQING CUI[1,2], AND IGNASI PUIGDOMENECH[3*]

[1]Mat. & Env. Chem., Stockholm University, Stockholm, Sweden, eva.bjorkman@mmk.su.se (* presenting author)
[2]Studsvik, Nyköping, Sweden, daqing.cui@studsvik.se
[3]Swedish Nuclear Fuel and Waste Management Co (SKB), Stockholm, Sweden, ignasi@skb.se

Background

During future glacial periods in Fennoscandia it may not be excluded that, at least temporarily, increased groundwater recharge and flows may occur. The glacial melt water may have large amounts of dissolved O_2, and this might affect the stability of spent nuclear fuel canisters in the repositories planned in Sweden and Finland [1]. Several processes are able to remove dissolved oxygen: reactions with Fe(II) and sulphide minerals in the rock matrix and in fracture fillings and microbial processes consuming CH_4 or DOC [2].

As the availability of microbial substrates might be substantially reduced during glacial periods, there is a need to confirm the consumption of O_2 by abiotic reactions with Fe(II) minerals. The relative importance of inorganic and microbial processes is difficult to obtain unless special precautions are taken [3,4]

Experimental details

Batch experiments were performed at ~22°C under sterile conditions in serum bottles filled with minerals, MQ sterilized water and a gas phase containing N_2 at ~1.3 bar to which a known amount of air was added. The O_2 in the head-space gas was analyzed for up to 727 days by GC, using the Ar in the injected air as reference.

Two different rock types were used: a quartz monzodiorite and a fine-grained granite with several size fractions ranging between 0.25 and 10 mm. A chlorite sample was used as a Fe(II)-rich reference mineral, and quartz and pure water as un-reactive controls. The materials were characterized by BET, pore size distribution, Mösbauer, and chemical analysis.

Results and Conclusions

The quartz and water samples showed stable O_2 concentration within ±500 ppm while oxygen decreased to different degrees in the rock samples and it was completely exhausted in the chlorite experiments demonstrating oxygen consumption by Fe(II) under sterile conditions. The importance of the surface area is evidenced from the reaction rates expressed as "moles O_2 day^{-1} m^{-2}" which overall vary between -2.7×10^{-8} and -1.3×10^{-8} independent on mineral type, iron content or size fraction used.

The rates obtained are comparable to previous laboratory studies and support the long-term safety evaluation [1] of spent nuclear fuel repositories during glacial periods.

A thermal and erosional history of cratonic lithosphere over billion-year time scales

TERRENCE BLACKBURN[1*], SAMUEL BOWRING[1], TAYLOR PERRON[1], KEVIN MAHAN[2], FRANCIS DUDAS[1]

[1]EAPS, MIT, Cambridge, MA, USA (*correspondance: terrence@mit.edu)
[2] Dept of Geol. Sci., Univ. of CU Boulder, CO, USA

The continental lithosphere contains the oldest and most stable structures on Earth, where fragments of ancient material have withstood destruction by tectonic and surface processes operating over billions of years. Though present-day erosion of in these remnants is slow, a record of how they have uplifted, eroded and cooled over Earth's history can provide insight into the composition and density of the continents and forces operating to exhume them over geologic time. Because the exhumation or burial of the Earth's surface has a direct effect on the rate of heat loss within the lithosphere, a continuous record of lithosphere exhumation can be reconstructed through the use of a temperature-sensitive radiometric dating technique known as thermochronology. The combination of thermochronologic data with thermal models for heat transfer in the lithosphere can be used to measure the processes operating to cool or heat the lithosphere in the geologic past. Thermochronologic systems sensitive to cooling at high temperatures is insensitive to the "noise" associated with near-surface cooling and therefore provides a measure of the background rate of erosion or burial associated with the vertical motions of a craton. The U-Pb thermochronologic system is sensitive to cooling at temperatures of ~400-650 °C, corresponding to lower crustal depths in cratonic regions of ~20-50 km. Here we utilize this technique to reconstruct an ancient and long-lived thermal history of volcanically exhumed lower crustal fragments, samples that resided at depth for billions of years before recent volcanism transported them to the surface as xenoliths. A high fidelity reconstruction of time-temperature paths for these samples is produced using the U-Pb system's dual decay scheme, where parent isotopes 238U and 235U decay at different rates to daughter isotopes 206Pb and 207Pb, respectively. Coupling this dual isotopic system with diffusion's length scale dependency, which causes different crystal sizes to retain Pb over different absolute time scales, results in a set of daughter isotopic compositions for a range of crystal sizes that is unique to the time-temperature history of the sample. Combining these measurements with thermal and Pb-diffusion models constrains the range of possible erosion histories. Measured U-Pb data are consistent with near zero erosion rates persisting over time scales approaching the age of the continents themselves. This indicates that the isostatic balance observed in the present-day continents has been largely maintained over geologic time, extending back at least to the onset of cooling within each terrane. Since this stability was first meet, the craton has experienced a balance between erosion and burial, with a corollary balance between the lithosphere's internal buoyancy forces and near zero isostatic uplift, further indicating a minimal change in the relative densities of the lithosphere and mantle over intervals lasting billions of years.

In shallow parts of sedimentary basins, low-temperature diagenetic processes (<90-100°C) produce discrete mineralogical changes on both the carbonates and clays. These processes are somehow challenging to investigate as most of the geothermometers are at their application limits. Furthermore, the low concentrations of trace elements in the newly-formed minerals (e.g., REE in fluorite, U in calcite) complicate the dating attempts. In this context, this study presents petrographic and geochemical data acquired on secondary minerals filling the fractures, vugs and primary porosity of three aquifers of the Mesozoic sedimentary sequence from Paris Basin, France.

The Oxfordian and Middle Jurassic limestone aquifers located respectively above and below Callovian-Oxfordian claystones are essentially cemented by successive stages of blocky calcite. Isotopic tracing ($\delta^{18}O$, $\delta^{13}C$ and $^{87}Sr/^{86}Sr$) and data acquired on hosted fluid inclusions (salinity, δD of paleo-fluids) reveal that the physical-chemical properties of calcite-forming waters were rather different for each of the aquifers and from present-day groundwaters. The aquifer located in Lower Triassic siliciclastic sedimentary rocks is buried at a 2000m depth and evidences a diagenetic alteration, among which quartz overgrowth, adularia precipitation and widespread illitization. Illite nanometric particles (<0.02 and 0.02-0.05 μm fractions) were separated, analyzed (DRX, EDS microprobe, $\delta^{18}O$, $^{87}Sr/^{86}Sr$) and K-Ar dated. Two ranges of K-Ar ages were obtained: 183 ± 2 Ma (2 samples), 150 ± 2 Ma (7 samples) and an additional age at 116 ± 2Ma. All ages are consistently younger than the Triassic sedimentation. They further strongly suggest that at least two mineralizing fluid flows occurred before the maximal burial of the sediments (Upper Cretaceous). These ages fit with the identified episodes of successive opening stages of the central Atlantic Ocean where increasing heat flows and associated fluid circulations have induced: (i) several Pb-Zn-F-Ba mineralizations along the margin of the basin, and (ii) extensive illitization in Triassic and Permian sandstones in many locations of Western Europe.

The study shows also that each studied aquifer underwent an individual and specific diagenetic history that highlights the role of the Callovian-Oxfordian claystones as an efficient hydrological barrier between the limestone units. This effective isolation is of major engineering importance as these claystones represent the currently studied target for a long-term geological disposal of radioactive waste.

Complementarity of computational molecular modelling and experimental techniques to study trace elements geochemistry

MARC BLANCHARD[1*]

[1]IMPMC, UPMC, CNRS, 4 place Jussieu, 75252 Paris Cedex 05, France, marc.blanchard@impmc.upmc.fr (* presenting author)

Chemical reactions at the interfaces between soils components and water play an important role in numerous natural processes, like in particular the fate and behaviour of potentially toxic trace metals. One efficient approach has recently emerged to address this question. It consists in the combination of X-ray absorption spectroscopy (XAS) and isotopic techniques. Besides this experimental approach, computational molecular modelling can also contribute significantly to improve our understanding of the atomic-scale processes that control the biogeochemical cycles of trace elements. This presentation will expose the complementarity of both experimental and theoretical approaches. Within the same theoretical framework, it is now possible (i) to calculate the local structural and electronic properties of any atom in the studied system and compare these properties with XAS data, (ii) to model XANES spectra, which allows a better interpretation of spectral features, and (iii) to determine the equilibrium fractionation factors of traditional as well as non-traditional isotopes, associated with any structural site of the system. Several applications will be presented, including the arsenic adsorption complexes at the hematite surface [1], the calculated XANES spectra of 3d transition metal compounds [2], and the isotopic properties of Al- and OH-bearing hematite [3].

Time-resolved SAXS study of nucleation and growth of iron(III) oxyhydroxides

MARK W. BLIGH[1*], ANDREW L. ROSE[2], RICHARD N. COLLINS[1], AND T. DAVID WAITE[1]

[1]University of New South Wales, Sydney, Australia, m.bligh@unsw.edu.au (*presenting author), d.waite@unsw.edu.au, richard.collins@unsw.edu.au

[2]Southern Cross University, Lismore, Australia, andrew.rose@scu.edu.au

Introduction.The process of hydrolysis and polymerization of Fe(III) oxyhydroxides plays an important role in the chemistry of natural waters. However, these transformations are rapid and occur over timescales that are much smaller than those typically studied. Time-resolved SAXS studies provide the capacity to investigate nucleation and the evolution of particle size distribution on a sub-second timescale. Different mechanisms of particle production have previously been identified, for example, a nucleation burst followed by monomer addition [1] and, nucleation followed by aggregation [2]. In this study we use TR-SAXS to examine polymerization of Fe(III) oxyhydroxides following rapid mixing, such that mixing times are less than reaction times. In this initial study, at [Fe] = 1 mM, required to produce sufficient scattering intensity, reaction times were sufficiently long only at pH 3 and 4. Investigation of higher pHs will require the optimization of a micro-fluidic device.

Results and Conclusions. The SAXS curves were analysed, both directly and by fitting a pair distance function, to produce values for the invariant Q, zero-angle scattering intensity $I(0)$, and radius of gyration R_g. Q is a measure of the total scattering mass while $I(0)$ is sensitive to particle size and number. At pH 3, with $[NO_3]$ = 6 mM, R_g stabilized at ~25 nm after only 30 s while both Q and $I(0)$ continued to increase till ~300 s. At times >300 s, Q was relatively stable while $I(0)$ decreased. In the same system at pH 4, R_g followed the same pattern as for pH 3, however maximum values for Q and $I(0)$ were attained after ~77 s, and decreased thereafter. These results show that at early times, small but increasing numbers of maximum sized particles coexisted with monomers or oligomers that were too small to scatter significantly in the q-range used to calculate Q. Such a system evolution implies that slow nucleation and relatively rapid particle growth proceeded concurrently until the maximum scattering mass was achieved. Particle growth appears to have occurred via a monomer addition mechanism ('monomers' here may be oligomers) since the stable R_g implies that significant aggregation is not occurring. The more rapid development of the maximum scattering mass at pH 4, compared to pH 3, is consistent with a higher rate of polymerisation of Fe(III) hydrolysis species and therefore more rapid production of stable nuclei. Whether the observed decreases of Q and $I(0)$ following attainment of maximum values are due to sedimentation or further transformation via dissolution and reprecipitation remains unclear and will be the subject of further investigation.

Introduction

Essential to an understanding of metamorphic rocks are the rates at which a metamorphic reaction can occur. Kinetics of porphyroblast crystallization includes rates of both growth and nucleation. Though some studies have been able to quantify growth rates, direct measurements of nucleation rates have remained enigmatic. We present a method to indirectly measure nucleation as well as growth rates of chemically zoned porphyroblasts by linking chemical and age data.

This project examined a garnet + muscovite + paragonite + biotite + chlorite + quartz + plagioclase schist from the Pinney Hollow formation at Townshend Dam, VT. Biotite-quartz-rich layers alternate with muscovite-paragonite-rich layers on a millimeter scale and define the foliation. Garnets are sub- to euhedral, vary in size from 5 to 30 mm in diameter, and display curved quartz inclusion trails continuous with foliation at the rims.

Method

The specimen was imaged in 3D using high-resolution X-ray computed tomography. Garnet porphyroblasts were extracted and portions of them with quantified Mn content underwent Sm-Nd geochronology methods to produce a Mn-age curve for the rock [1]. A subvolume from the interior of the specimen was separated and disaggregated, allowing extraction of 62 garnets. Morphological centers of each were exposed, polished, and chemically mapped (via SEM-EDS). The EDS characterization facilitated location of peak-Mn regions, from which core-rim linescans were performed via EPMA for quantitative zoning determination. Mn data were converted to ages via reference to the Mn-age curve [1], allowing determination of nucleation and growth kinetics.

Results

Townshend Dam garnets show concentric, smooth Mn zoning curves. Microprobe analyses yield central garnet MnO content ranging from 2.3 to 11 wt%, depending on the size of the garnet. Rims of garnets are Mn-poor with ca. 0.1 to 0.2 wt% MnO. Data collection is ongoing, but preliminary EPMA results indicate that among the analyzed garnets, the range of core X(Mn) is 0.047-0.249, corresponding (via the curve in [1]) to an age range of 384.8-378.1 Ma. Given this duration of nucleation (6.7 m.y.), the number of garnets (62), and the subvolume size (1210 mm^3), we calculate a nucleation rate of approximately 0.0076 nuclei per m.y. per mm^3.

Influence of alkalinity on the magnesium composition of amorphous calcium carbonate

CHRISTINA BLUE[1*], NIZHOU HAN[1], AND PATRICIA DOVE[1]

[1]Virginia Tech, Department of Geosciences, Blacksburg, USA cblue@vt.edu (*presenting author)

An increasing number of studies are showing that many calcifying organisms form skeletons by nonclassical growth. This biomineralization process begins with the accumulation of an amorphous precursor phase that subsequently transforms to an organic-mineral composite. Little is known about mineralization by this pathway because the last 50 years of research have focused almost entirely on traditional, step-growth processes.

To investigate the factors that influence the composition of amorphous calcium carbonate (ACC) and quantify their effects, we have developed a procedure for synthesizing this phase under controlled chemical conditions. The method uses a flow through reactor and high precision syringe pumps to prepare ACC from solutions that maintain a constant supersaturation and a well-characterized solution chemistry. This approach confers significant advantages over previous approaches such as the "Koga" method [1], that uses very high pH solutions (11.2–13.5), and the "ammonium carbonate" method [2], that produces highly variable supersaturation conditions and introduces significant amounts of ammonium ion to the mineralizing solution.

Using the new flow-through method, we are investigating the effect of alkalinity on the magnesium content of calcite that forms via the ACC intermediate phase. Previous studies have suggested that the magnesium levels in biogenic calcite may be correlated with the alkalinity of local growth environment [3]. The first phase of this project determined the effect of alkalinity on the magnesium content of the ACC at 24–25°C. The experiments were conducted by preparing two sets of syringes that contained solutions of 1) variable alkalinity using 40mM–150mM $NaHCO_3$ and 2) a 5:1 ratio of Mg:Ca (modern seawater) using $MgCl_2 \bullet 6H_2O$ and $CaCl_2 \bullet 2H_2O$. For the range of alkalinities used in this study, the effluent pH was 9.0–9.3. After achieving steady state output conditions, the ACC products were collected on 0.20 micron nylon mesh filter and characterized using SEM, Raman Spectroscopy, and ICP-OES. Future work will also determine the effect of alkalinity on the composition and structure of calcite that forms by the ACC pathway.

[4] Geoglobal Energy LLC, Santa Rosa, California, USA.

Volcanically-hosted geothermal energy is an important resource in Indonesia of which Salak Geothermal Field in W Java is the largest developed one [1]. All 5 power-producing plants on Java are located in the western and central crustal sectors [1] and there appears to be a correlation between the location of commercially-viable geothermal systems, such as Salak Geothermal Field, and the thickness of the local upper crust and/or the volume of sediment on the downgoing plate [2]. This implies that crustal input from the subducting slab or from upper crust is central to the development of productive geothermal resources in this part of the world. Java's upper crust can be divided into three lateral segments: thick crust of continental affinity in the west [3], grading into arc-type and oceanic crust in central Java into increasingly oceanic affinity eastwards [3; 4].

Here we combine He isotope data from gas, fluids, pyroxene separates and whole rock Sr and Nd isotope values from volcanoes along the Sunda Arc (from Anak Krakatau to Bali, East of Java) with literature data to further understand sources to the crustal contamination signals and their influence on geothermal systems.

Helium isotope values (in R/R_A notation) are lower in both crystal and geothermal samples (down to $3.4R_A$ in pyroxene at Gede volcano) in the central and western crustal sectors, when compared to the eastern sector (7.46 R_A from fumaroles at Kawah Ijen volcano). Equally, Sr (as demonstrated by [5]) and Nd vary systematically eastwards along the arc, with values showing a significant crustal influence in central and western Java. East of the Progo-Muria fault, which delineates the central and eastern crustal sectors, volcanic rocks and geothermal samples give a more mantle-like signal (i.e. in eastern Java and Bali). The correlation between upper crustal type and crustal contamination is present in all three isotope systems (He-Sr-Nd). Together with the location of all commercially productive geothermal plants in west and central Java we propose that regional crustal influences may be highly relevant in understanding the development of geothermal systems with exploitation potential in Indonesia.

Reconstruction of the North Atlantic Circulation back to the Last Interglacial by a combined proxy approach

E. BÖHM[1]*, J. LIPPOLD[1], M. GUTJAHR[2], J.GRÜTZNER[3], A. MANGINI[1]

[1] Heidelberg Academy of Sciences, INF 229, Heidelberg, Germany

Jens.Gruetzner@awi.de

Studies of past variations of the Atlantic Meridional Overturning Circulation (AMOC) are essential for evaluating possible future developments. In order to asses such past variations two new proxies (Nd isotopes and $^{231}Pa/^{230}Th$) have been applied frequently in recent years, but only two combined data sets are available to date [1,2]. The combined use of Fe-Mn oxyhydroxide-derived Nd isotopes (ε_{Nd}), a sensitive chemical water mass tag, and $^{231}Pa/^{230}Th_{xs}$, a kinematic circulation proxy, from identical sediment core samples allows to obtain information about both the rate of overturning circulation and water mass provenance.

Here we present neodymium isotope compositions of past seawater and $^{231}Pa/^{230}Th$ extracted from sediments from a high sedimentation rate location (< 10 cm/ka) in the western North Atlantic (ODP Site 1063, Bermuda Rise), back to the Last Interglacial (Eemian).

First measurements of ε_{Nd} have been accomplished for the time range from 53 to 150 ka with a temporal resolution averaging 3 ka. The Nd isotopic record suggests the presence of Southern Source Water during MIS 6 to MIS 6.4 as well as active deep water formation in the North Atlantic at the beginning of the Eemian Interglacial (MIS 5.5). The transition between these two different modes in AMOC is marked by a distinct drop in the ε_{Nd} values (-11.5 to -14). This is consistent with ε_{Nd} results from [1] and [2] at the transition from MIS 2 to MIS 1.1 which implies recurring millenial-scaled identical processes converting the AMOC from a Glacial mode into an Interglacial mode.

Numerous measurements of Pa/Th have been performed in the time range from 65 to 143 ka with a high temporal resolution (1 ka or less). Results show that the Pa/Th method reaches its detecting limit at 125 ka due to the short half life of ^{231}Pa ($T_{1/2}$=33 ka). The interval between 95 and 125 ka displays strong fluctuations (Pa/Th=0.046 to 0.079) with one pronounced peak at 119 ka (Pa/Th=0.095) indicative of a slowdown of the AMOC (no corresponding peak in opal). This is consistent with [3] who found a short cold event with near-glacial surface ocean summer temperatures in MIS 5.5.

Fe(II)-mediated reduction of Cr(VI) and U(VI) in the presence of Fe(III) oxyhydroxides

DANIEL D. BOLAND[1*], RICHARD N. COLLINS[1], CHRIS J. GLOVER[2], TIMOTHY E. PAYNE[1,3] AND T. DAVID WAITE[1]

[1]School of Civil and Environmental Engineering, The University of New South Wales, Sydney, Australia, daniel.boland@student.unsw.edu.au. (* presenting author)

[3]Institute for Environmental Research, Australian Nuclear Science and Technology Organisation, Lucas Heights, Sydney, Australia.

Reduction of both Cr(VI) and U(VI) generally leads to the precipitation of insoluble phases and, thus, decreases the mobility of these toxic metals. In this study we examined the reduction of Cr(VI) during the Fe(II)-catalysed transformation of ferrihydrite to goethite, and compared the results to our previous experiments examining U(VI) reduction in the same system [1].

Cr(VI) was sorbed to ferrihydrite, silica-coprecipitated ferrihydrite (Si-ferrihydrite) and goethite in pH 6.5 buffered solutions in the form of CrO_4^{2-}, and Fe(II) added at 1mM. Cr K-edge X-ray absorption spectroscopy (XAS) analyses of the resultant solids showed that there was an immediate reduction of Cr(VI) to Cr(III) under all treatments (Figure 1), preceding any changes to the Fe(III) oxyhydroxide initially present. This contrasts to U(VI) in the same system, whose reduction is dependent upon the presence of goethite. Ferrihydrite continued to transform to goethite as expected, which has implications for the reactivity of this now Cr-bearing substrate.

These results are consistent with what may predicted by the relative positions of Cr and U in the "redox ladder". They emphasise the validity of using localised thermodynamic calculations to predict the redox state of trace species present during Fe(II)-catalysed Fe(III) oxyhydroxide transformations.

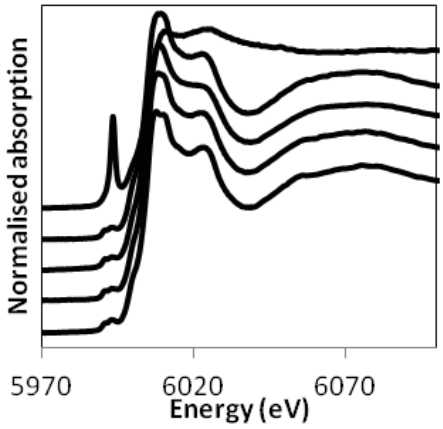

Figure 1: Cr K-edge XAS data. From top: Cr(VI) sorbed on ferrihydrite, following reaction with Fe(II) on ferrihydrite, Si-ferrihydrite and goethite, Cr (III)-substituted Fe(III) oxyhydroxide. Reduction is clear from the diminished pre-edge feature.

Introduction

A strong biological control over trace element or stable isotopic composition of marine biominerals is frequently viewed as a liability in reconstructing past ocean chemistry and temperature, and the significance of reconstructing the biological processes themselves is often overlooked. We propose that the chemistry of opal, produced by diatoms, and calcite, produced by coccolithophorids, predominantly reflects key biological processes for cellular carbon acquisition. Reconstruction of these biological processes in the past will reveal how marine algae responded to changes in atmospheric CO2, key to both the past and future carbon cycle.

Biomineralization effects on stable isotopes in coccoliths

Coccolithophorids exhibit strong biological effects in carbon and oxygen isotopic composition. Previously we hypothesized that the size-correlated range of vital effects in carbonate liths produced by different coccolithophore species was due to variable significance of carbon concentrating mechanims in their C acquisition. Our new culture experiments with coccolithophorids reveal strong plasticity in the magnitude of stable carbon isotope vital effects in coccoliths of *Calcidiscus leptoporus* and *Emiliania huxleyi* with variable CO_2. At high CO_2 coccoliths of both species are more isotopically enriched, but the magnitude is greater in *C. leptoporus* leading to reduced interspecific offsets at high CO_2. In the case of *E. huxleyi*, higher CO_2 conditions resulted in significant reduction in the magnitude of DIC accumulation in the intracellular carbon pool, and more positive carbon isotopic values inside the particulate organic matter. A model of carbon acquisition incorporating both photosynthetic and carbonate production is used to assess mechanisms for these relationships. Stable isotope data from size-separated deep-sea sediments dominated by small, intermediate, and large coccoliths show a range of vital effects which is distinct during several major Cenozoic proxy-inferred climate-CO_2 transitions. Furthermore, where vital effects are significant their magnitude scales with coccolith size in the same sense as modern cultures.

Biomineralization effects on diatom B content

From two species of diatoms, *Thalassiosira weissflogii* and *T. pseudonana*, cultured at a range of pCO_2 from 200 to 2000 ppmv, B content of cleaned diatom opal was measured by Laser Ablation-ICP-MS and Secondary Ion Mass Spectrometry. Determination of growth rate, type of carbon acquired, and silicon and carbon quotas during diatom growth provides data on biomineralization process. B content in *T. pseudonana* is correlated with bicarbonate uptake rate and with normalized Si quotas. For *T. weissflogii*, which is a bicarbonate-restricted user at the pH studied, B content seems to be regulated primarily by the borate/bicarbonate seawater ratio, at pCO_2 <1000ppmv . We present a simple cellular model of B and Si uptake by diatoms to quantitatively explore the mechanisms for variable B content and its potential as a proxy.

Oceanic Material recycled within the Subpatagonian Lithospheric Mantle (Cerro del Fraile, Argentina)

B. FACCINI[1] , C. BONADIMAN[1*], M. COLTORTI[1], M. GREGOÌRE[2], AND F. SIENA [1]

[1] Department of Earth Sciences, Ferrara University, Ferrara, bdc@unife.it

[2] DTP, CNRS-UMR 5562 Observatoire Midi-Pyrenées, Toulouse, France

A detailed petrological study of mafic and ultramafic xenoliths from the Cerro del Fraile (Southern Patagonia, Argentina) was developed in order to highlight: I) the mineralogical and geochemical composition of the lithospheric mantle beneath the area, II) the nature of the metasomatising agents which infiltrate the mantle wedge above the Antarctic subducting Plate, III) the processes that allow the mantle to be refertilised and IV) the nature of the material dragged down in the subduction zone and recycled within the south patagonian sub-arc mantle.

Major and trace element analyses of clinopyroxene and orthopyroxene in peridotitic and pyroxenitic rocks suggest that a proto-adakite, deriving from the melting of the subducting Antarctic plate, was responsible for both the metasomatic features of the peridotitic rocks and the crystallisation of the pyroxenites. A few composite xenoliths bridge the two processes - peridotite enrichment and pyroxenite crystallization - indicating that the variously depleted mantle reacts with the incoming melt to generate a newly fertile mantle domain. HREE and Al2O3 and MgO contents in pyroxenes indicate a partial melting degree varying from 10 to 25 %. The peculiar enrichment in Zr (-Hf), Th and U of the pyroxenes speaks in favour of the melting of oceanic sediments, which are composed of a remarkable amount of manganese nodules and micronodules and, possibly, organic matter. Some geochemical analogies have been found between the calculated metasomatic melts and the Austral Volcanic Zone adakites. In this case, the amount of sediments involved in the genesis of the infiltrating melts is larger than that previously proposed for the genesis of the erupted Patagonian adakites. Chemical-physical conditions favouring the upward percolation through the mantle wedge of these SiO2-rich and viscous melts are also discussed.

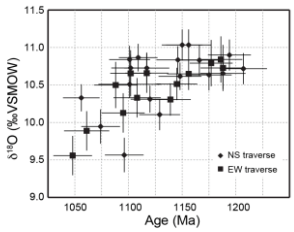
U-Pb age zoning in titanite by SIMS: New criteria for preservation

CHLOË E. BONAMICI[1*], REINHARD KOZDON[1], C. MARK FANNING[2], JOHN W. VALLEY[1]

[1]WiscSIMS, University of Wisconsin-Madison, Madison, WI, 53706, USA, bonamici@wisc.edu (* presenting author)
[2]Research School of Earth Sciences, Australian National University, Canberra, Australia, Mark.Fanning@anu.edu.au

We report a set of thirty-two U-Pb SIMS ages measured in situ along two traverses of a single titanite porphyroclast from the Carthage-Colton mylonite zone in the Adirondack Mountains, New York, USA. Ages span ~140 m.y. from 1190 Ma to 1050 Ma and generally decrease from core to rim; however, ages within the interior of the grain fluctuate by as much as 50 m.y. over length scales < 100 μm. Electron microprobe element maps and Th/U spot analyses (SIMS) reveal distinct core and rim compositional domains. These do not correlate with the observed grain-interior age fluctuations and thus argue against trace element growth zoning as the source of U-Pb age variability. Light microscopy and EBSD mapping verify that the grain has not been recrystallized and show that more than 50% of the grain suffered deformation-related mechanical twinning. Ages in twinned areas of the grain are younger and more variable than ages in untwinned areas, suggesting that the presence of organized planar defects may have affected Pb mobility and abundance. SIMS $\delta^{18}O$ zoning along traverses parallel to U-Pb traverses, indicates volume diffusion of oxygen during cooling from peak T of 700°C. The strong positive correlation between $\delta^{18}O$ and U-Pb age (Figure) is consistent with the presence of first-order, core-to-rim age zonation similar in shape and extent to the zonation developed by diffusive exchange of oxygen, and it agrees with experimental studies that show similar diffusivities for oxygen and Pb in titanite over the temperature range 600-800°C.

We conclude that U-Pb age zoning within the Adirondack titanite grain reflects heterogeneous Pb redistribution by a combination of volume and intragrain fast-path diffusion. The oldest ages, preserved in untwinned areas, correlate with the 1164 ± 11 Ma intrusion age of the Diana metasyenite that hosts the grain. The youngest, ca. 1050 Ma ages near the grain rim are consistent with Pb loss and age resetting by volume diffusion during granulite-facies metamorphism accompanying the Ottawan phase (1090-1020 Ma) of the Grenville orogeny. We interpret the transitional and highly variable ages in twinned areas as reflecting segmentation of part of the grain into smaller diffusion domains between twin boundaries that behaved as diffusion fast paths. An integrated whole-grain age on this Adirondack grain would, at best, constrain the minimum age for syenite intrusion or the maximum age of high-T Ottawan metamorphism. Knowledge and careful characterization of the correlation between U-Pb age and $\delta^{18}O$ zoning in titanite will permit retrieval of more accurate ages for each event and may additionally allow for applications of coupled U-Pb-$\delta^{18}O$ titanite geospeedometry.



Microbial communities in low-permeability uranium mine tailings

Uranium mine tailings management

The processing of uranium mine tailings at the Deilmann Tailings Management Facility (DTMF) at Key Lake was designed to stably co-precipitate ferrihydrite with various elements of concern (EOCs), such as As, Se, Ni, and Mo, present in the processed rock. During UO_2 extraction, tailings are milled to ≤100 μm diameter; on disposal in the DTMF, a saturated, diffusion-dominated matrix with restricted pore space (dry bulk density ~1.2 – 1.6 g/cm^3) results. The chemical stability of the DTMF relies upon maintenance of highly oxic, high pH conditions. However, microbes, given time and nutrients, have the potential to metabolically reduce the tailings which could result in the solubilization and subsequent mobilization of the EOCs. To date, the DTMF hasn't been studied from a microbiological perspective; it has been suggested that the high pH, radiation, and limiting nutrients in the DTMF would limit microbial growth and activity.

Characterization of the tailings microbial community

An in-depth analysis of microbial diversity, as well as their metabolic potential, within the tailings system has been undertaken using culture dependent and culture-independent analyses. A total of 60 tailings samples were obtained at 1 m intervals over a top 60 m of the tailings body and subjected to DNA extraction, as well as cultivation on a variety of microbiological media. A surprisingly high diversity (determined using 16s rRNA sequencing) of cultivatable bacteria under aerobic and anaerobic conditions were isolated over the tailings depth profile. These bacteria exhibited a range of characteristics reflective of being highly-adapated to life within the DTMF: of the 59 unique isolates, 69% were multiple metal resistant, 15% exhibited dual-metal hypertolerance, and a number were capable of reducing or oxidizing various metal elements.

Using extracted DNA from composited tailings samples from the upper, middle and lower 20 m layers of the DTMF profile, three *cpn60* clone libraries were assembled and sequenced. A total of 920, 952, and 693 sequences were generated for the upper, middle, and lower zones, respectively. Comparative phylogenetic analysis led to the classification of the different sequences from the three libraries into nine taxonomic groups: Gemmatimonadetes, Verrucomicrobia, Acidobacteria, Synergistetes, Planctomycetes, Actinobacteria, Bacteriodetes, Proteobacteria and Firmicutes. The prevalence of populations of metabolically-diverse, metal-resistant microorganisms capable of transforming metal elements suggests the potential for these organisms to influence the geochemical stability of the tailings. Integration of biological and geochemical data will aid in the construction of a predictive stability model that incorporates the role of organisms with unique metabolic activities.

Linking mackinawite (FeS) structure to redox activity

SHARON E. BONE[1*], KIDEOK KWON[2], JOHN R. BARGAR[3], GARRISON SPOSITO [1]

[1]Lawrence Berkeley National Laboratories, Berkeley, USA, SBone@lbl.gov (* presenting author), GSposito@lbl.gov
[2]Sandia National Laboratory, Albuquerque, USA, kkwon@sandia.gov
[3]Stanford Synchrotron Radiation Lightsource, Menlo Park, USA, bargar@slac.stanford.edu

The nanoparticulate tetragonal iron sulfide mineral mackinawite (FeS) is thought to be ubiquitous in wetlands, estuaries and groundwater where bacterially produced sulfide and ferrous iron mix. FeS has the potential to be used as a bioremediation tool because of its ability to reduce a range of contaminants including chlorinated organics, metals and metalloids.

The goal of our research is to link the molecular-scale structure of FeS to its reactivity towards environmental contaminants, in this case, the biomagnifying toxicant mercury. To this end, we have integrated X-ray spectroscopic, X-ray scattering, computational and wet chemical techniques to investigate FeS size and structure, and to identify which FeS moieties participate in reduction as well as what oxidized products result as a function of time, pH, and [Hg(II)] in batch reactors.

Using Hg L_{III}-edge extended X-ray absorption fine structure (EXAFS) spectroscopy we have found that Hg(II) forms a discrete Hg(0) phase after reaction with FeS. Density functional theory (DFT) computations show that surface Fe(II) in FeS preferentially binds Hg(II) relative to surface S(-II), suggesting a pathway by which electrons might be transferred to Hg(II) to produce Hg(0) and Fe(III). Using Fe K- and $L_{II,III}$-edge X-ray absorption spectroscopy, we have quantified Fe(III) formation in FeS suspensions. Fe(III) exists in octahedral coordination as a second, amorphous phase, possibly as a mixed Fe(II)-Fe(III) phase, which may be a pre-cursor to the Fe(II)-Fe(III) sulfide, greigite. Lastly, we used X-ray diffraction, electron microscopy and Fe K-edge EXAFS spectroscopy to derive a particle size distribution for FeS, and to determine FeS molecular-nanoscale structure before and after oxidation. We combined this information with thermodynamic modelling of equilibrium aqueous Fe(II) and S(-II) concentrations in order to identify the redox processes that occur in FeS suspensions.

Our research demonstrates that Fe(II) in FeS is key to FeS reactivity, dominating its surface chemistry and redox activity.

Timing the evolution of seawater chemistry during the Neoproterozoic: case study of the Svalbard succession.

P. BONNAND[1*], I. J. PARKINSON[1], I. J. FAIRCHILD[2], E. MCMILLAN[2], D. CONDON[3], G. P. HALVERSON[4].

The Neoproterozoic Era (1000-542 Ma) is a key period in the evolution of the Earth system. This period is characterised by the widespread occurrence of glacigenic sediments and by large variations in carbon isotope compositions of seawater [1]. These excursions are among the largest described in the geological record, and together with global periods of glaciation, make the Neoproterozoic one of the most dramatic periods of change in surface processes on Earth. Another major change that occured during this period is a purported increase in oxygen concentration in the atmosphere and associated changes in ocean redox [2]. In order to unravel the global record of evolving Neoproterozoic ocean chemistry, several successions around the world have been studied [e. g. 3]. However, the lack of precise radiometric constraints on suitably preserved samples in most Neoproterozoic sedimentary successions hinders the interpretation and correlation of geochemical signals. The Polarisbreen Group in northeast Svalbard is one of the best preserved Neoproterozoic successions and has great potential to significantly improve the record of Neoproterozoic environmental evolution, but to date has yielded no direct radiometric age constraints

In this study, we investigate the potential of the Svalbard succession to represent a type succession to assess the climate and chemical variations that occured during the Neoproterozoic. The Svalbard succession is characterised by the presence of 2 distinct glaciation episods which have been correlated with the first and second Cryogenian glaciations [3, 4]. Here, we present new constraints on the depositional age of two discrete glacial intervals in the Polarisbreen Group based on U-Pb detrital zircon data from siliciclastic sediments. We also investigate Sr isotopes and REE concentration in well preserved carbonate rocks through the succession in order to correlate the variation in Sr isotopes to the proposed Neoproterozoic seawater Sr curve [3] and assess variation in marine redox conditions during this interval.

These new data will allow a better correlation of the Svalbard succession with other Neoproetrozoic successions and provide a framework to characterise the evolution of seawater during the Neorpoterozoic.

Assessing the use of $^{13}C\{^{1}H\}$ CPMAS NMR for comparisons of boreal watershed soil and dissolved organic matter compositions

JENNIFER BONNELL*, CELINE SCHNEIDER, CHRISTINA BOTTARO AND SUSAN ZIEGLER[1]

[1]Memorial University, St. John's, NL, Canada, jennifer.bonnell@mun.ca (*presenting author)

Understanding high latitude ecosystems and their links to global carbon cycling depends greatly on our study of the composition of both dissolved and soil organic matter (DOM and SOM, respectively) and their interactions. DOM plays a major role in aquatic carbon and nutrient cycling, but may also reveal changes in landscape biogeochemistry. Headwater streams are intimately connected to and strongly influenced by the terrestrial environment such that stream DOM likely provides important chemical clues relevant to change in the watershed.

^{13}C cross polarization magic angle spinning nuclear magnetic resonance spectroscopy (^{13}C $\{^{1}H\}$ CPMAS NMR, hereafter referred to as CP) has been used extensively in the study of both DOM and SOM. It allows assignment of types of carbon in relative proportions, which informs our understanding of the chemical composition, source, and diagenetic state. It is well known that CP introduces a matrix effect caused by the dependence of signal strength of different carbon groups on the hydrogen environment surrounding it, resulting in types of carbon being over- or underrepresented in terms of relative proportion. ^{13}C single pulse NMR (^{13}C SPMAS NMR, hereafter referred to as SP) can be performed to determine the actual proportions of carbon types. Samples from a boreal forest headwater stream were run using both CP and SP to determine if an average correction factor (CF) could be applied by carbon type across a larger suite of DOM samples taken from a large boreal watershed in western Newfoundland. Five carbon types (aliphatic, carbohydrate, aromatic, carboxylic, and carbonyl) were assessed across all samples. Amplification or under representation of carbon types via CP was consistent in both stream DOM samples, and CFs were calculated for each carbon type. CFs were tested and consistently predicted results within 5%, on average (ranging from 0.59% to 7.7%), of carbon type percentages obtained via SP. The greatest effect observed was the underrepresentation of aromatic carbon, while both carbohydrate and aliphatic carbon were the most amplified.

This same methodological comparison was applied to litter and organic and mineral horizon soils (from the same watershed), as well as DOM derived from these soil horizons (leachates) to determine if these corrections would be consistent across sample types. While some similar CP effects were observed across both soil and leachate samples, the magnitude of these differences was less than that observed in stream DOM samples, and varied between soil and leachate samples. The larger CFs required for stream DOM samples, perhaps due to the lower carbon abundance relative to other matrix components, are particularly important as we consider how the chemical composition of stream DOM relates to the landscape. Obtaining and applying CFs for a specific study area to enable comparisons of the chemical composition of DOM in both soil and aquatic environments should facilitate our understanding of terrestrial-aquatic biogeochemical linkages, allowing a more accurate comparison across sample types.

A model for copper isotopic fractionation during weathering and transport

DAVID M. BORROK[1*], JESICA U. NAVARRETE[1], FOTIOS CHRISTOS A. KAFANTARIS[1]

[1]University of Texas at El Paso, USA, dborrok@utep.edu (*presenting author), jnavarrete2@miners.utep.edu, fkafantaris@miners.utep.edu

A consensus appears to be forming that the fractionation of Cu isotopes in natural systems is underpinned by redox reactions (chiefly changes from Cu(I) to Cu(II) and vice-versa). The heavier Cu isotope, ^{65}Cu, is preferentially incorporated in the oxidizied Cu species relative to ^{63}Cu. This has been speculated for coexisting minerals, coexisting fluid/mineral systems, and for biological systems, including microorganisms, plants, and mammals. Although additional reactions such as adsorption, organic complexation, and diffusion add complexity, Cu isotopes may prove to be a powerful tool for understanding current and historical redox processes in nature. The problem, however, is that we don't yet have a full understanding of how this redox-related fractionation process is reflected in different environments and over different scales.

Using experimental and field data collected from new and previous Cu isotope investigations, we present a conceptual model for the fractionation of Cu isotopes during the aqueous and oxidative weathering of Cu(I) sulfide minerals. The model suggests that the Cu isotopic signature of the fluid phase (relative to the mineral) is controlled by the relative rates of oxidation and leaching/transport.

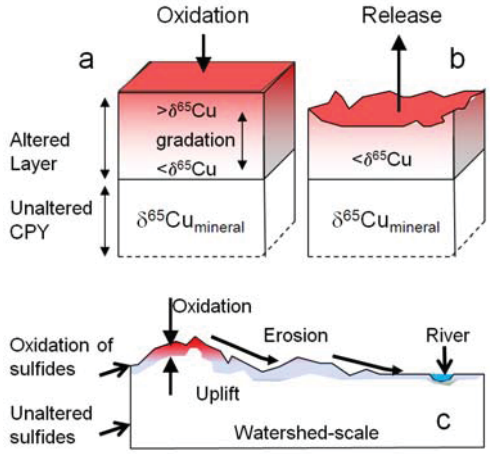

Figure 1: Conceptual model for Cu isotopic fractionation during chalcopyrite (CPY) oxidation, including (a) oxidation of Cu(I) to Cu(II) at the mineral surface followed by (b) the release of Cu into solution. Panel (c) is a cartoon watershed-scale version of this process.

We further examine how this model might be adapted from the molecular scale to watershed and continental scales, highlighting key knowledge gaps. Specifically, we address how Cu isotope controls might change from aqueous systems at low pH that are rich in dissolved Cu to higher pH systems where dissolved Cu is scarce and largely complexed by organic ligands.

[3] Istituto Nazionale di Geofisica e Vulcanologia, Roma, Italy,
[4] Institute of Geosciences and Earth Resources - CNR, Firenze, Italy

The Southern area of Tuscany (Italy) provides clear examples of natural analogues of carbon dioxide mineral sequestration. Our studies focused on the geological and geochemical characterization of the different natural manifestations of CO_2-trapping processes. Widespread serpentinite-hosted magnesite deposits have been investigated in the Southern Tuscany (Monti Livornesi, Colline Metallifere, Elba Island), together with shallower deposits of hydromagnesite in Montecastelli area. The magnesite deposits are a consequence of a realtively shallow hydrothermal circulation of Si- and CO_2-rich fluids intensively affecting serpentinite lenses, hosted by argillites [1].

The hydromagnesite incrustations (Figure 1), with the typically white rounded shape and vein or fracture fillings, represent an ongoing carbonation process on a gangue materials dumped from a serpentinite-hosted copper mine, close to Pomarance (Tuscany, Italy).

The study of these natural analogues complements laboratory experiments and possibly provides opportunity to constrain the boundary conditions and the mechanisms for CO_2-bearing phases to form. Here, we report a review of our geological mapping, petrological observation, mineralogical and geochemical analyses together with isotopical studies (C, O, Sr) of different outcrops in order to address: 1) the carbon source (deep versus atmospheric); 2) the fluid path-way during the alteration in relationship with the induced/reactived fracturation; 3) the areal diffusion and the efficency of the carbonation process; and 4) the mass balance of major and trace element during the alteration.

Eating Iron and Loving it: Ferrous Iron Metabolism in *Rhodopseudomonas palustris* TIE-1

ARPITA BOSE[1*], DIANNE K. NEWMAN[2], AND PETER R. GIRGUIS[3]

[1]Harvard University, Department of Organismic and Evolutionary Biology, abose@fas.harvard.edu, (* presenting author)

[3]Harvard University, Department of Organismic and Evolutionary Biology, pgirguis@oeb.harvard.edu

Iron is an essential element in biological systems, and its transport is thus a prime concern to all life. Iron also serves as an electron donor and acceptor for microbial respiration. However, a lot remains to be understood about these processes and we believe that studying iron specialists will provide fresh insight. *Rhodopseudomonas palustris* TIE-1, is an α-proteobacterial iron specialist that uses energy from light and electrons from ferrous iron Fe(II) to support photoautotrophy (photoferrotrophy). *R. palustris* TIE-1 is the only genetically tractable photoferrotrophic microbe, and we are interested in employing molecular and geochemical analyses to better understand A) how it copes with high Fe(II) concentrations, and B) how electrons are transferred from Fe(II) to the photosynthetic reaction center.

Bioinformatics was used to interrogate the genome of *R. palustris* TIE-1 for putative Fe(II) transporters. The *pioABC* operon, the genetic locus essential for photoferrotrophy, was also included in this analysis. This locus might be responsible for both iron and electron transport. A combination of techniques such as heterologous complementation, mutant analysis, and immunofluorescence was used to confirm the role of the identified loci in Fe(II) transport. To assess the role of the Pio proteins in electron transfer from Fe(II) to the photosynthetic reaction center, novel bioelectrochemical reactors were devised. Our data indicate that *R. palustris* TIE-1 employs different membrane-bound Fe(II) transport systems under aerobic, anaerobic and photoferrotrophic conditions. Although the role of the Pio proteins in iron transport remains unclear, we demonstrate that they allow *R. palustris* TIE-1 to accept electrons from a poised electrode in the presence of light, supporting net carbon fixation and growth. We refer to this process as "photoelectrosynthesis" (PES).

This comprehensive study provides a better understanding of Fe(II) transport in α-proteobacteria. We also show that a pure phototrophic culture can perform PES, which has not been demonstrated previously. The role of the Pio proteins in PES brings to light the use of a common protein module to perform electron transfer reactions in unrelated bacteria. Ongoing studies are aimed at further understanding this process at the molecular level.

The environment plays a key role in regulating the concentation of environmental toxins such as arsenic. Minerals are the matrix on which contaminants are retained, affecting both their aqueous concentrations and the transport properties. In some cases, minerals serve as either electron acceptors and donors for a variety of biogeochemical processes that affect the mineral form, surface area, and reactivity of sediments. This critical role is well established, yet suprisingly little is known about the distribution of some of the most important minerals in regulating arsenic concentration. Here, we quantify the concentrations of ferrihydrite in a variety of settings, and study the relationship between its concentration and dissolved arsenic levels from a variety of arsenic-affected environments. Ferrihydrite is a metastable mineral that only somewhat crystalline, and is highly reactive for both adsorption and microbially-mediate reduction. Its presence is often controversial given this metastability, yet the retention of arsenic and other ions is often not easily modeled with low surface area Fe minerals. Using a combination of sequential extractions and X-ray absorption spectroscopy to identify these phases, we find that there is clear evidence for the persistence of ferrihyrite or other poorly crystalline Fe(III) phases even in tropical environments where rapid Fe cycling often is assumed to convert it to hematite and goethite. We attribute the stability of these nanoparticulate forms of Fe(III) to the presence of adsorbed silicate or phophate or other phases on the mineral surface in these environments. A critical factor in the identification of this phase involves the differentiation of crystalline minerals that have distinct, but variable spectral signatures depending on factors such as morphology and particle size. The distribution of ferrihydrite and Fe(III) in sediments also appears affect As speciation, possibly by affecting Fe reduction. While ferrihydrite is found, it often appears to be less effective at minimizing aqueous As levels than crystalline oxides.

A new look on the barium cycle: Stable barium isotope fractionation in ODP sediments and calibration experiments

BÖTTCHER M.E.[1,*], VON ALLMEN, K.[2], PAYTAN, A.[3], NEUBERT, N.[1,2], BRUMSACK, H.-J.[4], SAMANKASSOU, E.[5], AND NÄGLER, T.F.[2]

[5]University of Geneva,Switzerland, Elias.Samankassou@unige.ch
[6]Present address: University of Hannover, FRG

We show by the analysis of the stable barium isotope composition ($^{137}Ba/^{134}Ba$) of natural marine barite ($BaSO_4$), that significant isotope fractionation takes place in the marine biogeochemical barium cycle. We have combined previous measurements of the S and O isotopic composition with new Ba isotope ratio determinations. We find that biogenic marine barites separated from sediments collected in different parts of the world´s Ocean with ages up to about 55 million years fall within a close range and have isotope ratios comparable to recently reported value for continental barium-bearing minerals (von Allmen et al., 2010). Whereas, cold seep barites, show isotope values close to modern biogenic barite, marine hydrothermal samples are enriched in the lighter isotope. Highest ^{134}Ba-enrichments are found in authigenic barite minerals formed above black shales in the deep sediments of ODP Leg 207 that are depleted in sulfate due to AOM-triggered microbial sulfate reduction.

Laboratory experiments were conducted to investigate the potential of different low-temperature reactions to result in barium isotope discrimination. These reactions include adsorption of dissolved Ba on MnO_2 and kaolinite, and the precipitation of anhydrous $BaCO_3$ and $BaSO_4$ under different experimental conditions (reaction process and temperature). The Ba minerals were generally enriched in light Ba compared to the aqueous solution, to magnitudes depending on precipitation conditions.

As an important finding, we can conclude that diagenetic barites at ODP Leg 207 record coupled transport induced isotope discrimination, probably superimposed by desorption/adsorption processes in the sulfate-depleted part of the sediment column. Despite the relatively short residence time, the barium isotopic composition of primary barites seem to have been relatively constant through the past 55 m.y.

It should be noted that S and O measurements of a Cambrian barite sample from China showed the influence of microbial sulfate reduction and were accompanied by a depletion in the heavy Ba isotope comparable to our findings from ODP Leg 207.

Environmental impacts of nanomaterials: physico-chemical evolution, exposure mechanisms and mechanisms disturbing the biological activity in aqueous environment

JEAN-YVES BOTTERO[1,2*], MELANIE AUFFAN[1,2], JEROME LABILLE[1,2], ARMAND MASION[1,2], JEROME ROSE[1,2]

[1] CEREGE UMR 6635 CNRS-Université Aix-Marseille, France (bottero@cerege.fr)
[2] GDRI I-CEINT International Center for Enviromental Implications of Nanotechnology

The new properties of materials at the nanoscale are at the heart of current scientific advances such as drug vectorization, cancerous tumor targeting, replacement of silicon in microelectronics by carbon, or the manufacture of more resistant materials... The main cause for this change in properties is the very high surface to volume ratio of nanoparticles and stronger reactivity. It is therefore impossible to simply transfer the physical, chemical, and thermodynamic knowledges on reactions occurring at the solution/microparticles interface to those occurring at the solution/nanoparticles interface (<20-30 nm). Thanks to the unique properties of nanoparticles, nanotechnologies will considerably grow in the near future. However, this growth stirs up awareness that we cannot ignore. In particular, people wonder about the impact of mass-produced nanoparticles that could spread into the environment.

To date, scientists master the manufacture and use of nanomaterials, however we do not know what are the risks for humans and ecosystems. No database exists regarding the amounts released within the ecosystems. However, nanoparticles due to their reactivity, their surface atoms are labile, their redox states can change easily, they are highly reactive towards aqueous compounds and can change from hydrophobic to hydrophilic. Before contacting biota they interact with many objects such as natural organic matter, clays, oxides…. It is impossible to study and understand the environmental biological effects of nanomaterials without a good knowledge of the exposure, their physico-chemical properties changes. The properties of nanoparticles able to disturb the biological activity depend on their size, on their mineralogy, their crystallinity, and their surface reactivity. All these parameters affect the toxicity via their oxido-reductive potential, the generation of Reactive Oxygen Species (ROS), their dissolution into toxic or non ions (*e.g.* Cd^{2+}, Zn^{2+}, Ag^{+}), or also the retention of toxic molecules on their surface (*e.g.* As, Cd, Co). The exposure i.e interactions with components , transfer within the water column or/and sediments is a crucial problem which can be resolved through experiments in mesocosms, search and analysis of Nps in media and analysis of the transformation after alteration of "nano products".

Dating drinking water in eskers from Amos, Abitibi, Canada

In Abitibi-Témiscamingue (Québec), eskers, glaciofluvial landforms formed by accumulations of sand and gravel, were deposited during the last deglaciation. 8000 years BP, peatlands developed around the esker flanks by drainage of the Lake Barlow-Ojibway. The eskers are known to be aquifers containing drinking water of exceptional quality, yet little is known about their hydrologic regime. A better understanding of these systems is necessary to assess the vulnerability of these aquifers to potential contaminants and to implement a suitable management plan for water resources. With a such goal, a multi-isotopic study was initiated in eskers of Amos region (Saint-Mathieu-Berry, Baraute and Harricana Moraine) using stable noble gases and ^{222}Rn to date these waters and trace fluid flow within the eskers and into surrounding peatlands. $^{3}He/^{4}He$ ratios have been preliminarily used to identify water mixing and to estimate groundwater residence times through the ^{3}H-^{3}He method and, when possible, U-Th-^{4}He age model [1].

First results point to the occurrence of tritiogenic ^{3}He in groundwater flowing in the Saint-Mathieu-Berry esker that provide drinking water to the town of Amos and the bottled water Eska. Using tritium contents measured in 2004 [2] and in 2011, this study yields an age of 21-23 years. Groundwater from two deep wells (40 and 70 m) from the Harricana moraine gives ^{3}H-^{3}He ages of 7-9 yrs.

Interestingly, the Barraute esker, which is buried under Quaternary clay and the well of Landriennne which taps water at the interface with the Proterozoic basement show $^{3}He/^{4}He$ ratios (R) (normalized to that of atmosphere or Ra) of 0.930±0.022 Ra and 0.946±0.024 Ra, respectively. R/Ra below atmospheric ratio suggests a possible contribution of radiogenic ^{4}He and thus, older water ages. This finding is in agreement with the higher salinity measured in these two wells compared to the regional background.

Rocks samples from the Harricana Moraine were selected for measurements of U and Th contents and to estimate the ^{4}He release rate from the protoliths composing this aquifer [1] in order to calculate meaningful U-Th-^{4}He ages for Barraute and Landrienne groundwaters.

Core differentiation of the IVA asteroid

R. A. BOUCHET[1*], J. BLICHERT-TOFT[1] AND F. ALBAREDE[1]

[1]ENS Lyon, LGLTPE, 69007 Lyon, FRANCE, romain.bouchet@ens-lyon.fr (* presenting author)

The group of IVA iron meteorites are regarded as magmatic cumulates that, together, have recorded most of the crystallization sequence of the core of a small planet (e.g. [1]). The main argument for a crystallization process rests on the chemical trends defined by the siderophile elements [2]. Using mathematical parameterization of element partition coefficients [3], we tested the hypothesis of fractional crystallization between a solid and a liquid by calculating the amount of sulfur in the liquid. Because the resulting sulfur concentrations did not follow a simple fractional crystallization law, we instead considered fractional crystallization between a solid and a mush. We calculated two key parameters from the trace element concentrations of the IVA irons [2]: the amount of sulfur in the liquid and the fraction of solid in the mush. The computed fraction of solid in the mush is very near unity during most of the differentiation history, implying that the underlying assumption of crystallization between a solid and a liquid suspension is invalid.

We therefore examined whether the chemical trends observed for siderophile elements in the IVA iron meteorites may record a compaction process rather than crystallization. Elements such as Au and Ni were progressively removed in the process, whereas compatible elements such as Ir and Pt became more concentrated in the residue. The correlation between cooling rates and Ni content in the IVA irons therefore signals a trend opposite to what is commonly admitted in the literature [4] and supports centrifugal solidification and cooling rates increasing as compaction proceeds. In addition, the calculated composition points to sulfur-saturated liquids. Upon compaction, these liquids rose in the solid metal where they were partially trapped as troilite inclusions, such as is observed in a number of IVA irons. The low Th/U ratio of these troilite inclusions [5] may reflect fractionation upon unmixing of minute amounts of silicate melts [6]. Although most of the silicates were subsequently lost, some occasionally survived as silicate inclusions [7].

Modeling stable isotope ratios of metals in the weathering zone: mass-balance controls

J. BOUCHEZ[1*], F. VON BLANCKENBURG[1] AND J. A. SCHUESSLER[1]

[1]German Research Centre for Geosciences (GFZ), Potsdam, Germany (*presenting author; bouchez@gfz-potsdam.de)

During the last decade, the stable isotope composition of metals and metalloids (e.g. Li, B, Mg, Ca, Fe, Cu, Zn, Sr, Mo) in the weathering zone were mapped out. The overarching aim is to improve our understanding of the processes fractionating isotopes and generating elemental transfers between the main compartments (e.g. bedrock, soil, surface water and plants). However, a conceptual framework is still lacking for interpreting isotope data in terms of isotope fractionation factors, or in terms of elemental fluxes. Such a framework represents a prerequestite to identify biogeochemical processes from isotope ratios measured in river material or in the sedimentary record.

To this end, we design a simple steady-state model based on elemental mass-balance equations, and simulate, at first-order, a weathering system from the scale of a soil column to that of continents. The model links (1) isotope compositions of the main compartments of the weathering zone (expressed in the δ-unit) (2) isotope fractionation factors Δ_{prec} and Δ_{up} (associated with precipitation of secondary weathering products, and with plant uptake, respectively) (3) elemental fluxes to, within and out of the weathering zone. The fluxes are expressed relative to the supply rate of the considered element into the weathering zone which is, at steady-state, denudation rate times bedrock chemical composition.

Using this model, we show how soil water or river water isotope composition δ_{water} will be offset from the bedrock composition δ_{rock} by an amount that is not only (1) depending on the flux weighted-average of Δ_{prec} and Δ_{up}, but also (2) increasing with increasing elemental flux of combined net precipitation of secondary weathering products and net litter formation, and (3) increasing with decreasing elemental flux resulting from the dissolution of primary minerals. (2) and (3) represent strong mass balance effects that likely depend on the considered element (and on its biogeochemical properties such as solubility, affinity for clay minerals, or importance as a nutrient) and the geomorphic regime of the considered setting (e.g. supply versus kinetically limitated weathering). These mass-balance effects have to be taken into account when linking isotope ratios with isotope fractionation factors and biogeochemical processes in the weathering zone.

Furthermore, the model shows that δ_{water} will depend strongly on the intensity of biological uptake only if a significant proportion of the considered element is exported as plant litter, establishing a prerequisite to the use of metal stable isotope ratios in the sedimentary record as a tracer of terrestrial biological activity.

The model also has important implications in terms of sampling strategy: it can be shown in particular that the effects of Δ_{prec} and of Δ_{up} cannot be disentangled using isotope composition of river water or of bulk sediment alone. For this purpose, separates of organic and secondary phases from river particulate load or from topsoil, are needed.

No REE into the Earth's core

M.A. BOUHIFD[1*], M. BOYET[1], D. ANDRAULT[1], N. BOLFAN-CASANOVA[1] AND J.L. DEVIDAL[1]

[1]Laboratoire Magmas et Volcans, Université Blaise Pascal, CNRS UMR 6524, 5 Rue Kessler, 63000 Clermont-Ferrand, France

Introduction

The earliest history of the Earth was marked by accretion and core formation within about 100 Myr [1, for a review]. Short-lived radioisotope systems such as ^{146}Sm-^{142}Nd (composed by two refractory elements) are useful in determining how the silicate Earth, for example, evolved during and after accretion. Recent Sm-Nd data show that all terrestrial samples have on average 20 ppm ^{142}Nd excess relative to chondritic meteorites [2]. It is thus evident that an enriched Hadean reservoir has to exist, unless the bulk Earth accreted with a Sm/Nd ratio that was higher than the chondrite average. Within several hypothesis [3], the enriched Hadean reservoir maybe the core since rare earth elements (REE) are not strictly litophiles in more reducing conditions [4]. In order to test this hypothesis, experiments at core-forming conditions (P, T, f_{O2}, etc) are needed to assess whether or not the core plays an active role in the observed ^{142}Nd anomalies.

To simulate Earth's core formation under conditions of segregation from a deep magma ocean, we performed multi-anvil experiments between 3 and 8 GPa at various temperatures between 2073 and 2373 K, to determine the partition coefficients of REE between molten C1-chondrite model composition and various Fe-rich alloys (including $Fe_{90}Ni_{10}$, $Fe_{83}Si_{17}$, and $Fe_{80}Ni_{10}S_{10}$). The run products indicate that the oxygen fugacity (f_{O2}) ranges from 1.5 to 5 log units below the iron-wüstite (IW) buffer, and is in agreement with core-formation models in which metallic liquid equilibrates with molten silicate under reducing conditions. The chemical compositions of the run products were determined by laser ablation ICP-MS and electron microprobe. Our results show a low liquid metal-silicate melt partition coefficients of all REE that range between 10^{-3} and 10^{-5} (an increase of the partition coefficients with decreasing the f_{O2} is observed). More importantly, our experiments show that the metal-silicate partition coefficients of Sm and Nd are similar within the investigated conditions, meaning that the Sm/Nd ratio is not fractionated by metal-silicate segregation. Another line of support of this conclusion is found by an independent work on the cosmochemical and petrological study of enstatite chondrites [5].

Conclusion

If the bulk Earth has chondritic ^{142}Nd/^{144}Nd ratio, an enriched Hadean reservoir has to exist within the deep mantle. In contrast, if the bulk Earth has an Nd isotopic composition distinct from that of the chondrites, then there is no need to invoke a hidden reservoir. In any case the Earth's core is out of the equation concerning the ^{142}Nd anomalies.

Mg,Fe-rich carbonates stability at lower mantle conditions

E. BOULARD[1]*, W. MAO[1]

[1]Stanford University, Stanford, U.S.A., boulard@stanford.edu (*presenting author); wmao@stanford.edu

Only a small fraction of the total carbon budget of the Earth is found at the surface; with the mantle and core likely being the largest carbon (C) reservoirs in the planet [e.g. 1, 2]. Carbonates are the main C-bearing minerals that are recycled into the deep Earth. Previous studies, focusing on the stability of Ca and Mg rich carbonates in the upper mantle, demonstrated the possibility of C to be recycled into the lower part of the mantle [e.g. 3]. A few experimental studies have been conducted on the stability of magnesite ($MgCO_3$) in equilibrium with silicates at lower mantles pressure and temperature (P-T) conditions. The decarbonation reaction: $MgCO_3$(magnesite) + SiO_2 (stishovite) -> $MgSiO_3$ (perovskite) + CO_2 (solid) has been reported at lower mantle conditions limiting the carbon cycle to about the first 1200 km deep (about 45 GPa - 2200 K) [4]. On the other hand, Seto et al. [5] supports the possibility for a deeper recycling of carbon in the Earth in relatively cold slabs, as they observed decarbonation of magnesite in equilibrium with mid ocean ridge basalt (MORB) at higher temperature. However, several carbonate phase transitions have been reported at higher P-T [e.g. 6].

We conducted high P-T experiements on iron-bearing carbonates stability. We used both *in situ* and *ex situ* analyses including synchrotron based X-ray diffraction and transmission electron microscopy to characterize the structure and the chemistry of the different phases in the samples. Two new high P-T phases were observed for two compositions: (1) the $(Mg,Fe)CO_3$ system above 85 GPa – 2000 K [7] and (2) the $FeCO_3$ composition above 40 GPa – 1500 K [8]. In both of these new phases, the structures determined from *ex situ* analyses led us to propose a change in the C environment as the C formed $(CO_4)^{-4}$ tetrahedra instead of triangular $(CO_3)^{-2}$ groups as in carbonates. We will discuss the influence of such structural changes on carbonate stability and its solubility within mantle silicate phases.

Upper crustal record of migmatites exhumation: the South Armorican Domain

PHILIPPE BOULVAIS[1*] ,ROMAIN TARTESE[1,2], MARIE-CHRISTINE BOIRON[3], MARC POUJOL[1], GILLES RUFFET[1],

[1]Université de Rennes 1,UMR CNRS 6118 Géosciences Rennes, 35042 Rennes, France - philippe.boulvais@univ-rennes1.fr (* presenting author)
[2]Open University, Planetary and Space Sciences, Milton Keynes, UK
[3]Université de Lorraine, UMR CNRS 7566 G2R, 54501 Vandoeuvre-lès-Nancy, France

The South Armorican Massif hosts a high-grade metamorphic domain mainly composed of medium to high-grade micaschists, migmatitic gneisses and anatectic granites [1]. At the end of the Carboniferous, these deep crustal units were exhumed rapidly during the extension associated with the collapse of the Hercynian chain [2]. To the North, this domain is limited by the listhospheric-scale South Armorican Shear Zone (SASZ). Giant quartz veins are associated with the SASZ and recorded important synmetamorphic fluid circulation [3]. Together with very low $\delta^{18}O$ values for some euhedral quartz, down to -2‰, low-salinity fluid inclusions argue for a contribution from meteoric fluids [3]. Corresponding $\delta^{18}O_{fluid}$ values estimated around -11‰ are probably related to the high palaeo-elevation of meteoric precipitation. Scarce, but significant, CO_2 fluid inclusions in euhedral quartz indicate also a metamorphic contribution. Metamorphic fluids were probably sourced from the exhumed metamorphic basement in the southern part of the Massif. Also, because of the synchronicity between the metamorphic event (exhumation) and the meteoric infiltration, it is proposed that the heat advected towards the surface by the exhumation of high-grade metamorphic rocks provided the driving force for meteoric fluid circulation on a regional scale.

The meteoric infiltration is recorded regionally by the mylonites which actually define the SASZ and by the syn-kinematic granites which emplaced along the SASZ. Low $\delta^{18}O$ values have been measured on some feldspar and zircon grains in the formers [4] while oxygen isotope disequilibirum was recorded by Qz-Fds pairs in the latters [5]. The muscovite Ar-Ar and monazite U-Th-Pb chronometers from these lithologies were highly disturbed [4,6]. In the Questembert granite, a classical example of a syn-kinematic granite, pervasive infiltration of oxydative meteoric water was facilitated by the penetrative character of the deformation (C/S planes are observed throughout the massif) and was probably responsible for the leaching of millions of tons of uranium while the granite was still at depth.

Petrology, geochemistry and petrogenesis of the Beattie Syenite, Porcupine-Destor fault zone, Abitibi Subprovince, Québec

JULIE BOURDEAU[1]*, ANDRÉ E. LALONDE[1], JEAN GOUTIER[2]

[1]University of Ottawa, Ottawa, Canada, bourdeau.julie.e@gmail.com*, aelzr7@uottawa.ca
[2]Ministère des Ressources Naturelles et de la Faune, Rouyn-Noranda, Canada, jean.goutier@mrnf.gouv.qc.ca

Abstract

The Beattie Syenite is composed of five lenticular bodies of syenitic rocks that occur immediately north of the Porcupine-Destor fault zone in the town of Duparquet, approximately 32 km north of Rouyn-Noranda in the Abitibi Subprovince. The principal body is 3.3 km long and 425 m in width and is flanked by a series of smaller lenses to the south and northeast. The intrusion has yielded zircon ages of 2682 ±1 Ma and 2682.9 ±1.1 Ma and hosted the major part of the Au-mineralization of the now defunct Beattie mine; a major producer of gold in the area from 1933 to 1956 (9.66 Mt at 4.88 g/t Au). A total of 5 principal petrographic units are defined on the basis of field relationships, petrography, mineralogy, and textures:

1) The Beattie syenite porphyry unit is composed of 2-10% of tabular euhedral feldspar phenocrysts (2-10 mm) set in a red feldspathic and aphanitic matrix.
2) The unaltered syenite unit is composed of 2-10% of euhedral feldspar phenocrysts (2-10 mm) in a fine-grained matrix. It is characterized by unaltered phenocrysts of amphibole and titanite and is the only unit with relicts of pyroxene.
3) The Central Duparquet syenite porphyry containing between 2-25% of coarse equant euhedral feldspar phenocrysts (5-16 mm) in a red or sometimes grey aphanitic matrix.
4) The megaporphyritic syenite unit is composed of very coarse alkali feldspar phenocrysts, 1-6 cm across, in a red aphanitic matrix.
5) The feldspar lath dyke unit occurs as numerous thin dykes, on the order of a few meters in width, that cross-cut all other petrographic units. The lath dykes display a characteristic trachytoid texture defined by the preferential alignment of alkali feldspar laths (1-3 cm) in a grey or red aphanitic matrix.

From petrographic observations, there is evidence of a syenitic magma which is exhibited by the occurrence of syenite dykes with trachytoid flow textures. Detailed petrographical and mineralogical studies reveal a series of hydrothermal events including the precipitation of albite, sericite, chlorite and carbonate minerals. Initial geochemical results indicate that the Beattie Syenite is part of the alkaline series, as defined in the ($Na_2O + K_2O$) vs. SiO_2 diagram, and is feldspar normative. Whole-rock normalized REE patterns demonstrate that all the petrographic units are comagmatic. Furthermore, with selective trace elements, the tectonic setting of the syenite according to [1] would correspond to a volcanic-arc environment.

Isotope fingerprints for the formation and the composition of the Earth

BERNARD BOURDON [1]*

[1]Laboratoire de Géologie de Lyon, ENS Lyon, UCBL and CNRS UMR 5276, Lyon France, bernard.bourdon@ens-lyon.fr

Building blocks

Most models for the formation and composition of the Earth usually focus on specific characteristics of its chemical or isotope composition. For example, since the formation of the Earth leads to substantial heating of planetary materials, volatile depletion and metal-silicate separation, it is sensible to consider only the refractory lithophile elements (RLE) to assess the potential building blocks of the Earth. In this context, the carbonaceous chondrites, notably the CI chondrites give the best match for RLE in the Earth's mantle and are often used as a starting material, although the processes mentioned above can affect the siderophile and volatile element concentrations in this starting material.

In contrast, when considering isotope observations, it appears that enstatite chondrites show an almost perfect match with many isotope systems, including oxygen, chromium, nickel and titanium. Then, if one considers the ^{146}Sm-^{142}Nd system, it appears that the terrestrial composition does not match with carbonaceous chondrites but could be better explained by ordinary or enstatite chondrites. However, the ^{146}Sm-^{142}Nd observations can also be explained by a non-chondritic Earth. Last, in the case of silicon isotopes, there is a clear offset between the terrestrial composition and that of chondrites. In summary, there seems to major issues in building the Earth from a single class of chondrites or from unprocessed chondritic material.

Processing of planetary materials

There are several processes that can modify the composition of the planetary materials that have formed the Earth, including thermal processing leading to volatile depletion (partial condensation or evaporation), grain sorting, impact-driven processes or metal segregation. In this presentation, I will examine the possible role of these processes in light of our recent isotope observations with a focus on Nd, Si, Mg, Mo and Sr isotopes and show how mixtures of various chondritic materials together with significant later processing is required to explain the composition of the Earth.

Molecular-scale basis of the ion exchange selectivity of clay minerals

IAN C. BOURG[1,*]

[1]Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, USA, icbourg@lbl.gov (* presenting author)

Ion exchange reactions on clay mineral surfaces play important roles in the aquatic geochemistry and mechanical properties of argillaceous media (soils, sediments, clayshales, engineered clay barriers). Despite more than a hundred years of investigation, fundamental aspects of the ion exchange selectivity of clay minerals, such as the activity coefficients of adsorbed species, the molecular-scale basis of ion exchange selectivity coefficients, and the structure of the electrical double layer (EDL), are poorly understood [1]. We report new molecular dynamics (MD) simulations elucidating the structure of the EDL on smectite surfaces contacting mixed NaCl-$CaCl_2$ electrolyte solutions at dilute concentrations ($\leq$ 0.1 mol_c dm^{-3}). Our simulations used methodologies known to correctly describe the structure and diffusion coefficients of water and solutes in smectite interlayer nanopores [2]. They complement our previous simulations of concentrated electrolyte solutions (0.34 to 1.83 mol_c dm^{-3}) on smectite surfaces [3]. Our results confirm the molecular-scale view of EDL stucture on phyllosilicate basal surfaces derived from X-ray reflectivity measurements of adsorption on mica surfaces [4]. They also provide insights into several fundamental aspects of the ion exchange selectivity of clays, such as the adequacy of the Gaines-Thomas or Vanselow conventions and the affinity of clay surfaces for $CaCl^+$ ion pairs [1].

Landscape-scale pedogenic relationships between soil carbon and secondary metal oxides in Hubbard Brook podzols, northeastern US

REBECCA R. BOURGAULT[1*], DONALD S. ROSS[1], SCOTT W. BAILEY[2], PATRICIA A. BROUSSEAU[3], JOHN P. GANNON[3], KEVIN J. MCGUIRE[3] AND THOMAS D. BULLEN[4]

[3]Virginia Tech, Blacksburg, VA, USA, patrb87@vt.edu, jpgannon@vt.edu, kevin.mcguire@vt.edu

[4]US Geological Survey, Menlo Park, CA, USA, tdbullen@usgs.gov

Abstract

Podzols are unique soils in which metals and carbon are intimately linked by the pedogenic process of podzolization. In this soil-forming process, organic matter (OM) chelated by Al, Fe and Mn leaches from the soil surface and accumulates in the subsurface spodic (B) horizon. Spodic materials (ill-defined associations of Al, Fe, Mn and C) in the B horizon are more resistant to decomposition than OM in the soil surface, in part due to the stabilizing effect of chelation and/ or sorption by Al, Fe and Mn. Podzols are found globally in a variety of environments, and therefore represent an important carbon sink. Research suggests that spatial variations in podzolization can result in part from hydrologic processes such as dominant flowpath direction, and reduction-oxidation processes driven by water table dynamics. These processes determine solubility, transport, and accumulation of Al, Fe, Mn and C. In this study, we document vertical and lateral distributions of total soil C in Watershed 3 (WS3), which is a forested, podzolized catchment in the Hubbard Brook Experimental Forest (HBEF), New Hampshire, in the Northeastern US. We will examine the relationships of C to total secondary Fe oxides and Mn oxides (extracted by citrate-dithionite), and poorly crystalline Al and Fe oxides (extracted by acid ammonium oxalate). Eighty pedons have been described, sampled, and extracted by horizon throughout WS3. In order to determine the role of hydrologic processes in determining soil chemistry in WS3, combined hydrometric monitoring and isotope tracers are used to document flowpaths, water table dynamics, and ground water chemistry and transport. Preliminary results indicate redistribution of spodic materials according to flowpaths. For example, where lateral flowpaths predominate, there is landscape-scale lateral podzolization: leaching/ loss of metals and C upslope, and accumulation of metals and C downslope. In contrast, pedon-scale vertical podzolization is more evident where flowpaths are dominantly vertical, such as on well-drained backslopes. As expected, the Mn:Fe ratio is higher in laterally deposited spodic materials as opposed to vertically deposited spodic materials, due to the fact that Mn is more sensitive to redox conditions and therefore more mobile than Fe. Understanding the spatial distributions of Al, Fe, Mn, and C at the landscape scale in WS3 may provide valuable information about the complex interactions between water and soils, metals and carbon in a forested, podzolized Northeastern US watershed.

An experimental study of the stability of the REE(III) in sulphate-bearing aqueous solutions

N. BOURQUE*, ART. MIGDISOV, AND A.E. WILLIAMS-JONES

McGill University, Earth & Planet. Sci., Montreal, QC, Canada (*correspondence: nicolas.bourque@mail.mcgill.ca)

During the past fifteen years, numerous studies of a variety of geological settings have demonstrated that the rare earth elements (REE) are mobilized by hydrothermal fluids [1, 2, 3]. As sulphate complexes of the REE are known to be among the most stable aqueous species at ambient temperature, it is therefore reasonable to propose that these species play an important role in REE transport in hydrothermal systems with high sulphate activity. However, published experimental data on the behaviour of REE sulphate species at elevated temperatures are limited to Nd, Sm, and Er [1] and therefore, evaluations of the mobility of the REE in hydrothermal sulphate-bearing solutions have been based mainly on the theoretical predictions of Haas et al. (1995). In view of this, we have systematically investigated the behaviour of the REE, including Y, in sulphate-bearing aqueous solutions and determined the properties of sulphate complexes of these elements at elevated temperature.

The technique employed in the experiments was identical to that described in Migdisov and Williams-Jones (2007). The experiments involved determining the solubility of REE oxides and fluorides in solutions with a range of sulphate concentrations, and were performed at temperatures up to 250 °C and saturated pressure of water vapour.

The data derived from the measured solubility of the REE solids show that the stability of REE sulphate species varies little with the atomic number of the REE. For example, the logarithm of the first formation constant of La (log β_1) at 200°C differs from that of Yb by less than 1 log unit. The same observation was made in earlier spectroscopic studies of Nd, Sm, and Er sulphate species [1]. This observation suggests that the REE are unlikely to fractionate in nature, if they are transported as sulphate species.

Minor and trace element composition of iron oxides from IOCG deposits worldwide and its application to mineral exploration

EMILIE BOUTROY[1*], GEORGES BEAUDOIN[1], SARAH-JANE BARNES[2] AND LOUISE CORRIVEAU[3]

[1]Université Laval, Département de géologie et de génie géologique, emilie.boutroy.1@ulaval.ca (* presenting author) Georges.Beaudoin@ggl.ulaval.ca
[2]Université du Québec à Chicoutimi (UQAC), Sciences de la Terre, sjbarnes@uqac.ca
[3]Geological Survey of Canada, Natural Resources Canada louise.corriveau@rncan-nrcan.gc.ca

There are significant variations in the concentration of trace elements in magnetite and hematite depending on the metallogenic environment at the time of formation of the deposit. This makes iron oxides useful as indicator minerals for mineral exploration.

Iron oxides are a major component of Iron Oxide Copper-Gold deposits (IOCG) and of Iron Oxide-Apatite deposits (IOA). Magnetite and hematite in IOCG (n= 84 samples) and IOA deposits (n= 6), representative of 8 major IOCG and IOA deposits, worldwide, representing a range of geological environments and ages of formation, were analyzed by electron microprobe analysis (EMPA). A subset of IOCG (n = 30 samples) and IOA (n= 6) was analysed by LA-ICP-MS. The IOCG deposits samples are divided based on the principal iron oxide present: (1) Hematite (n = 10), (2) Magnetite (n = 37) and (3) Hematite ± Magnetite (n =8). Similarly, IOA deposits are divided: (1) Magnetite (n = 3) and (2) Magnetite ± Hematite. In these types of deposits, iron oxides are in mineralization and in host rock alteration assemblages, and there are typically multiple generations of iron oxides. Iron oxides are studied according to their paragenetic stage: (1) ore stage and (2) hydrothermal alteration of host rocks. Hydrothermal alteration iron oxides are grouped according to the type of alteration: (1) Ca-Fe alteration (Am-Ap-Mag), (2) Na(Fe) alteration (Ab-Scp-Mag/Hem), (3) High temperature K-Fe alteration (Bt-Kfs-Mag) and (4) Low temperature K-Fe (Ser-Kfs±Chl±Cb-Hem). Preliminary results show hematite in Hematite-group IOCG deposits is depleted in Zn, Ni, Mn, V and enriched in K, Ti, Al, Si compared to magnetite in Magnetite-group IOCG deposits. In Magnetite-IOA deposits, magnetite is enriched in V, Al and Mg compared to Magnetite-Hematite-IOA deposits, which is enriched in Ca.

Compared to primary magnetite in Ni-Cu-PGE deposits, ore-stage magnetite in IOCG deposits are depleted in Ni, Cu and Cr and enriched in Ti, Al and Si.

Functional gene pyrosequencing sheds light on the distribution and diversity of a key nitrogen cycle gene (*nirS*) in marine systems

JENNIFER L. BOWEN[*1], DAVID WEISMAN[1], AMAL JAYAKUMAR[2], MICHIE YASUDA[1] AND BESS B. WARD[2]

[1]University of Massachusetts Boston, MA, USA Department of Biology, jennifer.bowen@umb.edu (*presenting author), weisman@lydon.com, michie.yasuda@umb.edu

[2]Princeton University, Princeton, NJ, USA Department of Geosciences, ajayakum@princeton.edu, bbw@princeton.edu

Introduction

Denitrification, a critical pathway in the nitrogen cycle that converts dissolved inorganic nitrogen to its gaseous form, plays a central role in removing nitrogen from the environment. Denitrification in estuaries, continental shelves, and oxygen minimum zones accounts for nearly 60% of the global fixed nitrogen loss [1]. There are two genes, *nirS* and *nirK* that encode functionally similar nitrite reductase enzymes that facilitate the denitrification process. The two genes do not appear to co-occur within a given microorganism but both genes are present in most environments. In the marine environment *nirS* tends to be more abundant than *nirK* [2]. Examining the structure and abundance of denitrifiers represented by the *nirS* gene in a variety of marine environments will shed new light on biogeochemical ecology of this critically important ecosystem service.

Results and Conclusions

We used functional gene pyrosequencing to examine the abundance and diversity of denitrifying bacteria in all three major oceanic oxygen minimum zones as well as in coastal sediments from Chesapeake Bay and a New England salt marsh. To assess the role of sequencing error in inflating our diversity estimates we sequenced amplicons of four clones and show that our data analysis pipeline successfully identifies and removes the overwhelming majority of spurious sequences (Fig. 1). The data indicate an astonishing degree of diversity in the *nirS* gene, with over 3500 taxa (defined operationally as sharing 95% sequence identity), found in salt marsh sediments alone. Pyrosequencing detects distinct differences in the composition of nirS assemblages in water column and sediment environments.

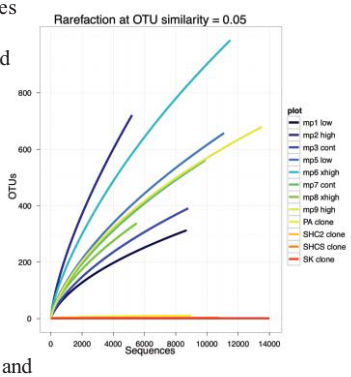

Figure 1: Rarefaction curves resulting from pyrosequencing of the nirS gene in salt marsh sediments and in control sequenced

[3]Alfred University, Kazuo Inamori School of Engineering, Alfred, NY, USA, jws4@alfred.edu

Solid-state NMR spectroscopy is uniquely equipped to study behavior at interfaces and in confinement within complex geochemical systems. The primary advantage of this technique is that it can simultaneously provide information on the molecular-scale structure and dynamic behavior over a broad range of rate scales difficult to probe via other methods (kHz to MHz) and on a site-specific basis. In this work, we share recent results from our ongoing variable temperature NMR studies of phyllosilicate/H_2O interfaces [1-4] by focusing on the influence that metal charge and hydration energy have on H_2O and metal ion structure and dynamics in the interlayer of Na- and Ca-hectorites between -120°C and 50°C. We find that near-surface ^2H_2O in 2-layer hydrates of Na- and Ca-hectorites are well modeled by simultaneous C2/C3 reorientation of a slightly compressed or extended hydration shell (with respect to an ideal octahedral hydration shell) at a rate in excess of 200 kHz between -50°C and 40°C [1]. Though our model and ^2H VT NMR show the hydration shell compression/extension varies slightly over the temperature range in each type of hectorite, the Ca^{2+} hydration shell geometry deviates less from the ideal case at all temperatures, consistent with the higher hydration energy of Ca^{2+} vs. Na^+. Associated ^2H T_1 relaxation experiments at several temperatures shows nearly identical reductions in T_1 with respect to temperature, though the ^2H nuclei in Ca-hectorite relax more quickly at all temperatures, suggesting a higher intensity of motion in the power spectrum at 45.6 MHz and that the power spectrum intensity increases with decreasing temperature for Na- and Ca-hectorite. With respect to the associated metal dynamics, both Na^+ and Ca^{2+} in 2-layer hectorite hydrates are dominated by rapid diffusion in 2 or 3 dimensions, though comparison of the ^{23}Na and ^{43}Ca VT NMR shows that Ca^{2+} experiences very rapid diffusion at much lower temperatures than Na^+ (-120°C vs. -20°C, respectively). These results are consistent with our recently published general principle that rapid diffusion becomes the dominant mode of metal cation motion for near-surface water and ions in smectites at lower temperatures as the metal hydration energy increases if the ionic radii are similar [1].

Characterization of naphthenic acids in oil sands tailings ponds by two-dimensional gas chromatography time-of-flight mass spectrometry (GCxGC-TOF-MS)

DAVID BOWMAN*, B. E. MCCARRY

[1]McMaster University, Department of Chemistry and Chemical Biology, Hamilton, Ontario
bowmand@mcmaster.ca (* presenting author)
mccarry@mcmaster.ca

Naphthenic acids are a complex mixture of aliphatic and polyalicyclic organic acids found naturally in hydrocarbon deposits. Oilsand ore is refined using the Clark hot water extraction procedure; naphthenic acids are extracted and end up in the process water. These waters are sent to large tailing ponds where particulate materials settle out slowly. Naphthenic acids are of environmental concern due to their toxicities in various mammals and fish; these concerns have lead to a zero discharge policy for oil sands tailings.[1] Naphthenic acids are known to be utilized by plants.[2] We have proposed that these compounds may be utilized by soil bacteria in the tailings ponds which may serve as a source for the generation of H_2S.

In this study, we are using two-dimensional gas chromatography time-of-flight mass spectrometry (GCxGC-TOF-MS) to provide profiles of complex mixtures of naphthenic acids (see Figure 1). Using this method it is possible to resolve over 8000 components in this sample. We hypothesize that the profiles of naphthenic acids will be altered by bacterial biodegradation and that these changes will be detectable using GCxGC. The extraordinary peak capacity and resolving power of two-dimensional gas chromatography makes it a suitable tool for the comparison of profiles of naphthenic acid mixtures.

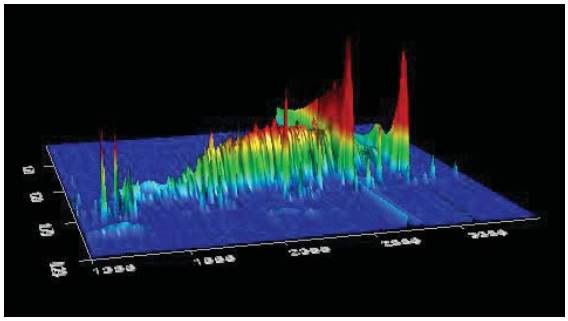

Figure 1: Two-dimensional total ion chromatogram (TIC) plot of naphthenic acids in oil sand process water sample (sample provided by Syncrude).

Mercury species and thiols from GEOTRACES cruises in the North and South Atlantic Ocean

K.M. BOWMAN[1], T. KADING[2], G.S. SWARR[2], C.H. LAMBORG[2]*, C.R. HAMMERSCHMIDT[1] AND M. RIJKENBERG[3]

[1]Wright State University, Earth and Environmental Science, Dayton OH USA (correspondence: bowman.49@wright.edu)
[2]Woods Hole Oceanographic Institution, Marine Chemistry and Geochemistry, Woods Hole, MA USA (*presenting: clamborg@whoi.edu)
[3]Royal Netherlands Institute for Sea Research, Marine Geology, The Netherlands

As part of GEOTRACES research activities, we have measured dissolved and particulate mercury (Hg) species, aerosol and rainwater total Hg and dissolved thiols from a US zonal transect in the North Atlantic Ocean as well as total Hg from a meridional transect in the South Atlantic Ocean from a Dutch/UK sponsored cruise. This is currently the largest database of its kind. Findings include: 1) total Hg profiles are nutrient-like in the upper 1000 m, but show a mixture of qualities in deep water that appeared to be controlled by water mass transport; 2) surface total Hg concentrations were strongly affected by rain inputs, productivity and the Amazon River plume; 3) dissolved elemental Hg frequently followed nitrate distributions; 4) monomethyl- and dimethyl-Hg showed distinctive peaks in the oxygen minimum zones; 5) methylated Hg concentrations showed a lower response to organic carbon remineralization rates than those recently reported for the Pacific and Indian Oceans; 6) thiols appear to be important complexing agents for Hg (and other metals) in surface waters; 7) thiol concentration distributions are similar to chlorophyll, and therefore do not predict methylated Hg concentrations well.

Transformations of aqueous U(VI) during redox cycling of Fe phases

MAXIM I. BOYANOV[1]*, DREW E. LATTA[1], MICHELLE M. SCHERER[2], EDWARD J. O'LOUGHLIN[1], AND KENNETH M.. KEMNER[1]

[1]Argonne National Laboratory, Argonne, IL, USA, mboyanov@anl.gov (* presenting author)
[2]The University of Iowa, Iowa City, IA, USA

The activity of dissimilatory iron-reducing bacteria or the corrosion of waste containers often result in the presence of Fe^{II} and Fe^{III} species in subsurface environments. Recent work has shown that dissolved Fe^{II} exchanges atoms with Fe^{III}-containing solids in a dissolution-reprecipitation equilibrium, which likely proceeds via formation of minor but highly reactive Fe^{II}/Fe^{III} species at the surface. The fate of dissolved or adsorbed U^{VI} during such transformations will depend on the reactivity and transformations of both major and minor Fe phases, with possible outcomes including reduction and precipitation of $U^{IV}O_2$ (uraninite), reduction and incorporation of U^{IV} atoms in other phases, and non-reductive solid-phase incorporation of U^{VI}. We examined the reaction of dissolved U^{VI} with a host of Fe^{II}-containing phases, including dissolved and carboxyl-adsorbed Fe^{II}, green rusts with different interlayer anions, magnetite, and NAu-2 nontronite clay, as well as with oxidized analogues such as maghemite and pyroaurite. The goal was to establish the uptake mechanisms and to characterize the molecular structure of the solid-associated U species.

Experimental Methodology

We used x-ray absorption fine-structure spectroscopy (EXAFS and XANES) at the U L_{III}- and Fe K-edge to probe the speciation of U and Fe in the hydrated solid phases after reaction. Samples were reacted under geochemical conditions relevant to the subsurface, including the presence of carbonate and/or phosphate.

Discussion of Results

U^{VI} was reduced to U^{IV} by sulfate, chloride, and carbonate green rusts; the speciation of reduced U^{IV} varied between that in uraninite and a non-uraninite, adsorbed/incorporated U^{IV} species. Pyroaurite sequestered U^{VI} as a U^{VI}-carbonate complex, presumably by interlayer ion exchange. Magnetite reduced U^{VI} to nanoparticulate uraninite when its Fe^{II}/Fe^{III} content exceeded 0.38. Reactions with more oxidized magnetite ($Fe^{II}/Fe^{III}<0.38$) resulted in oxidized U species. The latter had less uranyl character than U^{VI} adsorbed to maghemite, suggesting U uptake in a distinct phase. Reactions between U^{VI}, nontronite, and Fe^{II} also resulted in oxidized, non-uranyl U species that were distinct from nontronite-adsorbed U^{VI}. Carboxyl-adsorbed U^{VI} and Fe^{II} reacted only when Fe^{II}-OH-Fe^{II} bonds formed, resulting in a combination of uraninite and U^{IV} atoms coordinated to Fe atoms in the nucleated mineral. The presence of dissolved phosphate (U:P=1:1) in the same system inhibited uraninite formation and resulted in U^{IV} atoms in phosphate-coordinated sites. The diversity of U incorporation modes in these model systems highlights the complexity in predicting U fate in subsurface environments — non-uraninite U^{IV} and non-uranyl oxidized U were also significant species in biostiumulated sediments from a contaminated field site (Oak Ridge, TN), and in naturally reduced soil from Hedrick, IA, reacted with U^{VI}.

Nucleosynthetic Nd isotope anomalies in primitive enstatite chondrites

M. BOYET[1]* AND A. GANNOUN[1]

[1] Laboratoire Magmas et Volcans, Université Blaise Pascal, CNRS UMR 6524, 5 rue Kessler, 63038 Clermont-Ferrand, France Boyet@opgc.univ-bpclermont.fr

Introduction

The first high precision measurements of $^{142}Nd/^{144}Nd$ ratios in chondrites have revealed that different groups of chondrites are characterized by different ratios [1, 2]. In order to interpret properly the deviation of $^{142}Nd/^{144}Nd$ ratio measured between terrestrial samples and chondrite material, it is crucial to understand the cause of the ^{142}Nd deviation in the different groups of chondrites. Enstatite chondrites (EC) present similar isotope compositions to terrestrial samples for a large number of elements (O, N, Mo, Cr, Ti) and have also the smallest ^{142}Nd offset (-10±12 ppm, [3]). We have selected primitive EC belonging to the EH subgroup for further Sm-Nd isotope investigations using a step-wise acid disolution method. The goal of this study is to better characterize the carrier phase of Nd nucleosynthetic anomalies and define their isotope composition.

Methods and Results

Sample powders were subjected to the following sequential leaching procedure: (1) H_2O then acetic acid, (2) EDTA, (3) 6M HCl, (4) Aqua regia and concentrated HF-HNO_3 mixture.. The major and trace element compositions of each fraction have been measured by ICP-AES and ICP-MS, respectively. Sm and Nd were separated using a 3 steps chemistry procedure and isotopes were measured on the Thermo-Fischer thermal ionization mass spectrometer at Laboratoire Magmas et Volcan, Clermont-Ferrand.

Most of the REE (50 to 80%) are contained in the first two leachate fractions mostly derived from the dissolution of oldhamite and ninigerite as deduced from the major element compositions. The last fraction have small REE contents (5-20%) which is mostly derived from the dissolution of enstatite and djerfisherite. Nd isotopes anomalies (ratios normalized to $^{146}Nd/^{144}Nd=0.7219$) are always positive for ^{145}Nd, ^{148}Nd and ^{150}Nd and negative in ^{142}Nd in fraction (1) to (3). The largest isotope anomalies are always measured in the last fraction (residu) with ^{142}Nd excess ranging from +200 to +600 ppm. The largest effects are measured in ALH77295, which is the most primitive EC analysed in this study.

Discussion

The residues obtained after leaching treatment are strongly enriched in s-process nuclides. The different Nd isotopes plot along the same correlation lines defined for leachates and residues of carbonaceous and odinary chondrites [4] suggesting that all residues contain s-process rich presolar grains. The amount of Sm in each fraction was too small to allow precise measurement of the $^{144}Sm/^{152}Sm$ ratios, however the p-process variability seems to be relatively small.

Aerosol release of Fe into the ocean: the extreme cases

EDWARD BOYLE[1*] AND JESSICA FITZSIMMONS[1,2]

[1]Massachusetts Institute of Technology, Cambridge MA 02139 USA, eaboyle@mit.edu

[2]MIT/WHOI Joint Program in Oceanography, jessfitz@mit.edu

By now it is well-known that partial dissolution of Fe from atmospheric aerosols is a major source of iron for oceanic phytoplankton and nitrogen fixers. But many of the details of the process are only partially understood: (1) What regulates the degree of Fe dissolution? (mineralogy of the source and chemical processing within the atmosphere are believed to be important, with anthropogenic aerosols releasing more Fe either because of the source or processing from anthropogenic acidity and photochemical processing), (2) What determines the form that iron takes upon release into seawater? (it appears that most of the aerosol-released Fe is converted into organic or inorganic colloidal form in high-dust regions, although there is an expectation that soluble organic complexes should also be important), (3) How does the dust flux influence the biota? (both phytoplankton and nitrogen fixers).

In order to learn more about these issues, we will discuss the contrasting oceanic iron distributions under a high-dust region (tropical North Atlantic) and a low-dust region (southeast Pacific between Chile and Easter Island). Under the high-dust region, most of the surface water Fe is colloidal and is removed to low concentrations near the chlorophyll maximum. Phosphorus is depleted to extremely low concentrations, as any excess over Redfield N:P ratios is compensated by nitrogen fixation. Below that, iron increases in step with increasing AOU, and the C:Fe ratio is low (~100,000). Under the low-dust environment, Fe is relatively low (0.10-0.15 nM) and uniform in the upper few hundred meters (despite increasing AOU below the chlorophyll maximum) and then increases to much higher C:Fe ratios (~500,000). Dissolved inorganic phosphorus remains at fairly high concentrations (~0.20 uM) because insufficient Fe prevents nitrogen fixers from compensating for the low N:P ratio in the upwelling deep waters.

Evolution of bioturbation buffered Neoproterozoic oxygenation

RICHARD A. BOYLE[1*] & TIMOTHY M. LENTON [1]

[1]University of Exeter, UK, r.a.boyle@exeter.ac.uk (*presenting author)

A range of geochemical evidence suggests a major oxygenation of the ocean (and by implication atmosphere) at the end of the Neoproterozoic – a change that may well have been necessary (although not sufficient) for the proliferation of the earliest animal life. However, indications of a localised reversion to more anoxic (and sulphidic) ocean conditions during the Cambrian raise the possibility of a subsequent drop in atmospheric oxygen. Furthermore, an explanation for why oxygen stopped rising during the Neoproterozoic remains elusive. Here we hypothesize that the efficiency of phosphorous removal from the ocean was significantly increased by the onset of large-scale sediment bioturbation and resultant ventilation - caused by the proliferation of macroscopic animals. This was due to (a) increased microbial P sequestration under oxic sedimentary conditions, and (b) greater net organic carbon oxidation reducing the C:P burial ratio[1,2]. The resulting reduction in the concentration of phosphorus in the ocean suppressed new production and organic carbon burial, reducing the long-term source of atmospheric oxygen and thereby buffering its concentration on a multi-million year timescale. We suggest that a plausible scenario for the integrated evolution of the Earth system at the end of the Neoproterozoic is therefore "increased marine P concentration via weathering of the land surface following terrestrial colonisation $\longrightarrow$ increased marine production and organic carbon burial $\longrightarrow$ increased atmospheric oxygen $\longrightarrow$ drastic increase in biomass and motility of the (already multi-cellular and differentiated) animal biosphere $\longrightarrow$ increased bioturbation $\longrightarrow$ reduction in marine P reservoir size and stabilisation of global phosphate and oxygen cycles"[3,4]. We argue that these feedbacks and a trajectory along these lines can help explain why atmospheric O_2 and marine PO_4 fluctuations have been well buffered during the Phanerozoic.

Lead-isotope geochemistry of the Bagirkacdere lead– zinc deposit, Biga Peninsula, NW Turkey

BOZKAYA, GULCAN

Cumhuriyet University, Department of Geological Engineering, Sivas, Turkey, gbozkaya@cumhuriyet.edu.tr

The Biga Peninsula contains several base-metal skarn deposits associated with Oligo-Miocene age granitic intrusions. The Bagirkacdere lead-zinc deposit is a typical example of the skarn-type deposits occurring in the northern section of the Biga Peninsula (5.2 Mt at 3.8 % Pb, 2.18 % Zn). The mineralization developed within the Paleozoic meta-sedimentary (Torasan metamorphics) and meta-granitic rocks (Camlik meta-granitoids) as stratabound disseminations and thin veins in schists, marble and meta-granitoids of the skarn zone. Pyrite, sphalerite and galena are the main sulphide minerals and they are accompained by minor amounts of chalcopyrite, arsenopyrite and hematite. Limonite, malachite, smithsonite, anglesite and cerrusite are secondary alteration products. The skarn is dominated by garnet, calc-silicates, epidote, actinolite, diopsite, feldspar and quartz.

Lead isotope ratios for galena have mean values of $^{206}Pb/^{204}Pb$ 18.758, $^{207}Pb/^{204}Pb$ 15.698, and $^{208}Pb/^{204}Pb$ 38.958. . When the data are plotted on the model curves for average crustal Pb-isotope evolution [1], $^{207}Pb/^{204}Pb$ and $^{208}Pb/^{204}Pb$ ratios are close to or above the evolution curves and clearly indicate a crustal source. Possible Pb sources have been investigated using the plumbo-tectonic diagrams [2] and the $^{208}Pb/^{204}Pb$ vs. $^{206}Pb/^{204}Pb$ data points are distributed along a trend between the representative curves for the Lower and Upper Crust, but they are closer to the Orogenic and Upper Crustal curves. The isotope data has higher $^{206}Pb/^{204}Pb$ ratios that are close to the 0-age suggesting young (Cenozoic) Pb-model ages [1]. The Pb data for Bagirkacdere is similar to mineralization at Arapucandere and Koru, which are close to Bagirkacdere in the north part of peninsula, indicating that similar processes were operatring over a wide area.

The $\delta^{34}S$ values of galena and sphalerite from the Bagirkacdere deposit, which are close to 0 ‰, are consistant with dominantly magmatic sulphur reservoir [3]. The combined lead and sulfur isotope data indicate that the source of lead and other metals in the skarn is primarily derived from Tertiary granites.

Source, transport, and matrix controls on metal bioavailability in floodplain soils

DANIEL J. BRABANDER[1,2*], EMILY R. ESTES[1], YONGMEI SHEN[1], AND JAMES P. SHINE[1]

[1]Harvard School of Public Health, Boston, USA, , eestes@fas.harvard.edu, yshen@hsph.harvard.edu, jshine@hsph.harvard.edu

[2]Wellesley College, Wellesley, USA dbraband@wellesley.edu (*presenting author)

With the deposition of metal-bearing sediments from upstream sources, floodplains have the potential to serve as an exposure vector for heavy metals. Not only are floodplains frequently located proximate to population centers, transported metals may also be present in more bioavailable forms (adsorbed or in secondary mineral phases) than in source material. Thus, a complex set of transport and biogeochemical transformation processes determines the spatio-temporal distribution of metal-bearing phases. Given that complexity, which variables (source, transport, matrix, aging) control metal speciation and the fraction of metals that are bioavailable by ingestion and inhalation pathways?

We examine this question for lead-, zinc-, and cadmium-bearing soils in the Neosho-Tar Creek floodplain system in Miami, Oklahoma, USA. To identify the source of metals within floodplain soils we have combined major and trace element geochemistry with multivariable statistical analysis (PCA) to develop fingerprints for distinct metal sources (Figure 1). By combining this approach with X-ray diffraction (XRD) to broadly characterize soil mineralogy we have developed endmembers for mixing models that apportion the relative contribution of various metal-bearing phases (detrital primary ore minerals versus secondary iron oxides and hydroxides (FeOx) minerals).

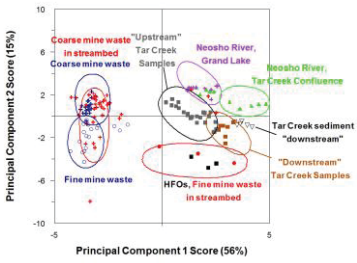

Figure 1: PCA of bulk element concentrations from floodplain soil and river sediment samples that demonstrate endmember sources and mixing relationships

Floodplain soil and sediment coring additionally allow us to reconstruct historic flood events and the temporal changes in metal flux, distribution, and speciation. We examine the role that shallow burial plays on the aging and in-situ weathering processes that result in FeOx mineral transformations. This combined approach will aid in estimating current and future risks associated with this evolving pool of bioavailable metals.

Calcite ($CaCO_3$) growth as a function of calcium-to-carbonate ratio in the presence of strontium: implications for the mechanism of inhibition

JACQUELYN N. BRACCO[1*], MEG C. GRANTHAM[1], ANDREW G. STACK[2]

[1]Georgia Institute of Technology, Earth and Atmospheric Sciences, Atlanta, USA, jbracco3@mail.gatech.edu (* presenting author)

[2]Oak Ridge National Laboratory, Chemical Sciences Division, Oak Ridge, USA, stackag@ornl.gov

One potential remediation method for toxic contaminants that has been proposed is to sequester the contaminant as an impurity in the crystal lattice of a mineral which incorporates the impurity. For example, radioactive strontium is present as a contaminant in a number of U.S. DOE sites and it may be possible to sequester it *in situ* through the engineered growth of calcium carbonate.[1] To enable targeted precipitation without porosity clogging and scale formation, separate injection wells of calcium and carbonate containing solutions have been proposed.

To understand this phenomenon, here we use atomic force microscopy (AFM) to examine the effect of strontium on calcite growth rates under solutions containing variable ratios of aqueous calcium-to-carbonate. Growth rates of the obtuse and acute step orientations on calcite were measured at two saturation indices as a function of the aqueous calcium-to-carbonate ratio and various aqueous strontium concentrations ranging from $0 - 9 \times 10^{-3}$ M. It was found that the amount of strontium necessary to inhibit growth correlated with the aqueous calcium concentration, but no correlation or inverse correlation was observed for carbonate. This suggests strontium is inhibiting attachment of calcium but not carbonate attachment or detachment.

At an average strontium-to-calcium ratio of 1.1 for the obtuse step orienation and 1.4 for the acute step orientation, the average step velcocity decreases to half of the maximum step velocity, which corresponds to the ratio where the concentration of strontium and calcium on the step at kink propagation sites is the same.[2] We propose that this corresponds to the cation exchange coefficent for calcium and strontium bound to precursor sites on the step.

The implications of this study are two-fold. Firstly, to ensure calcite growth is not inhibited by strontium, the concentration of calcium should be kept approximately higher than the cation exchange coefficient. Secondly, extensions of existing analytical models are unable to capture all the salient features of observed growth rates, indicating that improvement in analytical expressions can still be made.

Volcanogenic massive sulfide deposits host the evidence for sulfate-rich Archean oceans

JAMIE BRAINARD[1], ANDREW CHORNEY[1], AND HIROSHI OHMOTO[1]

[1]Penn State Astrobiology Center and Department of Geosciences, Penn State University, University Park, USA, JLB5156@psu.edu; APC5060@psu.edu; HQO@psu.edu

Recent researchers have suggested that the Archean oceans were sulfate poor (<0.1 mM SO_4^{2-}, compared to 28 mM today), because the atmosphere was supposedly poor in O_2 ($pO_2 < 10^{-6}$ atm) to completely oxidize the sulfur-bearing volcanic gases (H_2S and SO_2) and sulfide minerals in soils to SO_4^{2-}. However, such a scenario cannot explain the abundance of pyrite of Archean ages, much like those of younger ages, because these pyrites most likely formed by bacterial (or thermochemical) reduction of seawater SO_4^{2-}-.

One of the strongest lines of evidence for SO_4^{2-} rich Archean oceans comes from volcanogenic massive sulfide (VMS) deposits and alteration zones in their host rocks. VMS deposits, such as the black smoker deposits on MORs, formed on and beneath the seafloor by reactions between submarine hydrothermal fluids (typically ~50° to ~450°C) and the local seawater. The hydrothermal fluids evolved mostly through reactions between the underlying volcanic rocks and deep-circulating seawater, rather than derived directly from magmas. Therefore, the mineralogy and geochemistry of VMS deposits and their alteration zones reflect the chemistry of the contemporaneous ocean water. Phanerozoic VMS deposits are characterized by the abundance of pyrite and sulfate minerals, and by increased Fe^{3+}/Fe^{2+} ratios in the alteration zones due to the involvement of sulfate-rich seawater: some of the H_2S used to form the pyrite was generated by reduction of seawater sulfate by FeO components in rocks, resulting in the increases of Fe^{3+}/Fe^{2+} ratios. The ~3.2 Ga Panorama Formation of Western Australia hosts many VMS deposits with mineralogy, geochemistry, and associated alteration zones that are essentially identical to those of Phanerozoic ages, suggesting that the processes of submarine mineralization and the sulfate content of the seawater at 3.2 Ga were essentially the same as today.

Many other Archean VMS deposits and their alteration zones host barite ($BaSO_4$), such as the ~3.46 Ga Big Stubby deposits in Western Australia, the 3.26 Ga Fig Tree deposite in South Africa, the 2.6 Ga Geco deposit in Canada, and the 2.7 Ga Hemlo deposits in Ontario, Canada, suggesting that the Archean oceans remained sulfate-rich. The only major difference between the sulfate in the Archean oceans and that in the Phanerozoic oceans was the $\delta^{34}S$ values, between +2 and +5‰ during the Archean, but between +10 and +35‰ for the Phanerozoic. This difference has caused the $\delta^{34}S$ values of sulfides in Archean VMS deposits to be less than +5‰, where as those of Phanerozoic ages could be higher than +5‰, because the H_2S in the hydrothermal solutions came from the leaching of sulfides in igneous rocks ($\delta^{34}S \approx 0$‰) and from the partial reduction of seawater sulfate. These data suggest that the Archean oceans were as sulfate-rich as today's oceans due to the weathering of pyrite in rocks under an O_2-rich atmosphere.

Oxygen isotopes & Mg content in brachiopod calcite: equilibrium fractionation and a new paleotemperature equation

UWE BRAND[1*], K. AZMY[2], A. LOGAN[3], A. M. BITNER[4], B. DURZI[5], T. DURZI[6], M. ZUSCHIN[7]

[1]Department of Earth Sciences, Brock University, St. Catharines, Canada, uwe.brand@brocku.ca (* presenting author)
[2]Memorial University, St. Johns, Canada, kazmy@mun.ca
[3]University of New Brunswick, Saint John, Canada, logan@unbsi.ca

[5]18 Paradise Close, Grand Harbour, Cayman Islands
[6]University of Guelph, Guelph, Canada, tdurzi@uoguelph.ca
[7]University of Vienna, Vienna, Austria, martin.zuschin@univie.at

Modern brachiopods and ambient seawater were collected at fourteen localities from the Arctic to the Antarctic. The brachiopods were analysesd for Mg, $\delta^{13}C$ and $\delta^{18}O$, and their ambient seawater was measured for temperature, salinity and $\delta^{18}O$. Our materials were supplemented by those of Lowenstam [1]. $\delta^{18}O$ values of marine carbonates increase by about 0.06 or 0.17 ‰ per mol% $MgCO_3$ [2,3], and failing to adjustment for this 'Mg-effect" has a profound impact on water temperatures determined with standard paleotemperature equations. This Mg-effect on $\delta^{18}O$ values applies to all marine invertebrates secreting shells or tests made of calcite with variable amounts of $MgCO_3$, such as articulated brachiopods, foraminifera and enchinoderms. The Mg content of our brachiopods varies from a low of 250 to a high of 30,660 ppm, which needs to be accounted for by the oxygen isotope impact of the Mg-effect. We propose a new paleotemperature equation that considers the pristine biogenic calcite (δc) and accounts for both the Mg-effect as well as the established seawater oxygen isotope (δw) correction:

$$T°C=14.5-3.5((\delta c\text{-Mg effect})-\delta w)+0.13((\delta c\text{-Mg effect})-\delta w)^2$$

The 'Mg effect' is defined as the $MgCO_3$ content of brachiopod calcite*0.17 ‰ (per mol% $MgCO_3$, accepting the latest study results [3]). Without adjustment for the Mg-effect, paleo seawater temperatures and compositions may be different than actual ones.

Without considering the effect of $MgCO_3$ on the oxygen isotopic composition, most modern brachiopods were found to precipitate shell carbonate in equilibrium with ambient seawater [4,5]. To re-evaluate the exceptions, *Thecidellina* and *Hemithiris* were collected from several localities. After making allowance for the Mg-effect on their $\delta^{18}O$ compositions and water-$\delta^{18}O$ corrected, calculated seawater temperatures were significantly similar to measured ones. $\delta^{18}O$ values of other modern brachiopods deemed problematic, after adjustment for the Mg-effect also offered up equilibrium water temperatures. Thus, we can state that modern, calcitic, articulated brachiopods incorporate oxygen isotopes into shell calcite in equilibrium with ambient seawater, and this will be of critical importance to other modern and fossil calcitic carbonates.

X-ray Spectromicroscopy: Illuminating the biogeochemical cycles of elements in the marine environment

JAY A. BRANDES[1*], ELLERY D. INGALL[2], AND JULIA M. DIAZ[3],

[1]1Skidaway Institute of Oceanography, 10 Ocean Science Circle, Savannah, GA 31411 USA,jay.brandes@skio.usg.edu (* presenting author)

The geochemical cycling of elements on Earth's surface is intrinsically linked to biological processes. These links include biologically-mediated formation/solution of minerals, sorption/desorption onto surfaces modified by organic matter, and biological activity. All such processes begin at the nanoscale. Therefore the ability to examine biologically generated or modified sediments, soils and other particulates at nanoscales provides a fundamental view into the cycling of elements. Unexpected insights are often generated using instruments capable of examining the nanoscale composition, speciation, redox state and co-association of elements within particulates. For example, in the marine environment, one can consider the generation and sequestration of carbon by phytoplankton as being limited by the availability of necessary nutrients, such as phosphorus (P) and iron (Fe). X-ray spectromicroscopy of P within planktonic organisms, sinking particulates, and underlying sediments has revealed a wide array of P types, including organic P compounds, polyphosphates, apatites and other P-containing minerals. Further examination of the associations of P, Fe and other elements also shows a variety of nutrient removal mechanisms. The results begin to show how P is sequestered in the environment, first through the preservation and burial of poorly organized but relatively pure biogenic polyphosphates and calcium phosphates, then through transformation into more ordered, and substituted mineral phases. Overall the picture of P chemistry at sub-micron scales reveals a complex system interacting both with biologically produced particulate P and terrestrially- or aeolian-derived P mineral phases.

Mesozoic MORB

P. A. BRANDL[1*], M. REGELOUS[1], C. BEIER[1] AND K. M. HAASE[1]

[1]GeoZentrum Nordbayern, Friedrich-Alexander Universiät Erlangen-Nürnberg, Erlangen, Germany, philipp.brandl@gzn.uni-erlangen.de (* presenting author)

Formation of the oceanic crust at mid-ocean ridge spreading centres and its subsequent evolution has an important influence on sea-level, the carbon cycle and seawater chemistry over timescales of 10-100 Ma. Previous geochemical studies of ancient MORB (e.g. [1, 2, 3]) reported chemical differences between Mesozoic and young mid-ocean ridge basalt (MORB) that were interpreted as the result of a 50-60°C higher upper mantle temperature [1, 2]. Higher mantle temperature on average would cause shallower depth of mid-ocean ridges, rising sea-levels and global warming by increased CO_2 emission.

We present new major and trace element data, measured using electron microprobe and LA-ICPMS techniques, for more than 360 glasses from 30 DSDP-ODP-IODP drill sites. The age of the oceanic crust at these sites ranges from 6 Ma up to 160-170 Ma, and all sites were drilled into normal oceanic crust far from hotspots. We have analysed exclusively fresh volcanic glasses, since whole-rock samples may be compromised by alteration and accumulation of phenocrysts.

We find that there are small but significant differences between fractionation corrected major element compositions of old (drilled) and zero-age (dredged) samples, e.g. for Na_{72}, Fe_{72}, Ca_{72}, and Al_{72}. We can exclude any analytical bias, alteration effects or uncertainties in fractionation correction for these differences. For both, Pacific and Atlantic, there is no clear systematic change in fractionation corrected major element composition of drilled MORB with time, as would be expected for a change in mantle temperature [1]. Some of these differences between zero-age and drilled MORB samples could arise if the oceanic crust is compositionally layered. MORB drilled from off-axis represent younger flows erupted further from the ridge axis. In contrast, most samples in the zero-age MORB dataset were dredged from the ridge axis, which eventually make up the lowermost section of the oceanic crust [4].

Lavas erupted off-axis may sample different parts of the melting region and/or undergo different fractional crystallisation histories to lavas erupted at the ridge axis. This effect could mean that average MORB compositions calculated using only samples dredged from the ridge axis are not completely representative of the extrusive section of the oceanic crust.

The Shergottite Chronology Debate: In Support of Young Igneous Crystallization Ages

ALAN BRANDON[1]*

[1]University of Houston, Department of Earth and Atmospheric Sciences, Houston, TX, 77204, USA, abrandon@uh.edu

The shergottite meteorites provide powerful constraints on early differentiation in Mars ([1,2] and references therein). These constraints depend on having well determined igneous crystallization ages for the rocks, from which initial ratios for radiogenic isotope systems are calculated. Shergottite ages interpreted to be igneous, ranging from 474 to 166 Ma have been obtained from internal isochrons using the Lu-Hf, Sm-Nd, and Rb-Sr systems (e.g. [1,3]). Recently, these young igneous crystallization ages have been called into question [4,5,6]. Secondary Pb-Pb isochrons for different shergottites give purportedly circa 4.1 Ga ages and have been interpreted to be the true igneous ages while the younger ages represent resetting from shock or fluid-rock interaction [4,5,6].

This issue is examined here by first presenting the petrological, mineralogical, and lithophile isotope evidence that supports the young ages as being igneous. Second, these relationships are evaluated using Re-Os isotopes [7]. One strong piece of supporting evidence for young ages is the EETA 79001 Re-Os isochron (Figure 1). The two lithologies sampled come from portions of the meteorite several centimeters apart, give an isochron age of 164±12

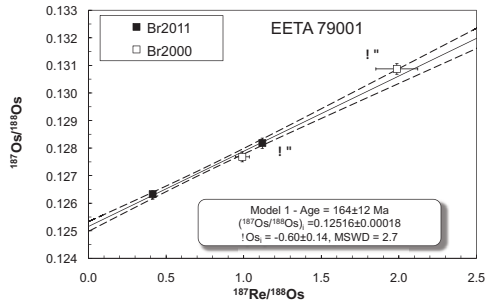

Figure 1: Re-Os isotope systematics of EETA 79001, modified from [7]. A and B designate fractions analyzed from litholigies A and B, respectively. Data from [7] – Br2011, from [8] – Br2000.

Ma (±2σ), concordant to internal mineral isochron ages for ^{87}Rb-^{87}Sr of 173±10, 177±12, and 174±3 Ma, for ^{147}Sm-^{143}Nd of 169±23 Ma, for ^{238}U- ^{206}Pb of 150±15 Ma, and for ^{232}Th-^{208}Pb of 170±36 Ma [9,10,11]. It is not likely possible to generate such systematics from shock unless diffusion rates are orders of magnitude faster than expected. Additional evidence will be presented that examines this issue.

Replacement of Barite by Radiobarite at close to equilibrium conditions and room temperature

FELIX BRANDT[1*], MARTINA KLINKENBERG[1], KONSTANTIN ROZOV[1], GUISEPPE MODOLO[1], DIRK BOSBACH[1]

[1]Forschungszentrum Juelich, IEK-6, Juelich, Germany, f.brandt@fz-juelich.de (*presenting author); m.klinkenberg@fz-juelich.de; k.rozov@fz-juelich.de, g.modolo@fz-juelich.de, d.bosbach@fz-juelich.de

The solubility control of Ra by coprecipitation of a $Ra_xBa_{1-x}SO_4$ solid solution has been demonstrated in many cases and can be modeled reliably (Doerner & Hoskins, 1925). However, an open question is whether a Ra containing solution will equilibrate with solid $BaSO_4$ under repository relevant conditions. Here, Radium enters a system in which barite is in equilibrium with the aqueous solution. Previous studies have indicated that Ra uptake is not limited by pure adsorption but involves a significant fraction of the bulk solid, i.e. barite partially or fully recrystallizes to radiobarite (Bosbach et al., 2010; Curti et al., 2010). Here, we present experimental data from batch recrystallization experiments at room temperature in which a pure barite solid was put into contact with an aqueous solution with an initial Ra/Ba ratio of 0.3 ($5 \cdot 10^{-6}$ mol/L Ra) at neutral pH. Two barites of different morphology and surface area were used during the recrystallization experiments at close to equilibrium conditions and with variation of solid to liquid ratio.

The experimental results show a decrease of the Ra concentration to $3.5 \cdot 10^{-9}$ to $7 \cdot 10^{-9}$ mol/L within the first 70 days of the experiment at a solid/liquid ratio of 5 g/L. At a solid/liquid ratio of 0.5 g/L a slower decrease of the Ra concentration to $2 \cdot 10^{-8}$ mol/L is observed after 180 days. The decrease of the Ra concentration is apparently not related to the specific surface area of the barite crystals. The final radium concentrations are in the range as can be expected from thermodynamic calculations assuming full reequilibration of the barite to a $Ra_xBa_{1-x}SO_4$ solid. Different thermodynamic models describing the mechanism of Ra incorporation into barite are discussed: (1) Ba – Ra exchange into the crystal volume, combining the Ra – Ba exchange with the Ba – Ba recrystallization rate at equilibrium conditions (Curti et al, 2010);

(2) the formation of a Ra-Ba-Phase on barite surfaces. The formation of a Ra-Ba phase on the barite surfaces could be possible because all experiments are already slightly supersaturated with regard to $Ra_xBa_{1-x}SO_4$ after about one day. Crystallization rates calculated according to this model are in a similar range for all experiments when normalized to the barite surface area.

The results of this study will provide the basis for further spectroscopic and microscopic investigations in order to obtain a molecular-level understanding of the Ra incorporation into barite.

Back to the Future: The Art of Weathering

SUSAN BRANTLEY[1*] HEATHER BUSS[2] MARJORIE SCHULZ[3]

[1]The Pennsylvania State University, Earth and Environmental Systems Institute, University Park, PA, USA, sxb7@psu.edu (*presenting author)
[2]University of Bristol, School of Earth Sciences, Bristol, UK, h.buss@bristol.ac.uk
[3]U.S. Geological Survey, 345 Middlefield Road, Menlo Park, CA, USA, mschulz@usgs.gov

Geologists and soil scientists attempt to go back to the future to read the geochemical record written in regolith. If we could do this, we could use earthcasting models to project the surface earth in the future just as we use forecasting models to project the weather. But going back into geological time to read the record in soil profiles is both a science and an art due to the interdependence of chemistry, physics, and biology at the earth's surface. The art of earthcasting is also hard because such models must have the capacity to span timescales ranging from seconds for hydrogeochemical effects up to tens of millions of years or longer for tectonic processes.

We discuss the contributions of one scientist, Art White (recently retired from the U.S. Geological Survey, Menlo Park, CA, USA), who spent a career investigating geochemical processes and how they affect mineral-water reactions in pursuit of understanding the surface Earth. Art recognized that soil profiles are records of biogeochemistry that can be interpreted using kinetics and thermodynamics. With the use of geochemical, physical, hydrological and biological measurements, regolith formation rates can be constrained and geochemical descriptions can be made quantitative. Art's work in the laboratory – including a 16 year experiment – and at several field sites as part of the USGS WEBB program, including Panola, Georgia; the Luquillo Mountains, Puerto Rico; and the Santa Cruz terraces, CA; resulted in a series of papers that have greatly influenced our understanding of the earth's surface. Today, much of this work is termed Critical Zone science: Art was one of the originators of the Critical Zone Exploration Network and is therefore one of the original CZEN masters. His contributions helped lead to the big programs in Critical Zone science in the U.S.A. and elsewhere. Art and the many scientists before him (back to even the 16th century when soil profiles were first studied) set the stage for today's "artists of weathering". Now, new field opportunities, theoretical models, analytical tools, microbiological observations and sensors are elucidating the beauty and art of the Critical Zone.

Low temperature alkaline pH hydrolysis of oxygen-free Titan tholins

The largest moon of Saturn, Titan, is known for its dense, nitrogen-rich atmosphere. The organic aerosols which are produced in Titan's atmosphere are of great astrobiological interest. particularly because of their potential evolution when they reach the surface and may interact with putative ammonia-water cryomagma[1].

In this context we have followed the evolution of alkaline pH hydrolysis (13wt% ammonia-water) of Titan tholins (produced by an experimental setup using a plasma DC discharge named PLASMA) at low temperature. Our group identified urea as the main product of tholins hydrolysis along with several amino acids (alanine, glycine and aspartic acid). However, those molecules have also been detected in non-hydrolyzed tholins meaning that oxygen gets in the PLASMA reactor during the tholins synthesis[2]. So the synthesis system has been improved by isolating the whole device in a specially designed glove box which protects the PLASMA experiment from the terrestrial atmosphere.

After confirming the non-presence of oxygen in tholins produced with this new experimental setup, it is necessary to perform alkaline pH hydrolysis in oxygen-free tholins in order to verify that organic molecules cited above are still produced or not... Moreover, a recent study shows that the subsurface ocean may contain lower fraction of ammonia (about 5wt% or lower[3]), than previously used. Thus new hydrolysis experiments will take this lower value into account. Additionally, a new report [4] provides upper and lower limits for the bulk content of Titan's interior for various gas species. It also shows that most of them are likely stored and dissolved in the subsurface water ocean. But considering the plausible acido-alkaline properties of the ammonia-water ocean, additional species could be dissolved in the ocean and present in the magma. They could also be included in our hydrolysis experiments.

The preliminary results of those experiments will be presented.

Submarine and Sublacustrine Groundwater Discharge

Groundwater/surface water interaction has been the subject of intense investigation in both marine and freshwater settings in recent years. Although many study methods can be used interchangeably in these systems (e.g., seeepage meters), those that rely on salinity contrasts to distinguish surface water from groundwater (e.g., electrical resistivity profiling) cannot. A schematic spatial framework that was recently developed for dividing submarine groundwater discharge (SGD) phenomena [1] can also be applied to large lakes with some modifications. Some natural radioisotopic tracers of SGD developed in marine systems can be used in freshwater settings [2]. Conversely, a regional approach to examining groundwater occurrence and flow in a watershed containing large lakes, as has been undertaken for the Great Lakes [3], might be productively applied to a coastal ocean region.

In addition to the salinity contrasts, one major geochemical difference between discharge of groundwater to fresh or saline surface water is the influence on eutrophication. Because nitrogen is typically the limiting nutrient in marine systems, whereas phosphorus limits productivity in most freshwater systems [4], SGD plays a much larger role in eutrophication of marine systems than in freshwater systems. Dissolved nitrogen species tend to be concentrated in coastal groundwater, but phosphorus is particle reactive and unlikely to be delivered to surface water in large quantities from groundwater in most lakes. Most phosphorus comes from runoff and sediment recycling in freshwater systems.

Unusual groundwater vent features have been documented in both marine and lake settings, especially along carbonate-dominated coasts. Among the most spectacular are brackish sinkhole springs in Florida and Lake Huron, the latter of which include extensive purple cyanobacterial mat communities [5].

Conclusion

Significant opportunities exist for advancing understanding of elemental cycling and other features of groundwater/surface water interaction in large water bodies with more exchange of methods and results among scientists that work in marine and freshwater settings.

Contemporary saprolite production rates and aggressiveness of pore waters: Comparison between Nsimi and Mule Hole small experimental watersheds

JEAN JACQUES BRAUN[1]*, JEAN-CHRISTOPHE MARECHAL[2], JEAN RIOTTE[1,3], MUDDU SEKHAR[1,4]

[1]IFCWS IISc-IRD joint laboratory, Bangalore, India, jjbraun1@gmail.com (* presenting author)
[2]BRGM, Montpellier, France, jc.marechal@brgm.fr
[3]GET, Toulouse, France, jeanriotte1@hotmail.com
[4]Dept. of Civil Engg., IISc., Bangalore, India, sekhar.muddu@gmail.com

Introduction

Thanks to geochemical, mineralogical and hydrological studies and using Chloride Mass Balance approach, we compare two ridge top weathering profiles (WP) developed on granodioritic basement from Mule Hole (South India) and Nsimi (South Cameroon) small experimental watersheds (SEW). The objective is to get deeper insight into (i) the contemporary saprolite production rates and (ii) the combined effect of precipitation and evapotranspiration on the aggressiveness of the draining solutions.

Field settings

The Nsimi SEW presents the contemporary weathering conditions for a 36 meter deep, mature weathering cover under humid climate (Mean Annual Rainfall = 1660 mm/yr, Actual EvapoTranspiration (AET) = 1270 mm/yr) with a Recharge (R) = 332 mm/yr out of which 90% of the solutes are discharged into the springs/brook and 10 % through the groundwater[1][2]. The Mule Hole SEW presents the contemporary weathering conditions for a 17 meter deep, immature weathering cover under sub-humid climate (MAR = 1280 mm/y, AET = 1100 mm/yr) with R = 45 mm/yr out of which 100% of the solutes are discharged through the groundwater as underflow from the watershed[3][4][5]. Moreover, the Nsimi groundwater saturates the entire saprolite whilst the Mule Hole groundwater saturates the fractured bedrock only.

Results and conclusions

Considering (i) Na as representative of the dissolution of plagioclase crystals and conservative during saprolitization processes and (ii) steady state of the inter-annual recharge for a 10 years period, the current saprolite production rates (SPR) are of 22 mm/kyr for Mule Hole and 2 mm/kyr for Nsimi, respectively.

Even with a very low R/MAR ratio (0.04) compared to Nsimi, the chemical weathering at Mule Hole is active and related to the groundwater exports. However, the high Nsimi R/MAR ratio (0.2) allows the solution to be still aggressive with respect to the plagioclase at the bedrock interface leading to their complete breakdown in a few centimeters. For Mule Hole, plagioclase are still present in the saprolite and the soil cover.

The source of carbon in cave air CO_2 under mixed woodland and grassland vegetation

DANIEL O. BREECKER[1*], ASHLEY E. PAYNE[1], JAY QUADE[2], JAY L. BANNER[1], CAROLYN E. BALL[3], AND KYLE W. MEYER[1]

[1]The University of Texas at Austin, Austin, USA, breecker@jsg.utexas.edu (* presenting author)
[2]The University of Arizona, Tucson, USA
[3]The University of Florida, Gainesville, USA

We measured concentrations and stable carbon isotope compositions of CO_2 in the atmospheres of several caves in central Texas and southern Arizona in order to identify the sources of CO_2 -carbon. The vegetation above all of the caves studied is a mixture of grasslands (C_3 and C_4 vegetation) and woodlands (dominantly C_3 juniper and oak trees). We tested the hypothesis that the deepest rooting plants have a dominant influence of the $\delta^{13}C$ value of CO_2 in the caves. Within caves, we monitored CO_2 at individual locations on monthly and daily time-scales. We also measured CO_2 in the pore spaces of soils dominated by different vegetation types above each cave. The $\delta^{13}C$ value of respired CO_2 ($\delta^{13}C_r$) was calculated for all gas samples from the measured $\delta^{13}C$ values and CO_2 concentrations by rearranging equations derived by Davidson[1]. The sources of cave CO_2 were then identified by comparing soil and cave air $\delta^{13}C_r$ values. In three of the caves, mean cave air CO_2 $\delta^{13}C_r$ values were within 0.5 ‰ of mean $\delta^{13}C_r$ values in woodland soils (-23 to -24‰ vs VPDB), even when measured $\delta^{13}C$ values of cave and soil CO_2 were different by up to 2.5‰. The $\delta^{13}C_r$ values in grassland soils above these three caves were 3-5 ‰ higher than cave and woodland soil values. In one cave covered primarily by grassland and roads, the cave $\delta^{13}C_r$ values were intermediate between grassland and woodland values. When cave-air CO_2 concentrations were below 1000 ppmV, cave $\delta^{13}C_r$ values were more negative than woodland soil values by 20‰ or more, likely the result of preferential degassing of $^{12}CO_2$ from CO_2-supersatured drip water[2]. The consistent agreement between soil and cave air $\delta^{13}C_r$ values indicate that the same mixing and diffusion equations, which are used to calculate $\delta^{13}C_r$ and have been previously applied to soils, also apply to cave atmospheres. Our results suggest that unless cave CO_2 concentrations are <1000 ppm the majority of CO_2 advects or diffuses into these caves from soils as a gas rather than being transported in aqueous solution. Calculated $\delta^{13}C_r$ values suggest that juniper and/or oak trees supply most of the carbon to CO_2 in the atmospheres of these caves, likely because these trees have deeper roots than the other plants in these ecosystems. A one-dimensional numerical model of CO_2 production and diffusion that uses depth-dependent $\delta^{13}C_r$ values as input supports our empirical results and our hypothesis that deeply rooted trees control the $\delta^{13}C_r$ values of cave air CO_2, even if deep respiration rates are small compared with those in the shallow subsurface. We further suggest that if a vegetation signal is archived in the carbon isotope composition of speleothem calcite, then it may be biased toward deep-rooted plants.

Sulfide-silicate partitioning of PGEs (and Au): Implications for noble metal behaviour in magmatic systems

JAMES M. BRENAN[1*]

[1]University of Toronto, Toronto, Canada, brenan@geology.utoronto.,ca (* presenting author)

There is considerable variation in sulfide-silicate melt partition coefficients for the noble metals (PGEs and Au), with most direct measurements (analysed by bulk methods) yielding values of 10^4 or less [e.g., 1]. More recent estimates, which combine separate metal solubility measurements in sulfide and silicate, have suggested partition coefficients exceeding 10^7 [2,3]. Resolving this discrepancy is essential for developing accurate models of noble metal behaviour during melting, and validating metal concentration mechanisms in magmatic systems.

In this study, sulfide and silicate were equilibrated at known fO2-fS2 conditions, with run-products analysed by LA-ICPMS to ensure exclusion of sulfide contamination from the silicate melt analysis. Experiments were done at 1200 deg. C and 1 atm with fS2 controlled using the Pt-PtS buffer and fO2 estimated to be FMQ-1. Three different synthetic basalts were employed, differing in their FeO content (5-15 wt%), with the added sulfide melt composition having FeS stoichiometry + 1 wt% each of Cu and Ni. Glass + sulfide were packed in crucibles made from natural chromite, then loaded, along with the sulfide buffer, in silica ampoules, which were evacuated, then sealed. Samples were held for 1 to 4 days at temperature, then quenched in cold water. Run-product glasses were free of obvious sulfide contamination, as evidenced by uniform, and low time-resolved signals for the PGE and Au.

Concentrations of Ru and Os in run-product glasses were always below detection (approx 20 and 5 ppb, respectively), yielding minimum sulfide/silicate partition coefficients of >10^5 (Ru) and >10^6 (Os). Measurable, but low, abundances for other PGE and Au were determined, with calculated sulfide/silicate partition coefficients of >10^5 (Pd, Rh, Ir, Pt) and 4000-11000 (Au). Partition coefficients for Pd, Rh, Ir and Pt were found to increase with increasing concentrations of these elements added to the sulfide melt, with little or no change in the silicate melt concentration. This is interpreted to reflect a low level of sulfide contamination in the silicate melt, and argues for even higher partition coefficients for these elements. Thus, results are in line with the large partition coefficients estimated from combined sulfide and silicate PGE solubility data. Application of these data to sulfide-saturated partial melting models yields levels of PGE and Au in calculated melts which are much lower than observed for MORB or OIB; only at the point of near complete sulfide exhaustion are calculated and observed abundances similar. An alternative to residual sulfide, such as a combination of olivine, chromite along with an alloy phase, may be required to account for levels of these elements in oceanic basalts.

The concentration of He in the atmosphere (residence time ~10^6 years) is governed by the balance between its release from the solid earth and its loss into space. Due to the burning of fossil fuels, which is known to be rich in He, an increase of the atmospheric He concentration over the past decades has been predicted. However, the predicted increase is small, and the precision of currently available measurement techniques is insufficient to verify this potential increase.

An alternative approach to study this possible increase in the atmospheric He concentration is to analyse the $^3He/^4He$ ratio in historic air samples. The $^3He/^4He$ ratio in fossil fuels is commonly one to two orders of magnitude lower than in the atmosphere. An increase of the He concentration in the atmosphere due to burning of fossil fuel would therefore correspond to a decrease of the atmospheric $^3He/^4He$ ratio that might be detectable with currently available measurement techniques. However, while some studies claim to have found evidence for a decrease in the $^3He/^4He$ ratio in the atmosphere during the last few decades, other studies were not able to confirm this observation.

In an attempt to resolve this long-standing controversy, we conducted isotopic analyses of *all* the atmospheric noble gases (He, Ne, Ar, Kr and Xe) in air samples from a well-defined archive of marine boundary layer air in the southern hemisphere (Cape Grim Air Archive, Australian Bureau of Meteorology and CSIRO). In our presentation we will report the results of these analyses and discuss them in terms of a possible change in the atmospheric He concentration. The $^4He/^{20}Ne$ ratio in particular turned out to be a very sensitive proxy for this purpose. Because the $^4He/^{20}Ne$ ratio in fossil fuels is about 8 orders of magnitude lower than in the atmosphere, the addition of noble gases from fossil fuels to the atmosphere has a much stronger effect on the $^4He/^{20}Ne$ ratio than on the $^3He/^4He$ ratio. At the same time, if He and Ne are not separated from each other before analysis in the mass spectrometer, the $^4He/^{20}Ne$ ratio can be quantified with a better precision than the $^3He/^4He$ ratio. Broadening the atmospheric He analysis to include other noble gas isotopes therefore allows us to put much firmer constraints on possible changes in the atmospheric He concentration that may have resulted from the burning of fossil fuels during the last few decades.

Improving ^{182}Hf-^{182}W ages in altered CR chondrites

T. BRETON*, G. QUITTÉ AND F. ALBARÈDE

CNRS UMR 5276, ENS de Lyon, Université Lyon 1, Lyon, France, thomas.breton@ens-lyon.fr (* presenting author)

Introduction

Despite their high content of segregated metal and their diverse degrees of alteration, CR chondrites are considered among the most primitive meteorites in the solar system. Applying the ^{182}Hf-^{182}W chronometer to these samples therefore seems interesting to better constrain the earliest stages of metal segregation. While NWA 721 and NWA 801 yield ^{182}Hf-^{182}W ages of ~5 Ma after CAIs, Renazzo is surprisingly ~50 Ma younger [1], which suggests that the ^{182}Hf-^{182}W chronometer may have been disturbed in this particular sample.

Hf and W behavior in natural processes

Although the ^{182}Hf-^{182}W chronometer may have been reset by thermal metamorphism [2], Renazzo seems free of thermal overprinting. However, this meteorite shows evidence of strong aqueous alteration [3] and Pourbaix (Eh-pH) diagrams indicate that tungsten is affected by this process [4]. $\varepsilon^{182}W$ values, which are corrected for mass dependent fractionation, will not be harmed, whereas the Hf/W (parent/daughter) ratios will. Hafnium is indeed far less mobile than W that, in neutral to high-pH fluids, are most likely lost as tungstate. The internal isochron is thus disturbed and the apparent age is younger.

A simple single-stage model suggests that aqueous alteration rotates the isochron around the y-intercept. Thus, the y-intercept seems suited to determine the timing of metal-silicate segregation, even in altered samples. This model reduces the time interval between NWA 701 / NWA 801 and Renazzo to 14 ± 14 Ma.

Tafassasset: an old unaltered CR chondrite

Tafassasset, an anomalous CR chondrite [5, 6] is metamorphosed but not aqueously altered. If alteration affects the Hf-W isochron, this meteorite is of particular interest to experimentally infer the timing of metal-silicate segregation in the CR parent body(ies). Seven different mineral phases (pure metal, several magnetic phases, silicate phases and two bulks) have been separated and analyzed. The W concentrations are 800 ppb and 15 ppb in metal and silicates, respectively. MC-ICPMS and N-TIMS measurements were performed, depending on the amount of W available in each fraction. Both techniques yield the same results within uncertainties. Data plot on a well defined line in an isochron diagram. Ages calculated from the slope or from the initial of this isochron relative to CAIs [7, 8] are consistent with each other: metal-silicate equilibration in Tafassasset occurred less than 2 Ma after Allende CAIs. This meteorite is thus older than the other CR2 chondrites analyzed so far, and among the oldest known chondrites.

Interaction of selenite with iron sulphide minerals: a new perspective

ERIC BREYNAERT[1,*], DIRK DOM[1], ANDREAS C. SCHEINOST[2], CHRISTINE E.A. KIRSCHHOCK[1], ANDRÉ MAES[1]

The geochemistry of selenium, exhibiting valence states from +VI to –II, is of key importance due to its role as a highly toxic essential micronutrient and as a significant component of high level radioactive waste (HLRW). XAS studies conducted at circum-neutral pH have shown that pyrite (FeS_2), the most relevant redox-active mineral in Boom clay, reduces selenite to a solid-state Se(0) phase. This observation raises several questions. First, why does an Fe-free Se(0) phase form in presence of pyrite, while selenite is reduced to $FeSe_x$ by troilite and mackinawite (FeS)?[1-4]. What is the exact identity of this Se(0) phase, which has been observed by several authors? Why is a dissolved, low oxidation-state selenium species encountered in association with the Se(0) phase; and what is its identity? Correlating selenium redox chemistry with sulphide mineral oxidation pathways allowed to link these observations to the different oxidation behaviour of acid-soluble and acid-insoluble metal sulphides [5].

Acid insoluble metal sulphides such as pyrite, molybdenite or tungstenite exhibit oxidative dissolution only. Upon six consequent one-electron oxidation steps, a thiosulphate anion is liberated (thiosulphate pathway). In contrast, acid soluble metal sulphides (troilite, mackinawite, sphalerite, etc.) exhibit also non-oxidative dissolution thereby liberating sulphide species (H_2S, HS^-,S^{2-}). Under oxidative dissolution in presence of Fe^{III}, they release sulphide cations (e.g. H_2S^+). The latter can spontaneously dimerize into disulphide species, which may further react to polysulphide (polysulphide pathway) and finally elemental sulphur.

The end products of Se(IV) reduction by acid-soluble iron sulphur minerals are fairly well known, but the solid and liquid phase species present during interaction of SeO_3^{2-} with pyrite are poorly characterized. The solid phase reaction product could not yet be assigned as a specific phase, but clearly identified as a Se^0 compound. Trigonal (grey) selenium could be excluded as a canditate.[4]

The presence of an unexpected high concentration of reduced, dissolved species in presence of pyrite, led to a new pyrite-centered reduction mechanism. Based on this mechanism, a hypothesis about the identity of the unknown dissolved species was put forward. In addition, the new mechanism explains all current experimental observations, especially the presence of the currently non-identified dissolved species and the unexpected relation between Se(IV) reduction and pH.[6]

Soil mycorrhizal fungi act through biochemical interactions at nanometre scale to dissolve minerals and transport weathering products to plant symbionts through metre-scale mycelial networks. This symbiosis has profound consequences for rates of carbon sequestration from the atmosphere to soil, and rates of nutrient mobilisation from soils, that are apparent on global and geological time scales [1]. Previous research within our consortium has shown convincingly the nanoscale weathering of minerals by hyphae in direct contact with minerals [2], and at the same time the transport and redistribution of mineral- and plant-derived nutrients (carbon, phosphorus) within the rhizosphere and the plant itself [3].

A key factor in this biologically-driven weathering system is the relationship between the energy supplied from the plant to the mycorrhiza, and the rate of weathering of minerals. Critically, what is the nature of the feedback between the plant root and the distal hyphae that controls allocation of photosynthate within the mycelial network in response to nutrient uptake? Here, we present the results of numerical modelling and simulation of hypha-mineral weathering and hyphal network growth which couples a mechanistic model of element release from minerals with fluxes of carbon and mineral nutrients between the plant root and the whole mycelium. Our models indicate that the efficiency of mycorrhizal weathering is sensitive to both geochemical and biological parameters and is time-dependent. We hypothesize that pore-scale variations in weathering efficiency as mycorrhizae progressively spread through soil provide a mechanism to drive hyphal growth behaviour (e.g., exploratory vs. exploitative) and direct photosynthate demand.

High precision Zn concentration and stable isotope composition data were acquired for 21 metal samples of 15 different iron meteorites of groups IAB, IIAB and IIIAB. Troilite nodules were also analyzed, in addition to leachates and leachate residues of troilites separated from the IAB iron Toluca. All results were obtained by MC-ICP-MS using a Zn double spike technique for correction of instrumental mass bias.

The metal samples of each group display a discrete range of Zn concentrations – about 80 to 250 ppb for IIABs, 1 to 3 ppm for IIIABs and 10 to 35 ppm for IABs – at similar and overlapping $\delta^{66/64}$Zn values. These results are in accord with earlier studies [e.g., 1], which inferred that IAB irons are derived from a volatile rich parent body, whilst IIABs and IIIABs are from more volatile depleted precursors. They furthermore support previous stable isotope work, which concluded that volatile element depletion in the solar nebula was not associated with significant isotope fractionation because it did not involve partial Rayleigh evaporation or condensation [e.g.,2].

The Zn isotope compositions of the metal samples are ubiquitously heavy with $\delta^{66/64}$Zn of between about 0‰ and +2.5‰. In comparison, both the silicate Earth, which contains the bulk of the Earth's Zn budget, and most chondritic meteorites are characterised by $\delta^{66/64}$Zn values of about 0.0±0.5‰ [3,4]. Considered together, this suggests that metal–silicate segregation during planetary differentiation is associated with minor but resolvable Zn isotope fractionation, whereby isotopically heavy Zn is enriched in the metal phase.

Furthermore, distinct negative trends of decreasing $\delta^{66/64}$Zn with increasing Zn content were observed for each meteorite group. Such systematic variations were also seen for four sub-samples of the IIAB iron meteorite Sikhote – Alin. Hence it is likely that the trends are caused by small-scale heterogeneities in the distribution of Zn within the meteorites. Furthermore, our analyses and previous work [e.g., 5] suggest that the correlations reflect the variable occurance of isotopically light and Zn-rich phases, most likely chromite and/or daubreelite associated with troilite inclusions, within a metal matrix characterised by low Zn contents and high $\delta^{66/64}$Zn values.

Constraints on seawater sulfate concentrations through examination of temporal trends in δ^{13}C of methane seep carbonates

THOMAS F. BRISTOW[1*], JOHN P. GROTZINGER[2],

[1]NASA Ames Research Center, Moffett Field, USA, (thomas.f.bristow@nasa.gov)
[2]California Institute of Technology, Pasadena, USA, grotz@gps.caltech.edu

Since the relatively recent discovery of ecosystems based on energy derived from anaeorobic methane oxidation (AMO) more than 50 ancient examples have been recognized in the geological record [1]. Ancient methane seeps are recognized by endemic seep fauna and/or lithological, textural evidence of the passage and metabolism of methane bearing fluids. Highly ^{13}C-depleted carbonates (<-30‰ PDB) that precipitate from carbonate alkalinity generated by AMO provide an additional diagnostic indicator of ancient seeps; no other biogeochemical process is known to produce carbonates with such isotopic signatures at Earth-surface conditions.

Examination of the temporal occurance of seep deposits reveals that the majority of examples are reported from the Phanerzoic. Furthermore, δ^{13}C depletion to <-30‰ PDB in seep carbonates is not observed until the Early Carboniferous [2]. Because the main oxidant utlized in AMO at modern methane seeps is sulfate, it has been hypothesized that the temporal and isotopic trends of seep carbonates may reflect the influence of changing oceanic sulfate concentrations on AMO rates [3]. This hypothesis was investigated using 1D reaction-transport model that simulates the δ^{13}C of porewaters and precipitation of carbonates in a porous sedimentary profile where AMO is the main biogeochemical process.

AMO rates and controls on rates at modern methane seeps are well documented [4]. The model was tuned using porewater data collected from cores taken at Hydrate Ridge – a site with one of the highest integrated AMO rates observed in recent seeps. With these parameters we are able to estimate minimum threshold ocean [SO_4^{2-}] required to produce the levels of δ^{13}C depletion in seep carbonates observed in the geological record. Preliminary results show that low ocean [SO_4^{2-}], thought to characteristize much the Proterozoic and Archean, provides a plausible explanation for the absence of geochemical evidence for seeps in this period. Although the Paleozoic record of seeps is sparse, model calculations support S-isotope and fluid inclusion data indicating mM [SO_4^{2-}] in the early Paleozoic oceans, with a rise to >10 mM levels in the Late Devonian/Early Carboniferous, corresponding with the rise of land plants [5,6]. Implications for Ediacaran ocean [SO_4^{2-}] will also be discussed. Our investigation shows that secular variations in ocean [SO_4^{2-}] provide a plausible explanation for the temporal distribution and δ^{13}C of seep carbonates and highlight the need to refine criteria for recognizing ancient methane seep ecosystems.

The unusual nature of the Proterozoic biomarker record and the Mat-Seal hypothesis

JOCHEN J. BROCKS[1*], MARIA M. PAWLOWSKA[2], AND NICHOLAS J. BUTTERFIELD[2]

[1] The Australian National University, Research School of Earth Sciences, jochen.brocks@anu.edu.au

[2] University of Cambridge, Earth Sciences, mmp30@cam.ac.uk and njb1005@cam.ac.uk

Petroleum and bitumens are concentrates of hydrocarbon fossils of biological lipids (biomarkers). These biomarkers often contain significant biological and environmental information and can remain stable over hundreds of millions of years. However, bitumens of pre-Ediacaran age (>635 Ma) are scarce in the geological record and frequently adulterated by younger contaminants [1].

In this study, we re-analysed most known pre-Ediacaran bituminous deposits and determined 10 basins that contain clearly indigenous biomarkers dating back to 1,640 Ma [2, 3]. After exclusion of allochthonous hydrocarbons, the molecular fossils detected in these Precambrian sequences are distinct from their Phanerozoic counterparts. The pre-Ediacaran bitumens show significantly higher concentrations of 'unresolved complex mixture' (UCM), low concentrations or absence of eukaryotic steranes, the presence of putative bacterial aromatic steroids, high relative concentrations of mono- and dimethyl alkanes, and a conspicuous carbon isotopic enrichment of straight-chain lipids relative to acyclic isoprenoids and total organic carbon. Here we propose that these unusual characteristics primarily derive from non-actualistic taphonomic processes based on the pervasive presence of microbial mats in the Precambrian. This 'mat-seal effect' was broken with the onset of bioturbation in the Ediacaran when the primary source of fossil biomarkers switched from the benthos to the plankton.

The disturbance of soft sediments and associated microbial mat cover by infaunal burrowing was one of the most important geobiological innovations in the Neoproterozoic-Phanerozoic transition. This "Cambrian substrate revolution" [3] had profound effects on contemporaneous ecology [4], sedimentology [5] and sulphur geochemistry [6]. We argue that it also fundamentally altered the way in which organic matter was incorporated and preserved in the sedimentary record, giving rise to typical Ediacaran and Phanerozoic petroleum reserves, and potentially contributing to increasing atmospheric oxygen levels.

What cooled the Earth during the last 20 million years?

WALLACE S. BROECKER[1*]

[1]Lamont-Doherty Earth Observatory of Columbia University, Palisades, New York, USA, broecker@ldeo.columbia.edu (*presenting author)

Abstract

During the last 20 million years earth temperature decreased but the CO_2 content of the atmosphere appears to have remained constant. Further, large changes in the Mg to Ca ratio and in the isotopic content of lithium in sea water also took place during this time interval. Explaining the lack of a CO_2 change constitutes a dilemma.

Capabilities of LA-ETV-MC-ICPMS for the measurement of Sr isotope ratios in Rb-rich samples

R. BROGIOLI, L. DORTA, B. HATTENDORF* AND D. GÜNTHER

[1]Laboratory of Inorganic Chemistry, ETH Zurich, Wolfgang-Pauli Strasse 10, 8093, Zürich, Switzerland

The successful use of LA-MC-ICPMS for the determination of Sr isotope ratio in the field of geochronology has been demonstrated for samples with relatively low Rb concentration [1, 2]. Its applicability for samples with higher Rb content is however still a challenge, mainly because mathematical correction of the isobaric interference of ^{87}Rb on ^{87}Sr affects the accuracy of the method [3, 4].

In an earlier study we investigated the effect of heating laser generated aerosols within an Electrothemal Vaporizer (HGA600 MS, Perkin Elmer, CAN) prior to the introduction into the ICPMS. Passing the laser generated aerosol through a commercial electrothermal vaporizer heated to 2000°C before the ICP allowed to attenuate the Rb interference by almost two orders of magnitude [6] for a silicate glass reference standard (NIST SRM610, Rb/Sr ~1). This same approach was now used for the measurement of Sr isotope ratios by LA-MC-ICPMS. To benchmark the Rb removal efficiency and the accuracy of Sr isotope ratio, a wide range of reference standard material were tested: NIST SRM610 (Silicate glass, Rb/Sr = 1), MPI-DING ATHO-G (rhyolite glass, Rb/Sr = 0.54), MPI-DING T1G (diorite glass, Rb/Sr = 0.28), USGS BCR-2G (basalt glass, Rb/Sr = 0.14) and $Li_2B_4O_7$ fused disks of NIST 607 (potassium feldspar, Rb/Sr = 8) . Depending on crater size adopted for the analysis and the ETV heating temperature, Rb signal was decreased by factor ~5 (for NIST SRM 607) to 100 (for NIST 610 and BCR-2G) resulting in an improved accuracy for the measured ^{87}Sr/^{86}Sr ratio.

Rb is not the only element interfering with Sr isotope analysis, doubly charged rare earth elements, metal oxides or calcium polyatomic ions are known to affect results accuracy [3]. For this reason $Li_2B_4O_7$ fused disks of NIST SRM987 (Sr carbonate) were spiked with Er, Yb, Hf, Ca, Fe, Ga, Zn to investigate the formation of potential interferences and the applicability of mathematical corrections. This study will show that he use of electrothermal vaporization coupled to LA sampling has the potential to widen the range of samples suitable for accurate *in-situ* determination of Sr isotope ratio.

Biogeochemistry of mercury in contaminated sediments of East Fork Poplar Creek

SCOTT C. BROOKS[1*], DAVID KOCMAN[2], CARRIE MILLER[1], XIANGPING YIN[1], AMI RISCASSI[1]

[1]Oak Ridge National Laboratory, Oak Ridge, TN, USA, brookssc@ornl.gov (* presenting author)

[2] Jožef Stefan Institute, Ljubljana, Slovenia, david.kocman@ijs.si

Mercury use at the Oak Ridge Y-12 National Security Complex (Y-12 NSC) between 1950 - 1963 resulted in contamination of the East Fork Poplar Creek (EFPC) ecosystem. Hg continues to be released from point sources and diffuse contaminated soil and groundwater sources within the Y-12 NSC and outside the facility boundary. In general, methylmercury (MeHg) concentrations in water and in fish have not declined in response to improvements in water quality and exhibit trends of increasing concentration in some cases.

Therefore, our study focuses on identifying ecosystem compartments and/or characteristics that favor the production, as well as degradation, of MeHg in EFPC. Detailed geochemical characterization of the surface water, interstitial pore water, and creek sediments were performed during quarterly sampling campaigns in 2010 and 2011 at two locations. One site is 3.7 km (NOAA) and the other 20 km (NH) downstream of the headwaters and source of the point discharges. Vertical profiles of interstitial pore water collected from fine-grained deposits at the creek margin showed decreases in nitrate, sulfate, and oxidation-reduction potential (ORP) with depth as well as increases in dissolved manganese, iron, and small increases in sulfide. The results indicate the progression of terminal electron accepting processes with depth in the upper 30 cm of these fine grained sediments. Dissolved (passing 0.2 μm pore) MeHg concentration was positively correlated with depth suggesting these areas served as a source of MeHg. MeHg in the surface water is associated with phases small enough to pass a 3 kiloDalton filter. In contrast, interstitial water collected from the cobbly center channel of the creek did not exhibit these redox gradients. The observed constant or decreasing MeHg concentrations with depth suggest that the interstitial water in the fast flowing sections of the creek is rapidly exchanging with the surface water and these sections do not serve as MeHg sources. Total Hg concentration in sediment cores from the creek margin was variable, 0.057-24 mg/kg and 0.02-155 mg/kg, at NH and NOAA respectively. MeHg measured on a subset of these sectioned cores ranged from 0.71-17.5 μg/kg at NH and 1.08-46.7 μg/kg at NOAA. Large intra- and inter-site variability of Hg distribution in these samples is partly attributed to the very heterogeneous sediment texture that ranged from coarse- to fine-grained. Methylation potential, measured using enriched stable isotopes of Hg on intact sediment cores, was significantly correlated with ambient MeHg concentration at both sites.

[2]Centre for Radiochemistry Research The University of Manchester, Manchester, M13 9PL. gareth.law@manchester.ac.uk

Background and methodology

Management and geological disposal of our nuclear waste legacy requires an in-depth understanding of biogeochemical processes that occur in the subsurface and their influence on radionuclide speciation and mobility. Here, we explore molecular-scale processes involved in radionuclide immobilisation at the solution-mineral interface and the indirect, but potentially crucial role which microorganisms play in such reactions. The research focuses on two common rock-forming minerals, biotite and chlorite that contain both ferric (Fe(III)) and ferrous (Fe(II)) iron within their octahedral layers. The experimental systems were focussed around "unaltered" or as-sampled biotite and chlorite, and "bioreduced" biotite and chlorite. For the bioreduced minerals, biotite and chlorite were exposed to the model Fe(III)-reducing subsurface microorganism *Geobacter sulfurreducens* in the presence of an electron shuttle (AQDS) to promote reduction of bioavailable Fe(III) within the mineral moeity to Fe(II). After this, unaltered or bioreduced biotite and chlorite were suspended in solutions containing undersaturated Tc(VII), U(VI) or Np(V). The solubility of the redox active radionuclides was then monitored and the variations in the solid phase speciation of the radionuclides was characterised by X-ray absorption spectroscopy (XAS).

Results and implications

G. sulfurreducens was able to reduce Fe(III) associated with biotite and chlorite thus priming the minerals with Fe(II) for "indirect" reductive transformations. However, the interactions of the different radionuclides with the mineral systems differed. There was evidence for reductive transformation of Tc(VII) to Tc(IV) in the bioreduced biotite and chlorite, presumably mediated by labile Fe(II) associated with the bioreduced minerals [1,2]. By contrast, there was poor reactivity towards Tc(VII) in the unaltered samples. Ongoing work with the actinides shows some selectivity for the different mineral surfaces with both sorption and potentially reductive precipitation pathways possible.

Overall, these results show that relatively small increases in Fe(II) content (up to 0.12 mmoles per gram) in the bioreduced minerals can have a profound effect on mineral reactivity and radionuclide behaviour compared to bacterial-free systems. This suggests that indirect reduction of microbially reduced minerals may be an important pathway to immobilisation in rock environments typical of geological disposal sites for radioactive wastes.

Effects of pore fluid chemistry on diagenesis.

J. BROUWER*, A. PUTNIS

Institut für Mineralogie, Westf. Wilhelms Univ. Münster, Germany, brouwer.janneke@gmail.com

Sediment compaction by dissolution – precipitation creep

Sediment compaction occurs largely through dissolution-precipitation creep, also called pressure solution, a process that is driven by gradients in stress. Grains dissolve at grain contacts that support the load of overlying sediments, and solutes precipitate at pore walls, leading to a decrease in permeability. Pore fluid chemistry can be expected to significantly affect sediment compaction behavior and therefore how permeability changes with time. However, not much research has been done to study such chemical effects. Recently, [1] studied the effect of additives on calcite compaction. We investigate the influence of trace elements in solution that affect dissolution and precipitation rates, and the effect of mineral replacement on compaction behavior.

Experiments

We present results of uniaxial compaction experiments on cylindrical (10 mm. length, ø 2.3 mm.) aggregates of various alkali halides. A stress of 1.2 MPa is applied and compaction monitored using a simple set-up after [2]. We show that certain trace metals in solution may affect compaction rates of NaCl, but not of KCl. We investigate the effect of mineral replacement during compaction in the solid-solution system $K(Br_xCl_{1-x})$. A reservoir containing a saturated solution of KCl or KBr is placed on top of the cylindrical aggregate of KBr resp. KCl. The results show that reaction leads to enhancement and localization of compaction, leading to fast reduction in permeability. The change in permeability with time, and therefore fluid infiltration and reaction progress, is not only influenced by the compaction rate, but also by solid volume changes related to the reaction.

Conclusion

Mineral and pore fluid chemistry is an important factor in sediment compaction behavior. Chemical disequilibrium leading to mineral reaction during compaction leads to enhancement and localization of compaction.

Impact of radiation on the microbial reduction of iron oxides

ASHLEY R. BROWN[1*], PAUL WINCOTT[1], DAVID J. VAUGHAN[1], SIMON M. PIMBLOTT[2], ROYSTON GOODACRE[3] AND JONATHAN R. LLOYD[1]

[2]Dalton Nuclear Institute and School of Chemistry, University of Manchester, Manchester, UK

[3]Manchester Interdiscplinary Biocentre and School of Chemistry, University of Manchester, Manchester, UK

The microbial reduction of Fe(III) in geodisposed nuclear waste or radwaste contaminated land can play a significant role in controlling the mobility of a range of long-lived radionuclides, including U(VI), Np(V) and Tc(VII). As such environments are likely to receive large radiation doses, radiation induced changes to the iron mineralogy may impact upon microbial respiration and subsequently alter the stability of the radionuclide inventory. Hence, characterization of radiation damage to Fe(III) mineralogy and the resultant impact upon microbial respiratory processes is essential in the preparation of a geological waste disposal safety case. In this study aerobic irradiation (1 MGy gamma) of hematite and ferrihydrite led to an increase in the rate of Fe(III) reduction by the Fe(III)-reducing bacterium *Shewanella oneidensis* MR-1 in the presence of an electron shuttle, riboflavin. Sequential extractions of iron in microbial cultures containing irradiated ferrihydrite suggested a 10% increase in ferrous iron partitioned into an operationally defined iron carbonate phase. A 15% increase in microbially reduced iron in irradiated hematite systems was incorporated into a combination of a putative carbonate phase, an easily reducible fraction and also increased dissolved Fe(II). Mossbauer spectroscopy of irradiated ferrihydrite suggests conversion to a more crystalline phase similar to akaganeite, whilst anoxically irradiated hematite appears to show a decrease in Fe coordination. This study suggests that structural changes in the mineralogy by irradiation lead to an increase in bioavailabilty of ferric iron. This may have positive implications to the geological disposal of nuclear waste, as reducing conditions may be accelerated by radiation-induced microbial iron reduction, potentially mediating the enhanced stability of key radionuclides.

Geochemical insights from accessory phases in a sanukitoid-like suite: Towards understanding temporal changes in subduction style

E. BRUAND[1*], C. STOREY[1], M. FOWLER[1]

[1]School of Earth and Environmental Sciences, Portsmouth, United Kingdom, emilie.bruand@port.ac.uk (* presenting author)

Crustal evolution is governed by plate tectonics and it has been shown that between the Archean and the Phanerozoic major changes in subduction style occured. Among others, the chemistry of different plutonic rocks through time and the understanding of their petrogeneses have helped to define different stages in the evolution of plate tectonics on Earth. Although TTG, the direct product of melted oceanic lithosphere, were the main plutonic rocks generated during the Archean, an important change around 2.7 Ga led to the genesis of rocks that are the result of melting of a metasomatized mantle wedge: the sanukitoids. This observation is often interpreted as the result of a change from shallow to steep subduction. Modern plate tectonics generally generates calc-alkaline suites but exceptions can occur such as the Caledonian (Paleozoic) high Ba-Sr plutons in Northern Scotland. The latter have been interpreted as a "modern" analogue of sanukitoids [1].

In this contribution, we present a study of accessory minerals from this Caledonian sanukitoid-like suite (ultrabasic to acidic). Whole-rock chemistry (trace elements, radiogenic and stable isotopes) is well constrained [1] but the study of accessory phases reveals additional petrogenetic constraints [2]. Indeed, accessory phases are important beyond their modal proportion because they commonly contain elements that are not incorporated easily into major rock forming minerals. The incorporation of trace elements and more particularly rare earth element (REE) in their structures make them ideal to delineate petrogenetic processes. In particular, the study of apatite, titanite and zircon will test the ability of accessory phases to retain the signature of their tectonic affinity. We present a detailed petrographic study and the systematic analysis of trace elements and O isotopes of these phases in a range of fractionated plutonic rocks from appinitic (ultrabasic) to granitoid composition. These results have an important impact in the understanding of accessory phases saturation during the magma genesis and thus offer another way to study the petrogenesis of these sanukitoid-like rocks. This approach will be extended to other magma compositions to further our insight into petrogenetic processes and tectonic affinity that may be available from accessory phase studies.

Mineralogical and geochemical evidence for syngenetic precious metal enrichment in a deformed volcanogenic massive sulfide (VMS) system

STEFANIE M. BRUCKNER[1*], STEPHEN J. PIERCEY[1], PAUL J. SYLVESTER[1], STEPHANIE MALONEY[2], LARRY PILGRIM[2]

[1]Memorial University, Dept. of Earth Sciences s.brueckner@mun.ca (* presenting author)
[2]Rambler Metals & Mining Canada Ltd., Baie Verte, NL, Canada

Introduction

The early Ordovician Ming Mine (487 Ma; total resource 12.5 Mt ore @ 1.52 wt% Cu, 1.69 ppm Au, 8.11 ppm Ag, and 0.45 wt% Zn), NW Newfoundland, Canada, is a type example of a precious metal-enriched VMS deposit. Moderate deformation and metamorphism makes deciphering the origin of Au-Ag-enrichment (e.g., syngenetic vs. epigenetic) difficult. However, mineralogic and geochemical evidence support a syngenetic origin with Au-Ag coming via a magmtic contribution to the primary VMS hydrothermal fluid [1, 2, 3]. Mineralogical observations show a complex sulfide mineral assemblage in stringer and massive sulfide mineralization. Besides base metal sulfides (e.g., pyrite, chalcopyrite, sphalerite, galena, pyrrhotite), sulfosalts rich in magmatic suite elements (e.g., arsenopyrite, tetrahedrite-tennantite, stannite, boulangerite, loellingite), Te-bearing phases (e.g., BiTe, coloradoite), Ag-phases (e.g., miargyrite, unnamed AgCuFeS phase, argentotetrahedrite, AgHg alloy), and electrum occur throughout the deposit, but are slightly more enriched in the upper part of the deposit. Main, minor and trace element analysis by electron microprobe (EPMA) show the emrichment of magmatic suite elements (e.g., As, Bi, Hg, Sb, Sn, Te) as major, minor and trace constituent in base metal and other sulfides phases.

Results and Conclusions

Electrum and Ag-phases occur as: (1) free phases in gangue or on pyrite/chalcopyrite margins; (2) as inclusions in pyrite, arsenopyrite, pyrrhotite, and galena; (3) along veinlets in and on grain boundaries of pyrite and arsenopyrite; (4) in odd myrmekitic-like textures; and (5) in close proximity to each other and tetrahedrite-tennantite. EPMA data on 17 elements in sulfide and precious metal phases reveal: (1) no invisible gold in any phase; (2) a high Hg-content (12 – 17 wt%) in electrum; and (3) sphalerite with a varying Fe-content (2 – 9 wt%). The mineralogical and geochemical features of the ores favor a syngenetic, magmatic origin for precious metal enrichment. However, later deformation remobilized some metals, especially Au and Ag, as evidenced by textural relationships and the absence of invisible gold.

From aqueous to solid solutions: A process understanding of trace metal incorporation into solid structures

JORDI BRUNO[1,2*]

[1]Amphos 21 Group Barcelona, Catalunya, jordi.bruno@amphos21.com (* presenting author)
[2]UPC BarcelonaTech, Barcelona, Catalunya, jordi.bruno@upc.edu

Introduction

Aqueous-solid solution systems are ubiquitous in natural and anthropogenic systems and they influence the fate and mobility of heavy metals and radionuclides.

The process understanding of the structural incorporation of trace components into existing or forming solid phases is essential to the assessment of the potential environmental consequences.

Objective of the presentation

In my presentation I will introduce some of the key concepts involved in the suite of processes that are involved in the transition of a trace component from the aqueous to the solid solution both from the kinetic and thermodynamic points of view.

I will devote particular attention to recent solution chemical and spectroscopic data that has been recently acquired in the frame of the EC Funmig project[1] and I will frame it to the conceptual developments presented in [2]

I will also propose some ways forward to integrate the experimental information on the structural incorporation of trace elements into the current models used in current environmental assessments.

On the use of hydrochemical mixing models to conceptualize hydrogeology in fractured rocks

JORGE MOLINERO[1], JORDI BRUNO[1] (*)PAOLO TRINCHERO[1], AND LUIS MANUEL DE VRIES[1]

[1]Amphos 21 Consulting SL, Barcelona, Spain, jordi.bruno@amphos21.com (* presenting author)

Abstract

Mixing models are broadly used in hydrogeology as a tool to understand groundwater systems. Simple mixing models are based on inferring the relative abundance of assumed end-member waters from measured concentrations of conservative species in the mixture. However, simple mixing methodologies present clear limitations for complex systems with the influence of several initial and boundary waters. For these cases, more sophisticated mixing models have to be used by using statistical multivariate techniques such as Principal Component Analysis.

On the other hand it is also known that mixing modeling presents practical limitations, basically derived from the uncertainties in the definition of the end-members, as well as mixing artifacts associated to groundwater sampling procedures by drilling and pumping, that use to magnify the apparent mixing in the system.

In addition to the abovementioned practical limitations, we claim in this work that mixing models are also subjected to conceptual limitations that can lead to serious misuses, especially when applied to fractured rocks. This is due to the fact that matrix diffusion phenomena introduce a "memory" effect in the system previously affected by the influence of different waters. This fact could make mixing modelers to misunderstand the real groundwater behavior.

We present a series of synthetic numerical simulations to illustrate that hydrogeological models based on computed mixing models, of known end-member waters, are unable to properly conceptualize the real hydrogeological behavior of a fractured rock aquifer.

Mechanisms governing nanoparticle transport in porous media

STEVEN BRYANT*[,1], HAIYANG YU[2], MICHAEL MURPHY[2], TIANTIAN ZHANG[2], ANDREW WORTHEN[3], KI YOUL YOON[3], KEITH JOHNSTON[3], CHUN HUH[2]

[2] Dept. of Petroleum and Geosystems Engineering, The University of Texas at Austin, Austin, USA

[3] Dept. of Chemical Engineering, The University of Texas at Austin, Austin, USA

Abstract

The prospect of using engineered nanoparticles for subsurface applications raises practical questions. How far can nanoparticles be transported through porous media? If multiple fluid phases are present, does this affect the transport distance? Do the nanoparticles travel at their injected concentration and at the velocity of the carrier phase? The science needed to answer these questions raises its own set of interesting problems. Can nanoparticle transport be treated like solute transport, or must the nanoparticles be treated like colloids? If the latter, what forces govern the interaction between nanoparticle and the solid surface of the porous medium? If nanoparticles attach or adhere to the solid, can they detach? Is the nanoparticles/solid interaction reversible? In this talk we review a large set of transport experiments conducted in our laboratory. The data provide some insight into key mechanisms of nanoparticle transport and retention. For example, we typically observe small amounts (much less than a monolayer) of irreversible adsorption, and even smaller amounts of reversible adsorption. Experiments with variable flow velocities indicate that nanoparticle adsorption capacity is a dynamic, hysteretic property. For suitably engineered particle coatings, particle adhesion at fluid/fluid interfaces is the same magnitude as adhesion on the solid surface. We discuss a framework for modeling these phenomena.

Progress of weathering reactions in ultramafic rocks

KURT BUCHER

[1]Institute of Geosciences. University of Freiburg. Albertstr. 23b. D-79102 Freiburg. Germany. bucher@uni-freiburg.de

Section 7a: The Art of weathering

Chemical weathering results from a complex interaction between geochemistry, hydrology, biology, and physical erosion and is therefore site specifie [1].

Chemical weathering of dark green massive ultramafic rocks produces a distinct and remarkable yellow weathering rind when exposed to the atmosphere long enough. Crust formation on rocks from three European climates have been studied: a) Ronda Peridotite, Spain, b) Seiland Complex, Norway, c) Zermatt Ophiolite, Switzerland). Rinds from the three areas vary mineralogically and have very different thicknesses. The rind thickness depends on the mineralogy of the bedrock, atmospheric parameters and on the details of transport and kinetics of the chemical reactions.

Fig. Weathering rinds on dunite (Reinfjorden, N Norway)

The fundamental reaction "peridotite (serpentinite) + rainwater = weathering rind + runoff water" describes the crust forming process. This hydration reaction depends on the water supply from the rock surface to the reaction front. The transport mechanism is grain boundary diffusion. At the reaction front, kinetics controls the progress of the weathering reactions. The competing kinetics-diffusion control determines the rate of rind growth. The alteration zone must be wetted after a dry period and the reaction resumed at the front. The wetting-drying cycles may contribute significantly to the hydraulic properties of the weathering rind. Reaction details of the rind forming process are saved in the subtle structures of the crusts.

The propagation of the reaction front and the internal structure of the rinds have strong similarities to hydrothermal reaction veins [2]. It is evident that rind thickness development is not related to pervasive advective fluid flow.

Biomineralization of selenium: proteins as the reason for altered colloidal stability of nanoparticle suspensions

BENJAMIN BUCHS[1], MICHAEL W.H. EVANGELOU[2], PHILIPPE F.X CORVINI[1,3], MARKUS LENZ[1,4*]

Although biomineralization of selenium has been investigated in the frame of bioremediation for decades, the molecular principles behind it remain largely unknown. Despite of its microbial origin, biogenic elemental selenium typically consists of nanosized spherical particles (Figure 1), stabilized against gravitational settling. These particular properties were suspected to be mediated by organic molecules associated to the selenium particles. In this study, organic molecules associated with high-affinity to selenium bionanominerals were isolated from such molecules with low-affinity by density-based centrifugation. The proteic fraction was characterized via capillary liquid chromatography-electrospray ionization-tandem mass spectrometry (LC-ESI-MS/MS). A plenitude of proteins was found to strongly associate to biomineralized selenium formed by physiologically different microorganisms [1]. Interestingly, one protein - a metalloid reductase - did associate strongly to both biogenic nanoselenium and synthetically produced selenium surfaces, indicating some specific recognition properties. By means of electrophoretic measurements (zeta –potential) and settling experiments it was demonstrated that, indeed, the proteic fraction considerably alters the colloidal stability of selenium bionanominerals. Furthermore, it could be demonstrated that the aqueous transport will be considerably influenced by the environmental media composition (i.e. acidic vs. neutral waters; sea vs. surface waters; waters differing in dissolved organic matter content, etc.).

Buoyant asthenosphere affects mid-ocean ridge depths and melt patterns

W. ROGER BUCK[1*], CHRISTOPHER SMALL[2], AND WILLIAN B. F. RYAN[3]

[1]Lamont-Doherty Earth Observatory, buck@ldeo.columbia.edu (*presenting author)
[2]Lamont-Doherty Earth Observatory, small@ldeo.columbia.edu
[3]Lamont-Doherty Earth Observatory, ryan@ldeo.columbia.edu

The East Pacific Rise (EPR) is the fastest spreading ridge yet it is deeper that most other spreading centers. Along the 5000 km of the EPR the depth averages 400 m greater than the adjacent Pacific-Antarctic Ridge [1]. The other very deep section of ridge is the Australian-Antarctic Discordance (AAD). Analytic and numerical models show that dynamic thinning of asthenosphere with a lower density than the underlying mantle can explain the magnitude and wavelength of the depth anomalies along the EPR and the AAD [2]. At the EPR, fast plate divergence thins the asthenosphere by both sequestering it into diverging lithosphere and dragging it with the plates in contrast to the slower spreading, but faster migrating PAR [1]. The AAD asthenosphere is greatly thinned because of the restriction of asthenospheric flow due to nearby thick continental lithospheric roots combined with a moderately fast spreading rate [2]. The ADD is a major isotopic boundary. This can be explained if there is efficient mixing within the low-viscosity asthenosphere of the Indian and Pacific Ocean basins. Low-viscosity, low-density asthenosphere that is thinned beneath a spreading center should accentuate the asymmetry in melting related to migration of a spreading center as illustrated in Figure 1. This may help explain the observed pattern of oceanic crustal thickness variations as a function of ridge offsets and spreading directions [3].

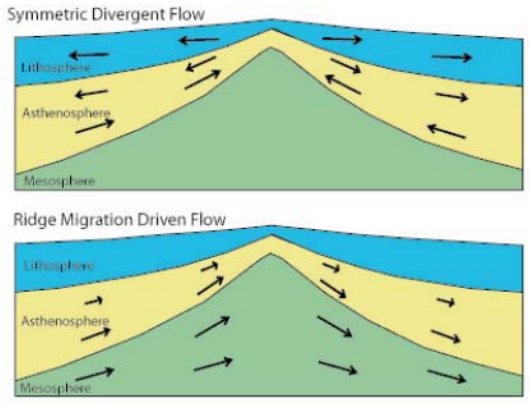

Figure 1: Flow under a migrating ridge should combine the effect of divergent and migration driven flow, but the asymmetry of upwelling and melting is accentuated due to relief on the base of the buoyant asthenosphere.

Using automated mineralogy to evaluate bioaccessibility of Pb-bearing mine waste

MARTHA BUCKWALTER-DAVIS[1*], HEATHER JAGGARD[1], SUZETTE MORMAN[2], GEOFFREY PLUMLEE[2], AND HEATHER JAMIESON[1]

[1]Queen's University, Kingston Ontario, Canada mbuckwalterdavis@gmail.com (*presenting author)
[2]U. S. Geological Survey, gplumlee@usgs.gov, smorman@usgs.gov

The toxic effects of Pb, especially on children, are well known. The concentration of Pb in waters draining mine tailings tends to be low due to the relative insolubility of galena (PbS) and weathering products such as anglesite ($PbSO_4$). A more hazardous route of exposure is the direct ingestion of windblown dust or contaminated soil, particularly if the ingested material contains the Pb carbonate mineral cerussite ($PbCO_3$), a highly bioaccessible form of Pb.

Detailed mineralogical examination of mine tailings from the New Calumet Pb-Zn mine in Quebec has shown that after decades of subaerial exposure, almost all Pb is hosted in primary galena and secondary cerussite ($PbCO_3$), with only trace amounts of anglesite and massicot (PbO). Some of the goethite formed from alteration of pyrrhotite contains detectable Pb.

Simulated gastric fluids (pH=1.5) were used to evaluate Pb bioaccessibility in the <250 micron fraction of six near-surface tailings samples (Pb_{total} =1740-4730 $mgkg^{-1}$). The percent of Pb that is bioaccessible ranges from 23% to 69% and is not correlated with total Pb. The bioaccessible Pb for some samples is below industrial soil clean-up criteria.

Automated SEM-based mineralogy provides the opportunity to rapidly characterize thousands of Pb-bearing particles in terms of mineralogy, grain size and degree of liberation from armouring silicates, all features which control bioaccessibility. We have used a FEG-SEM instrument with the Mineral Liberation Analyzer (MLA) software suite to characterize and quantify the Calumet tailings samples. MLA was developed for the metallurgical industry but has increasing environmental applications due to its ability to characterize fine grained sediments including tailings. Some difficulties were presented in distinguishing galena (low bioaccessibility) and cerussite (high bioaccessibility), due to overlapping peaks between S and Pb but these issues have been largely resolved with careful development of a standard reference library within the MLA software and use of X-ray mapping of Pb-bearing grains.

Sample GD-nonVEG (bioaccessibility = 38% Pb) is more fine grained with respect to all particles than sample MS-nonVEG (bioaccessibility = 23% Pb). The ratio (by analyzed area) of cerussite to galena is higher in MS-nonVEG than sample GD-nonVEG, which is contrary to what is expected based on the relative bioaccessibilites of these two minerals, but particle size analysis indicates that cerussite grains are larger in sample MS-nonVEG. Smaller particles have a larger surface area and are more leachable and bioaccessible, which may explain why GD-nonVEG is more bioaccessible while having relatively less cerussite. Research is continuing with efforts to improve the distinction of galena and cerussite and to better characterize very fine grained material.

[6]Scripps Institution of Oceanography, UCSD, USA

The Toba caldera located in Sumatra (Indonesia) is the result of the four successive eruptions at 1.2, 0.84, 0.5 and 0.074 Ma [1]. This study presents oxygen isotope data for a suite of whole rocks and quartz crystals erupted as part of the Young Toba Tuff (YTT), an eruption event producing 2,800 km^3 of material some 74 ka ago [1, 2]. Oxygen isotope data have been obtained from whole rock (conventional fluorination), single mineral grains (laser fluorination-LF) and *in-situ* (SIMS) in combination with cathodoluminescence (CL) imaging in order to establish the relative roles of magmatic fractionation, magma-crust interaction and crystal recycling occurring in the Toba magmatic system. The CL images of quartz crystals exhibit defined patterns of zoning that often coincide with fluctuations in $\delta^{18}O$ values, allowing correlation of textural and compositional information. Measured $\delta^{18}O_{quartz}$ values from SIMS and LF range from 6.7 to 9.4 ‰, independent of their position on the crystal. Whole rock values, in turn, range from 8.2 to 9.9 ‰. The $\delta^{18}O_{magma}$ values calculated from quartz (assuming $\delta^{18}O_{quartz\text{-}magma}$ = 0.7 ‰), suggest a minimum value of 6.0 ‰, similar to that expected from a mantle derived magma [3], and a maximum value of 8.7 ‰. Several quartz crystals, however, have rims with lower $\delta^{18}O$ values, suggesting a late, low-$\delta^{18}O$ contaminant. This indicates multiple sources to the Toba system, including at least two crustal components, one with high- and one with low-$\delta^{18}O$. Helium isotope data obtained from pyroxenes from the oldest Toba eruption (R/R_A = 0.7 and 1.8) are consistent with a significant crustal contribution.

Barometry calculations from feldspar and amphibole suggest the magma chamber system resided at similar depth (~10 km) for all four Toba eruptions. The system probably persisted as a crystal mush, which was repeatedly re-mobilised by fresh magma injections. Crystal recycling, consistent with compositional and textural features in most of the YTT quartz crystals, seems an integral part of how super-eruptions are assembled. Therefore, large volumes of isotopically heterogeneous sources were mixed to make the final YTT cocktail, including a late low-$\delta^{18}O$ contaminant, substantial high-$\delta^{18}O$ crustal contributions, and considerable amounts of recycled antecrysts from the three previous eruptive episodes of the Toba system.

Introduction. To investigate the transfer of CuO nanoparticles (CuONPs) from the medium to endobenthic species (*S. plana*, *N. diversicolor*), under environmentally realistic conditions, animals were exposed in field mesocosms to Cu (10 µg.L^{-1}) added either as CuONPs or as soluble Cu in comparison with controls for 21 days. The fraction of Cu under labile form was determined in water and sediment by using Diffusive Gradient in Thin film (DGT). Bioaccumulation of Cu was measured in the whole soft tissues of both species. Behavioural and biochemical biomarkers were determined in organisms.

Figure 1: Experimental intertidal mesocosms deployed in natural environment.

Results. No release of labile Cu from CuONPs was observed at days 7, 14 and 21. Cu bioaccumulation was shown in both species with CuONPs and with soluble Cu for clams. Impairments of behaviour (feeding and burrowing) were observed in both species. Antioxidant activities (CAT, GST) increased in both species for both chemical forms except for GST in worms exposed to soluble Cu. In clams exposed to both Cu forms, detoxification protein (MT) induction was observed and an apoptosis effect only under CuONP exposure. Concerning other biomarkers of defense (SOD, LDH, Laccase) and damage (TBARS, AChE, acid phosphatase) no significant effects were detected.

Conclusion. This experiment shows the suitability of mesocosms for studying the environmental effects of nanoparticles. Behavioral biomarkers and antioxidant defenses are the most sensitive tools to highlight the effect of soluble or nanoparticulate Cu forms.

Soil salinity: a driver in macroevolutionary processes?

ELISABETH BUI[1*], JOE MILLER[2]

[1]CSIRO Land and Water, GPO Box 1666, Canberra ACT 2601, Australia, elisabeth.bui@csiro.au (* presenting author)
[2]Centre for Australian National Biodiversity Research, GPO Box 1600, CSIRO Plant Industry, Canberra, ACT 2601, Australia

Recent evidence from Australia, one of the most biologically diverse areas of the world, with one of the most extensive arid zones and widespread natural salinity, suggests a role for soil salinity in biogeography and ecology. The distribution of plant species in Queensland responds strongly to a geochemical gradient as expressed by soil salinity and pH, starting at levels of salinity much lower than those for saline soil [1]. Statistical modelling shows that adding soil salinity to climatic and other soil variables in a Generalized Additive Model to account for site scores from a correspondence analysis of site by species data improved the results dramatically (Mean Squared Error decreased from 0.89 to 0.65 and R^2 improved from 0.41 to 0.57) [1]. Three *Acacia* species (*Acacia harpophylla* (commonly called 'brigalow'), *A. cambagei and A. argyrodendron)* that exhibit high salt tolerance are closely related species of microneurous *Plurinerves* as indicated by *Acacia* systematics [2].

Parallel investigations of thrips systematics and their behavioral ecology have shown that: 1) there are specific host-plant relationships of elongate and round gall thrips (*Kladothrips* spp.) on the *A. harpophylla* clade of Plurinerves; 2) phyllode-glueing thrips also show host specificity; and 3) thrips on *A. harpophylla* and *A. cambagei* display high species richness [2, 3]. Chronological phylogenetic analyses indicate that the approximate age of origin of gall thrips (*Kladothrips* spp.) is Miocene and that their subsequent diversification is closely linked to host-plant evolution [3]. Host affiliation with *Plurinerves* has been estimated to date from 7.5 My with a pronounced diversification episode for gall-thrips lineages affiliated with *Plurinerves* hosts between 3 and 6 My [3]. Aridity developed across Australia in the late Miocene [4]. The *A. harpophylla* clade of Plurinerves with host-specific gall-inducing *Kladothrips* occurs on alkaline and/or saline substrate throughout Australia. Other *Plurinerves* occur in a range of different habitats. Thus congruence between plant and insect phylogenies and co-speciation are apparent. While adaptive radiation may be a response to climatic change, more proximal environmental drivers include aridity, alkalinity, and salinity.

Independent lines of evidence—phytogeography, plant and insect systematics, and insect behavioral ecology—point to a potentially important role for soil salinity in macroevolutionary processes for the genus *Acacia*. The potential role of substrate chemistry in macroevolutionary processes should be investigated for other genera found in arid environments.

Sulphur and carbon isotope records across the terrestrial Permian-Triassic (P-T) boundary

THI HAO BUI[1*], JEAN-FRANCOIS HELIE[2], AND BOSWELL WING[1]

[1] McGill University, Earth and Planetary Sciences, thi.h.bui@mail.mcgill.ca (* presenting author)
boswell.wing@mcgill.ca
[2] Département des sciences de la Terre et de l'atmosphère, UQAM, PK-7720
helie.jean-francois@uqam.ca

The end Permian mass extinction (~ 252 Ma [1]) is known as the greatest biotic crisis in earth history with the disappearance of more than 90% of marine species and 70% of terrestrial vertebrate families [2]. To better understand the interaction of the carbon and sulphur cycles across the terrestrial P-T boundary, we collected 27 sedimentary rock samples at average resolution of 35 cm and 9 carbonate nodules along a section of ~10 meters in Karoo Basin, South Africa. We determined carbon and sulphur contents as well as carbon and sulphur isotope records of above samples.

The organic carbon contents of sedimentary rocks are quite low, less than 0.04 wt %. The average $\delta^{13}C$ value of organic carbon is around -25‰ throughout the section, but at 59 cm before the P-T boundary, this value increases to -23.8‰ and drops sharply to -26.5‰ over a distance of 110 cm. The background value of -25‰ is recovered within 19 cm. The $\delta^{13}C$ values of carbonate nodules in the ≈3 m preceding the boundary are around -8.5‰, while those found n the ≈5 m after the boundary are around -11.5‰. Total sulphur contents of sedimentary rocks are generally less than 0.01 wt%, with the exception of a sharp peak of ≈0.45 wt % at 5 cm above the boundary. Although their full pattern is noisier than that seen in the $\delta^{13}C$ record, the $\delta^{34}S$ values of Cr(II)-reducible sulphides and different sulphate species (water-soluble, acid-soluble, and acid-insoluble sulphates) all decrease by at least 8‰ within the 100 cm after the boundary.

The negative shifts of both $\delta^{13}C_{carbonate}$ and $\delta^{13}C_{organic}$ (≈ -3‰) at the boundary indicate a decrease in the ^{13}C content of carbon input into the P-T terrestrial system. Likewise, the sharp peak of total sulphur content coinciding with the boundary suggests a rapid addition of sulphur into the terrestrial environment. The shared initial decreases in $\delta^{34}S$ values suggest that this sulphur was depleted in ^{34}S. Multiple sulphur isotope compositions ($\delta^{34}S$ and $\Delta^{33}S$) of the different sulphate species are generally equivalent, indicating a shared sulphate source throughout the section. While the $\delta^{34}S$ values of the Cr(II)-reducible sulphides are compatible with bacterial sulphate reduction, the associated $\Delta^{33}S$ values are more negative than those typically associated with this process. Although the $\delta^{13}C$ and $\delta^{34}S$ records imply the coherent transfer of ^{13}C- and ^{34}S-depleted material to the PT terrestrial environment, the $\Delta^{33}S$ values complicate a straightforward identification of the source of this material.

Determining solute sources and water flowpaths in catchments using the Ca-Sr-Ba multi-tracer

THOMAS BULLEN[1*], SCOTT BAILEY[2] AND KEVIN MCGUIRE[3]

[1]U.S. Geological Survey, Menlo Park, CA, USA, tdbullen@usgs.gov (* presenting author)
[2]U.S.Forest Service, N. Woodstock, NH, USA, swbailey@fs.fed.us
[3]Virginia Tech, Blacksburg, VA, USA, kevin09@vt.edu

Determining solute sources and water flowpaths in catchments is essential for understanding how catchments function. For example, stream water chemistry is determined by multiple factors including delivery of water from different portions of the catchment and from different depths along hillslopes and processes such as mineral weathering, ion exchange and biological cycling. As part of a larger study aimed at understanding the inter-relationships of these factors, we are using a hydropedologic approach to interpret concentration and isotope ratios of the alkaline earth elements Ca, Sr and Ba in stream water, groundwater, the soil exchange pool and plants from a catchment at the Hubbard Brook Experimental Forest, New Hampshire, USA. This 41 hectare forested headwater catchment supports a beech-birch-maple-spruce forest growing on vertically- and laterally-developed Spodosols and Inceptisols formed on granitoid glacial till that mantles Paleozoic metamorphic bedrock. Across the watershed in terms of the soil exchange pool, the forest floor has high Sr/Ba and Ca/Sr ratios, weathered mineral soil has intermediate Sr/Ba and low Ca/Sr ratios, and relatively unweathered till has low Sr/Ba and high Ca/Sr ratios. Waters moving through these various soil compartments obtain Sr/Ba and Ca/Sr ratios reflecting these characteristics, and thus variations of Sr/Ba and Ca/Sr ratios of streamwater provide evidence of the depth of water flowpaths feeding the streams. $^{87}Sr/^{86}Sr$ of soil exchangeable Sr spans a broad range from 0.715 to 0.725, with highest values along the mid- to upper flanks of the catchment and lowest values in a broad zone along the central axis of the catchment associated with groundwater seeps. Thus, variations of $^{87}Sr/^{86}Sr$ in streamwater provide evidence of the spatial distribution of water flowpaths feeding the streams. In addition, we are using Ca, Sr and Ba stable isotope ratios ($^{44}Ca/^{40}Ca$, $^{88}Sr/^{86}Sr$, $^{138}Ba/^{134}Ba$) as novel tracers of Ca, Sr and Ba sources and transport pathways in catchments. Initial results indicate that: 1) Sr and Ba stable isotopes are fractionated by plants similarly to patterns observed globally for Ca stable isotopes; 2) organic soils have the lightest values and weathered mineral soils have the heaviest values of exchangeable Ca, Sr and Ba, with particularly heavy Sr and Ba associated with accumulation of humic materials (i.e., in Bh horizons); and 3) the total range of isotope ratios observed for the exchange pool on a mass percent basis increases unexpectedly in the order Ca<Sr<Ba, suggesting an important role for Ca-oxalate that contains lighter Ca than that sampled in the exchange pool. We hypothesize that while biologically-cycled Ca is efficiently retained in the organic soil-plant system (e.g. as Ca-oxalate), biologically-cycled Sr and especially Ba will be more easily leached by soil waters and delivered to the streams and thus their stable isotope ratios may provide an additional means to distinguish between shallow and deep water flowpaths.

XRF archaeometry for lithic characterization and provenance.

ADRIAN L. BURKE[1*], GILLES GAUTHIER[2]

[1]Université de Montréal, Anthropologie, Montréal, Canada, adrian.burke@umontreal.ca (* presenting author)
[2]Université de Montréal, Chimie, Montréal, Canada, gilles.gauthier@umontreal.ca

The use of XRF over the last forty years to determine whole-rock geochemistry and establish an internationally approved chemical nomenclature for igneous rocks [1] has proven to be vital for the geological community. Its use as an archeometric tool specifically for lithic materials has been limited and historically overshadowed by INAA. This is in part due to the lower amount of material required to perform the latter, which is more in line with archaeological conservation guidelines.

If one considers the silicate nature of lithic materials used in the fabrication of sharp-edged tools one is immediately confronted by the inability of INAA to determine the major component of such materials: silica. This precludes the use of rock type based chemical classifications which for aphanitic materials have proven to be crucial, and unbiased, when compared to macroscopic ones (mineralogy based). A complete set of major element oxide determinations, compatible with data found in geological publications, is essential to determine the rock type and in turn narrow possible geological sources . Most importantly, for igneous types, it permits the use of an internationally approved and established chemical rock nomenclature (basalt, andesite, rhyolite, etc.) [1].

Non-destructive methods were developed [2, 3] in order to comply fully with archaeological conservation rules, and in order to profit from the many advantages of XRF when characterizing archaeological lithic materials, such as relative cost, throughput, and the immediate reuse of samples (non-radioactive) for other specific archaeological and geochemical assays.

Concentration data for major and trace elements produced with a specific non-destructive method using long counting times, calibrations using certified rock reference materials, and a geochemical data treatment approach [4] – notwithstanding the caveats imposed by unprocessed samples (slabs versus fused beads and powder pellets) such as surface irregularities, inhomogeneities and varying thicknesses – will be shown here to be quite useful for 1) the correction of macroscopic misclassifications in archaeological collections, 2) the assessment of chemical variations among chert types (nodular, bedded, chemically precipitated, etc.), 3) the determination of specific chemical markers, 4) the evaluation of the geochemical effects of weathering, and finally 5) the determination of provenance.

Modern and deglacial radiocarbon depth profiles from the Southern Ocean

ANDREA BURKE[1*] AND LAURA F. ROBINSON[1,2]

[1]Dept. of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, USA, aburke@whoi.edu (* presenting author)

[2]Dept. Earth Sciences, University of Bristol, Bristol, UK, laura.robinson@bristol.ac.uk

Mixing and upwelling in the Southern Ocean is thought to be an important driver of glacial-interglacial atmospheric CO_2 change, but paleoceanographic records from this region are sparse. Radiocarbon is a useful tool for reconstructing past circulation change because it is produced in the atmopshere, enters the ocean through air-sea gas exchange at the surface, and then decays away as it is isolated from the atmosphere. Here we present twenty-two new radiocarbon measurements of U-Th dated deep-sea corals from the Drake Passage and combine them with forty previously published deep-sea coral radiocarbon data from this region [1]. Measured $\delta^{234}U$ values from these corals are within error of modern seawater values, consistent with closed-system behavior of the uranium series isotopes. These new corals come from twelve new dredge sites ranging from 328 to 1710 m water depth, and grew between 9.9 and 27.2 thousand years ago. These additional corals provide an increased depth resolution which allows us to reconstruct radiocarbon depth profiles within the Drake Passage at important time intervals during the deglaciation, such as the Younger Dryas, Antarctic Cold Reversal, and Heinrich Stadial 1. We compare these depth profiles to modern radiocarbon profiles from seawater dissolved inorganic carbon. Millenial scale changes in the vertical structure of radiocarbon in the Drake Passage suggest variation in the mixing and exchange of carbon between different water masses and the atmosphere over the deglaciation.

"Bubble-less" degassing of MORB magmas

PETE BURNARD[1*], AURELIA COLIN[2]

[1]CRPG-CNRS, Vandoeuvre-lès-Nancy, France, peteb@crpg.cnrs-nancy.fr

[2]Faculty of Earth and Life Sciences, VU University, Amsterdam, The Netherlands

Noble gas and major volatile systematics indicate that MOR magmas lose volatiles via open system distillation. However, given the low Stokes velocity of bubbles within basaltic magmas (~10 cm h^{-1} for a 300 μm vesicle), it is not possible to efficiently separate bubbles from their enclosing liquids and hence it is difficult to see how open system degassing can physically occur. However, if the magma – crust interface is sufficiently permeable, then volatile loss could be achieved via degassing directly into the crust, without necessarily passing through the vesicle phase. This "bubble-less" degassing could potentially be efficient because the partial pressure of volatiles in the enclosing crust should be very low in contrast to the partial pressure of volatiles within vesicles which is limited by their solubility at the pressure of the degassing magma.

In order that degassing directly into the crust can be efficient, three conditions need to be met: 1) the surface area of the magma-crust interface needs to be similar to or greater than the surface area of the sum of the vesicles; 2) the magma crust interface needs to be permeable; 3) the magma needs to be sufficiently convective to ensure that a significant fraction of the magma passes within the characteristic diffusion distance of the magma-crust interface.

We asses here condition #1. The surface area of bubbles in a magma depends on the bubble size distribution, the total vesicularity and magma pressure during degassing; typically specifc surface areas of magmas will be in the range 1 – 10 $mm^2\ g^{-1}$ for most MORBs (up to a maximum of ~50 $mm^2\ g^{-1}$ for the "popping rock"). Sill-like magmas have surface/volume ratios of between $1x10^{-2}$ and $1x10^{-5}$ (corresponding approximately to sills between 0.15 and 150 m) thick. Figure 1 shows that the total vesicle surface area of a magma is the same as or slightly higher than the surface area of the magma/crust interface. Given the uncertainties involved, it is possible that "bubble-less" degassing may be a potential mechanism through which magmas lose their volatiles. Further modelling will investigate conditions 2) and 3).

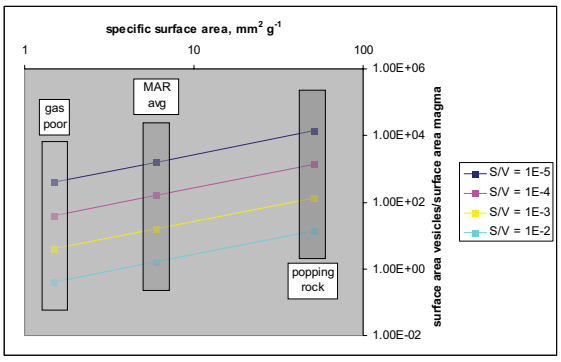

Figure 1: Variation of (vesicle surface area)/(magma-crust interface area) as a function of vesicle specific surface area ($mm^2\ g^{-1}$) for different magma geometries (different Surface/Volume ratios).

https://doi.org/10.1180/S0026461X00008434 Published online by Cambridge University Press

Diffusion compensation and application of Graham's law to noble gas diffusivities

PETE BURNARD[1*]

[1]CRPG-CNRS, Vandoeuvre-lès-Nancy, France, *peteb@crpg.cnrs-nancy.fr (* presenting author)

Diffusion Compensation

The temperature dependence (E_a) of slow-diffusing species tends to be greater than that of faster diffusing species, resulting in an interdependence between D_0 and E_a [1, 2, 3]. The net result is that the difference in diffusivity between two species in a given matrix will reduce with temperature, converging at a particular "compensation" or "isokinetic" temperature where the two (or more) species have the same diffusivities.

Graham's Law of effusion on the other hand states that, as far as gases are concerned, the relative diffusivity of two species is equal to the inverse of the square root of their masses:

$D_1/D_2 = \sqrt{(M_2/M_1)}$

In situations where experimental data are lacking, this relationship is often used to calculate the relative diffusivities of noble gas pairs. However, Graham's Law and "Compensation Temperature" relationships are mutually exclusive: according to Graham's Law, two noble gases should have the same Ea and differ only in D_0 (which should be constrained by $\sqrt{(M_2/M_1)}$). There cannot be compensation of diffusion with temperature for species following Graham's Law.

Non-Graham's Law behaviour

Recent results (Amalberti et al, this volume) show that He and Ar diffusivities in silicate glasses do infact differ in Ea: Graham's Law does not apply to diffusion of noble gases in silicate glasses (i.e. it is not possible to assume that $D_{He}/D_{Ar} = \sqrt{(M_{Ar}/M_{He})}$). The predicted isokinetic temperature for He and Ar diffusion in basaltic glasses is ~1000 K. The lack of conformity to Graham's law is easily understood: The Graham's Law relation is based on the two gas species of interest having the same kinetic energy (for example, for gases diffusing through a pinhole in the classic experiments by Graham in the 19th century). Volatile species diffusing through solid matrices are not expected to be isokinetic (they are not free gases) and Graham's law likely does not apply to diffusion of gases dissolved in solid matrices.

Implications

As a result, kinetic fractionation of different noble gases will only occur at "low" temperatures (the lower the temperature, the greater the potential for kinetic fractionation). Thus it does not appear likely that diffusion during magmatic processes (mantle melting or degassing of magmas) will be able to kinetically fractionate the noble gases. However, post-deposition (low temperature) processes out of equilibrium will create large He-Ar (and by extension, Ne-Ar, Kr-Ar etc) fractionation. The geological implications of these observations will be discussed.

Identification of chromitite and kimberlite occurences in the James Bay lowland using statistical analysis of detrital chromite compositions

MARCUS BURNHAM[1*], DAVE CRABTREE[1] & RIKU METSARANTA[2]

[1]Geoscience Laboratories, Ontario Geological Survey, Sudbury, Canada. marcus.burnham@ontario.ca

[2]Precambrian Geoscience Section, Ontario Geological Survey, Sudbury, Canada. riku.metsaranta@ontario.ca

Introduction

In 2001, under the Operation Treasure Hunt (OTH) program [1], the Ontario Geological Survey carried out a stream sediment sampling program in the James Bay lowland during which over 1000 stream sediment samples were collected and processed for kimberlite and metamorphic/magmatic massive sulphide indicator minerals and gold grains. Because the primary objective of this survey was to evaluate the potential of the region to host additional kimberlite pipes, an emphasis was placed on the compositions of the garnet fraction. However, with the recent discoveries of chromite, Cu-Ni-PGE-sulphide and Ti-V mineralisation in the McFaulds Lake or "Ring of Fire" area, the chemistry of the detrital chromite grains is being re-investigated through statistical analysis of the original OTH dataset (>5500 electron probe microanalyses [2]) supplemented by analyses of chromites from the bed rock (in particular lithologies associated with the McFaulds Lake area mineralisation and Attawapiskat kimberlite diatremes).

Statistical Analysis

Initial statistical analysis of the major and minor element contents of the chromites, using agglomerative hierarchical clustering (AHC) after log-ratio transformation of the data to remove the constant-sum problem [3], suggests that at least nine compositional groups can be recognised. These groups show spatial associations with the bedrock geology, most notably in their Ti, Fe^{3+}, Fe^{2+}, and V contents (Figure 1).

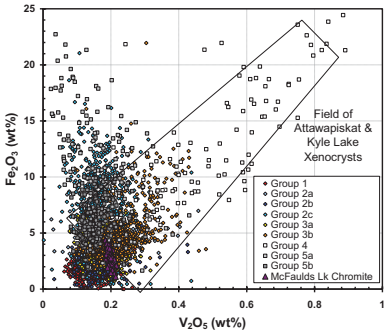

Figure 1: Compositions of detrital chromites from the James Bay lowlands. Field of Attawapiskat and Kyle Lake xenocrysts from [4].

Plastic Deformation in Olivine Polycrystals:In-situ diffraction and EPSC models

PAMELA C. BURNLEY[1*]

[1]University of Nevada Las Vegas, Department of Geoscience, Burnley@physics.unlv.edu

Introduction

An important problem in rock deformation studies is the so-called meso-scale problem; understanding how the behaviour of individual mineral grains deforming via grain-scale processes interact to produce the bulk behaviour of the aggregate. A number of models for thinking about this problem exist, ranging from various averages of isolated grain behaviour to those that are dominated by grain configuration, for example stress percolation (as observed in granular materials). It is likely that the degree to which any given model is useful for a particular material depends on the degree of mechanical heterogeneity and anisotropy of the material. We are investigating the deformation of polycrystalline olivine in this light.

Methods

We report on in-situ synchrotron x-ray diffraction from high pressure deformation experiments conducted using olivine in the D-DIA apparatus at beamline X17b2 at the NSLS. We observe the diffraction behaviour of x-ray reflections for lattice planes oriented nearly perpendicular to compression and at several other orientations including the transverse orientation. Sample strain is measured using radiograph of the sample (which is bounded by metal foils). We used elastic plastic self-consistent (EPSC) modelling[1] to analyse diffract-tion from the sample during deformation. The models assume that rheology of the bulk is controlled by the critical resolved shear stress of the slip systems and the orientation of the grains in the polycrystal.

Results and Discussion

The failure of the known olivine slip systems to meet the von Mesis criteria for arbitrary shape change causes the EPSC models to exhibit very strong work hardening and nearly elastic behaviour for many grain populations. This is in stark contrast to our experimental data which consistently shows little or no work hardening after yield.

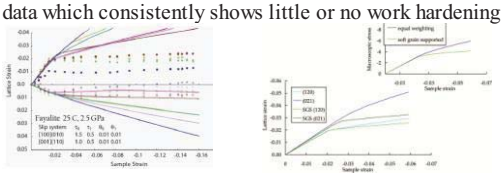

Figure 1: a) (left) Experimental diffraction results (points) for the (021), (010), (120), (002), (131) and (112) lattice planes in compression (above axis) and transverse directions (below axis). EPSC model is shown with matching coloured lines. **b)** (right) Modified EPSC model in which weakest grains dominate.

One possible reason that the deformation behaviour of polycrystalline olivine cannot be predicted with the EPSC model is that grains in the polycrystal that are well oriented for slip (soft grains) dominate the deformation behaviour or the aggregate, with grains that are not well oriented for slip passively "riding along" and not contributing to the aggregate strength. To test this, we assign a weighting factor to each grain depending on the degree of plastic strain that accumulates in the grain during deformation. Using this strategy the EPSC model more closely mimics the lack of work hardening as well as smaller difference in lattice strain between the (120) and (021) reflections.

Integrated 3D multimodal CARS microscopy, Raman spectroscopy, and microthermometry of gas-rich inclusions in the Marcellus shale-gas system

R. C. BURRUSS[1*], M. EVANS[2], A. D. SLEPKOV[3], A. F. PEGORARO[4] AND A. STOLOW[4]

Gas-rich inclusions in fracture filling cements in the Marcellus Shale and younger Devonian age formations in the Appalachian basin record a complex history of gas generation, migration, and alteration during evolution of the Alleghenian orogen[1]. Quartz and calcite cements contain multiple overlapping fluid inclusion assemblages (FIAs) formed during crystal growth and deformation. To resolve the complex sequences of gas generation and migration recorded by FIAs we applied a nonlinear optical microscopy method capable of 3D, molecule-specific imaging with sub-micrometer resolution: multimodal coherent anti-Stokes Raman scattering (CARS) microscopy. Our implementation of CARS microscopy[2] produces molecule-specific images in the range of 2100 to 4000 cm^{-1} (N_2, CH_4, H_2O) and simultaneously creates second harmonic generation (SHG) images of inclusions with associated quartz microstructures, and two-photon excitation fluorescence (TPEF) images of higher hydrocarbons. The CARS images show the distribution of methane-rich and aqueous phases in inclusions and the TPEF images show the distribution of gas-rich inclusions that contain trace levels of higher hydrocarbons. Individual gas-rich inclusions within distinct 3D FIAs identified with multimodal CARS were analyzed by conventional confocal Raman spectroscopy for minor components (C_2H_6, CO_2, H_2S, N_2) and internal pressure[3]. 2D maps of inclusions with microthermometric measurements were correlated with 2D projections of 3D SHG images. Integration of measurements on individual inclusions with 3D images allows identification of FIAs with distinct spatial orientation and differences in composition (C_2H_6, CO_2, higher hydrocarbons) and density. 3D imaging with CARS microscopy is a major advance in our ability to assign FIAs with distinct compositions to distinct orientations of microstructures formed during kinematic evolution of the orogen. These observations provide new insight to the temporal evolution of hydrocarbon gas generation and migration during evolution of the Marcellus shale-gas system.

Pore-water diffusive fluxes of ^{224}Ra and CO_2 in Bedford Basin, Nova Scotia.

WILLIAM BURT[1*], HELMUTH THOMAS[1], KATJA FENNEL[1], JOHN N. SMITH[2], AND EDWARD HORNE[2]

[1]Dalhousie University, Department of Oceanography, Halifax, NS, Canada willburt@dal.ca, helmuth.thomas@dal.ca, katja.fennel@dal.ca, (*presenting author)

[2]Bedford Institute of Oceanography, Fisheries & Oceans Canada, Dartmouth, NS, Canada John.Smith@dfo-mpo.gc.ca, Ed.Horne@dfo-mpo.gc.ca

Introduction and aim of the study

On the seafloor, chemical processes occurring within sediments create pore-waters highly enriched in various chemical constituents. Many of these processes are fuelled by particulate organic matter (POM), generated during primary production in the euphotic zone and settled onto the surface sediments. Biological transformations of POM in the surface sediments, aerobic or anaerobic, eventually increase pore-water concentrations of dissolved inorganic carbon (DIC), and depending on redox conditions, also alkalinity (A_T). Furthermore, the decay of radioactive elements in the sediments constitutes a further source of chemical species enriched in pore-waters, such as the decay of sediment-bound ^{228}Th ($t_{1/2}$=1.91y), which yields high concentrations of its shorter-lived daughter ^{224}Ra ($t_{1/2}$=3.66 d). We investigate the diffusive flux of three such constituents, the short-lived radium isotope ^{224}Ra, DIC and A_T, from pore-waters into the deep waters of Bedford basin (Nova Scotia, Canada), in order to shed light on both the biogeochemical behaviour of ^{224}Ra and on the return flow of DIC and A_T into the water column from POM respiration on the surface sediments.

Results and Discussion

We apply a 1-D diffusive mixing model (Moore, 2000) to near-bottom profiles of excess ^{224}Ra activity. The recurrence of sharp Ra gradients supports the assumption of a diffusion-dominated mixing regime. We yield vertical eddy-diffusion coefficients (K_Z), along with estimates of ^{224}Ra activity at the sediment-water interface, from which we derive ^{224}Ra fluxes per unit area of sediment. Subsequently, we apply K_Z values to the near-bottom gradients of DIC and A_T, in order to estimate benthic DIC and A_T fluxes from Bedford Basin sediments into the overlaying water column.

Integrating our findings over a full annual cycle, the benthic return flux of DIC constitutes as much as 50% of the annual primary production [2], suggesting substantial additional delivery of organic carbon to deep sediments in the basin. Input from nearby sewage outfalls, re-suspension and transport of sediments at shallower depths [3], and high retention levels within the basin [4] may provide the mechanisms required for this enhanced carbon delivery. Finally, we do not observe any significant release of A_T from the surface sediments to the overlaying water column, which can be seen as an indicator of primarily aerobic respiration of the settled POM, fuelled by sufficiently high dissolved oxygen levels. Assessing global N cycling in subduction zones from data on metamorphic rocks: Implications for the evolution of N in Earth's reservoirs

VINCENT BUSIGNY*, PIERRE CARTIGNY, PASCAL PHILIPPOT

IPG-Paris and Univ. Paris Diderot, Sorbone Paris Cité, France, busigny@ipgp.fr (* presenting author), cartigny@ipgp.fr, philippot@ipgp.fr

In order to evaluate the budget of nitrogen buried to the mantle in subduction environments, we performed quantitative and N isotopic analyses of Alpine metamorphic rocks subducted to different depths, and on their non-metamorphic analogues. The samples investigated represent a complete section of the oceanic lithosphere including from bottom to top, serpentinized peridotites, metagabbros, metabasalts and overlying metasediments.

A global annual flux of N subducted by metagabbros has been estimated at about 4.2 ($\pm$ 2.0) $\times 10^{11}$ g/yr with an average δ^{15}N-value of 1.8 $\pm$ 0.8 ‰ (1σ). This flux is about half that of sedimentary rocks, which indicates that gabbros carry a significant portion of the subducted nitrogen. The net budget between subducted N and that outgassed at volcanic arcs indicates that ~80% of the subducted N is not recycled to the surface.

On a global scale, the total amount of N buried to the mantle via subduction zones is estimated to be 3 times higher (13.2 $\times 10^{11}$ g/yr) than that released from the mantle via mid-ocean ridges, arc and intraplate volcanoes and back-arc basins. This implies that N contained in Earth surface reservoirs, mainly in the atmosphere, has been progressively transferred and sequestered into the mantle, with a net flux of ~9.6 $\times 10^{11}$ g/yr. Assuming a constant flux of subducted N over the Earth's history suggests that an amount equivalent to the present atmospheric N may have been sequestered into the silicate Earth over a period of 4 billion years.

Considering a present day mantle value of ~ -5‰, an average δ^{15}N value of subducted nitrogen of about 3.4 ±1.4 ‰ implies that the secular evolution of the mantle δ^{15}N value should have increased through time, whereas that of the crust and atmosphere should have decreased.

The interfaces where intact bedrock weathers to disaggregated material, such as saprolite and soil, are often hidden deep within the critical zone. The majority of weathering studies in the field focus on the shallow critical zone: soils, sediments, regolith, saprolite, and outcrops. However, weathering of primary minerals along bedrock fractures located in the groundwater or deep vadose zones may supply significant weathering products to streams and oceans.

We investigated the deep critical zone in the Bisley watershed in the Luquillo Critical Zone Observatory from two 9.6 cm diameter boreholes drilled with a hydraulic rotary drill to 37.2 and 27.0 m depth. Continuous core samples through coherent rock were taken using an HQ-wireline barrel. Bulk solid-state chemical analysis and powdered XRD were performed on rock and saprock samples. Thin sections were examined by optical microscopy and SEM. A history of low- to moderate-grade metamorphism is reflected by the presence of epidote, prehnite, pyrite, and tourmaline. Fresh rock contains abundant plagioclase and chlorite, with lesser quartz, K-spar, and pyroxene.Weathering rinds developed on fracture surfaces are porous and contain abundant secondary Fe(III)-oxides.

Drilled cores revealed repeated zones of highly fractured rock, identified as corestones, embedded within layers of regolith. Some corestones are massive and others are highly fractured. Subsurface corestones are larger and less fractured in the borehole drilled along the spine of a ridge, compared to the borehole drilled near a stream channel. As corestone size is thought to be a function of fracture spacing, the location of the valleys and ridges in the watershed may be controlled by the fracture spacing of the underlying bedrock.

Drilling terminated in coherent rock, thought to be bedrock based on a model that hypothesized a thickness for the corestone zone [1]. The 2 drilled boreholes and a resistivity profile [2] are only 20-50m apart and of similar elevation. However, all 3 have different profiles demonstrating that this is a complex landscape that needs both geophysics and drilling to understand. Even so, all of the profiles indicate that the weathering zone is well below the stream channel; thus weathering depth is not controlled by local base level. Furthermore, weathering rinds on fracture surfaces at depth indicate that water and oxygen are transported below the stream channel; thus not all of the water in the watershed is discharged to the stream.

Efficiency of covers made of low sulphide tailings to control AMD from surface impoundments

BRUNO BUSSIÈRE[1*], MICHEL AUBERTIN[2]

[1]Université du Québec en Abitibi-Témiscamingue, Institut de recherche Mines et Environnement, (*presenting author), Bruno.bussière@uqat.ca
[2]École Polytechnique de Montréal, Département de génie civil, géologique et des mines, Michel.Aubertin@polymtl.ca

Introduction

It is now recognized that one of the best options to reclaim acid-generating tailings impondments is to use an oxygen barrier. Water contamination can be controlled by limiting the oxygen flux reaching the reactive tailings. Different types of oxygen barriers can be used, including engineered covers that rely on a high moisture content in one of its layers to prevent oxygen migration [1,2]. The authors work has shown that when appropriate soils are not available close to the mine site, low sulphide tailings can advantageously be used as a component of layered covers.

Main results

Different laboratory and *in situ* tests were performed over the last 20 years or so by the authors and collaborators to evaluate the response and performance of covers made with low sulphide tailings to limit water contamination. The initial series of tests used «naturally» low sulphide tailings as the moisture retaining layer in covers with capillary barrier effects (CCBE). Results showed that it was possible to maintain the water quality below the regulation criteria with such type of CCBE placed over reactive tailings. The control tests on exposed acid-generating tailings (without the cover) showed that the pH of the leachates droped below 3, with concentrations in dissolved metals in the hundreds of mg/l [3]. Another series of tests were performed in the laboratory to evaluate the feasibility of artificially producing the low sulphide tailings by a flotation process, and to use the desulphurized tailings as moisture-retaining layer in a CCBE. When the tailings are properly desulphurized, testing results showed that water contamination was effectively prevented, producing a leachate that meets water quality criteria [4]. An additional series of experiments were performed to evaluate the performance of monolayer covers made of low sulphide tailings, in combination with the elevated water table technique [5]. These column tests results show that the water table level is the most important parameter affecting the monolayer cover performance to control acid generation. The water table must be located at a minimum depth below the cover to prevent water contamination.

Conclusion

Results from different experiments at different scales showed that low sulphide tailings can be an efficient material to be used in engineered covers designed to control acid production from reactive tailings. In adddition, the use of low sulphide tailings valorises a mining waste and reduces the borrowing of natural soils and the related pertubations.

Shear-Induced Melt Bands with Anisotropic Viscosity and Implications for Melt Extraction at Mid-Ocean Ridges

SAMUEL BUTLER[1*]

[1]University of Saskatchewan, Department of Geological Sciences, Saskatoon, Canada, sam.butler@usask.ca (* presenting author)

Introduction

Melt at mid-ocean ridges is produced over a broad lateral area but is mostly extracted in a narrow region in the vicinity of the ridge crest. Geochemical evidence also indicates that it is extracted rapidly, necessitating a mechanism to focus melt towards the ridge axis. When systems of partial melt are subjected to an externally driven strain-rate, melt segregates into bands of low and high porosity provided that the viscosity of the solid matrix decreases with increasing porosity and that the system is larger than the material compaction length. These bands have been suggested as candidates for focusing melt flow towards the ridge axis[1]. Experimental investigations of these systems have shown that the bands form at roughly 25° to the direction of maximum compression, regardless of the degree of strain-rate dependence of the matrix viscosity. In contrast, numerical and theoretical investigations show that bands should grow fastest if they are oriented parallel to the direction of maximum compression of the background flow if the viscosity is strain-rate independent and isotropic. Recently, it has been suggested that the matrix viscosity should be anisotropic because of the anisotropic arangement of melt at the grain scale caused by stress and that this anisotropy could result in low angle bands as observed in the experiments[2]. In this contribution, I will present numerical simulations of melt bands with anisotropic viscosity.

Results

When matrix viscosity is anisotropic with orientation appropriate for the orientation of grain-scale melt seen in experiments at low strain, the bands do form at angles that are consistent with those seen in experiments. However, in experiments at high strain, the melt in seen to reorient and the resulting viscosity anisotropy results in simulated bands that are not consistent with those seen in experiments.

The effects of buoyant interstitial fluid are also investigated and it is found that a large degree of buoyancy results in two sets of band orientations and short wavelength bands.

The Mayon Volcano (Philippines) plumbing system: Insights from crystal zoning patterns and volatile contents

JOAN CABATO[1*], FIDEL COSTA[2], CHRIS NEWHALL[3]

[1]Earth Observatory of Singapore, joan.cabato@ntu.edu.sg (* presenting author)

[2]Earth Observatory of Singapore, fcosta@ntu.edu.sg

[3]Earth Observatory of Singapore, cnewhall@ntu.edu.sg

Mayon is a persistently degassing volcano, producing vulcanian-strombolian eruptions every few years, and perhaps a plinian eruption every century. We investigate the plumbing system beneath Mayon using phenocrysts, microlites and melt inclusions, which record processes in the magma chamber and conduit. We also inspect matrix glass composition to relate the magmatic history all the way to the last stages of cooling during an eruption.

Eruptive products of Mayon are consistently basaltic andesite in composition. Petrological data for this study are derived mostly from bread-crust bombs of the 2000 eruption, which have inclusions of up to 40cm in size. These inclusions have the same bulk composition and phenocryst populations as the host rock, the difference lies only in their more crystalline matrix. The coarse microlites in the inclusions imply relatively slow degassing rates, revealing an upward magma movement slower than that of an eruption, as would occur during convection in the conduit.

Similarity in the phenocrysts of the host and inclusions indicate the same magma at depth. Plagioclase phenocrysts show complex patterns, from oscillatory zoning to pervasive sieve textures that may occur multiple times in a single crystal. The most calcic end member resorbs more sodic zones, forming geometrically complex zones rich in glass that result to the sieve texture. Clinopyroxene and orthopyroxene phenocrysts are also zoned, but show less complexity than the plagioclase. In many cases, pyroxene cores are more iron-rich than the rims, although iron-rich outermost rims are also common. These textures and zonations can be explained by the mixing of at least two end-members in the reservoir, one more primitive (An80, Mg#75) and probably more volatile-rich than the other (An60, Mg#65). The extent to which these patterns reflect a single – versus multiple – replenishment, is unclear.

Fe-Mg diffusion modelling in pyroxenes suggests timescales of less than 10 years between mafic injection and subsequent eruption. Preliminary volatile data from melt inclusions in tephra fall deposits of the 2000 eruption yield source depths of about 9km. Additional volatile analyses of different Mayon eruption deposits are underway to further characterise the inner workings of the volcano.

Titan tholins: A synopsis of our current understanding of simulated Titan aerosols

MORGAN L. CABLE[1*], SARAH M. HÖRST[2], ROBERT HODYSS[1], PATRICIA M. BEAUCHAMP[1], MARK A. SMITH[3] AND PETER A. WILLIS[1]

[1]NASA Jet Propulsion Laboratory, California Institute of Technology, Pasadena, USA, morgan.l.cable@jpl.nasa.gov (* presenting author)

[2] University of Colorado, Boulder, USA, sarah.horst@colorado.edu

[3]Universty of Houston, Houston, USA, markasmith@nsm.uh.edu

What Are Tholins?

Since the term 'tholin' was first applied by Carl Sagan to the dark organic residue formed from gas phase activation of cosmically relevant mixtures, [1] many hundreds of papers have been published on the generation and/or analysis of this material. In particular, the similarity of tholin optical properties to those of the Titan haze has caused new investigations into laboratory simulation of these aerosols. Much has changed both in terms of our abilities to simulate conditions of the Titan atmosphere and to analyze the samples produced.

We will summarize work involving laboratory analogues of Titan complex organic material (tholins) in the context of recent discoveries. Our current understanding of Titan as a prebiotic system is constantly evolving, and recent data from the Cassini-Huygens mission has greatly improved physical and chemical constraints on models of the atmosphere. However, laboratory experiments are still necessary to provide critical insight for defining the next series of *in situ* experiments to perform on Titan, which will better elucidate processes occurring in the atmosphere and on the surface.

Are Any Tholins Titan-Like?

A variety of complex organic aerosols produced using gas phase activation techniques (cold plasma/corona discharge, hot plasma/spark discharge, UV irradiation, etc.) have all been labeled 'tholins', despite the fact that their physical and chemical properties can be enormously different. This variability begs the question: which, if any, of these tholins are truly Titan-like?

We examine various tholin generation methods and compare the organic material produced to the expected composition of the aerosols in Titan's haze and precipitates settled onto the surface. Tholins are assessed in terms of their optical properties, physical characteristics and chemical composition. We also investigate the possibility of additional chemistry occurring on the surface of Titan, and examine potential *in situ* analysis techniques that could be used on future landed missions to search for evidence of this chemistry. Finally, we develop a metric to classify tholins based on how effectively the relevant properties of the Titan atmosphere (temperature, pressure, energy density, etc.) are replicated during tholin formation. This metric should also help inform the next generation of chemical protocols and instrumentation for use on the surface or in the atmosphere of future Titan *in situ* missions.

Oceanic gabbro signature in Mangaia melt inclusions

R.A. CABRAL[1]*, M.G. JACKSON[1], E.F. ROSE-KOGA[2], J.M.D. DAY[3], K.T. KOGA[2], N. SHIMIZU[4], M.J. WHITEHOUSE[5], A. PRICE[1]

[4]Woods Hole Oceanographic Institution, Woods Hole, MA 02543
[5]Swedish Museum of Natural History, Laboratory for Isotope Geology, SE-104 05, Stockholm, Sweden

Lavas from Mangaia exhibit an extreme HIMU (high-μ, or high $^{238}U/^{204}Pb$) signature that has been attributed to melting of ancient recycled oceanic crust within ocean island basalt (OIB) mantle sources [1]. In a landmark study, Saal *et al.* [2], measured extreme lead isotopic diversity in melt inclusions (MI) from Mangaia, spanning half of the global range observed in OIBs. In Pb-isotopic space, these MI display a trend towards an unradiogenic end member similar to MORB. However, the origin of Pb isotope diversity and the identity of the unradiogenic end member could not be resolved due to lack of coupled major-trace-volatile element abundances for the MI.

This study examines homogenized olivine-hosted MI in Mangaia lavas. We present the first coupled measurements of major-trace-volatile element abundances and Pb-isotopic measurements on the same MI. Critically, we identify Pb-isotopic variability in our MI, and Pb-isotopic ratios correlate with ratios of major, trace, and volatile elements. For example, the anomalous MI with MORB-like Pb-isotopic ratios exhibit geochemical signatures associated with oceanic gabbro, including elevated Sr/Nd, Ca/Al, Cl/La, and K/La.

It is difficult to constrain the origin—modern plate or ancient recycled lithosphere—of the gabbroic signature. One hypothesis is that the gabbroic signature in the MI derives from melting of the gabbroic section of ancient, recycled oceanic crust [3]. Alternatively, Saal *et al.* [4] suggested that a gabbroic signature in OIB lavas derive from shallow assimilation of gabbros during magmatic ascent. The primary difference between these two hypotheses is that the former requires gabbros processed in a subduction zone, and the latter does not. The elevated Cl/La and K/La in the anomalous melt inclusions is not consistent with subduction zone processing, as Cl and K are fluid mobile and should be lost from the down-going slab. By contrast, altered oceanic gabbros have elevated (Cl, K)/La. Based on the current dataset, we favor the hypothesis that the anomalous gabbro signature (and Pb-isotopic diversity) in Mangaia MI owes to assimilation of Pacific oceanic crust during magmatic ascent.

Petrologic evidence for rapid exhumation of Alpine UHP rocks from > 100 km depth

MARK J. CADDICK[1*], ROBERT J. TRACY[1], NANCY L. ROSS[1]

[1]Department of Geosciences, Virginia Tech, Blacksburg, Virginia, United States, caddick@vt.edu (* presenting author)

We report on a whiteschist from the Brossasco Zone in the Dora Maira UHP Alpine massif – a sample that preserves a remarkably well-constrained record of its late-prograde to peak pressure history, and allows exploration of the processes, mechanisms and timescales of burial and exhumation in rocks reaching ultra-high pressure conditions. Thermodynamic modeling suggests that the abundance and composition of the major phases (garnet, kyanite, Mg-phengite, phlogopite, Na-phlogopite, quartz/coesite, talc and rutile) are consistent with equilibration at ~ 3.5 GPa, 775 ˚C. Well-preserved palisades-textured quartz around large coesite inclusions in garnet attests to this high-pressure phase of the rock's history, whilst complete coe-qtz inversion during exhumation is reflected in the matrix. Unusual evidence of the path taken to reach maximum *P* and *T* can be inferred from asymmetric, high-Ca bands within pyrope-rich (~ prp_{92}) garnet. These bands, which mimic their host crystal's shape and contain ~ 3 times higher X_{gro} than the host, are sharply defined at their inner margin (towards the crystal core) but decay gradually to a low-Ca rim. We interpret this as fractionation of Ca from a finite matrix source during garnet growth. Thermodynamic constraints strongly indicate that the precursor host for this Ca was lawsonite, which is now entirely absent from the sample but helps to constrain the early heating history.

Indicators such as retained strain in matrix quartz crystals and sharp boundaries in garnet zoning profiles suggest that exhumation and cooling were very rapid. Diffusion modeling of garnet zoning yields best-fit timescales of ~ 5 Myrs, consistent with exhumation timescales previously inferred from isotope geochronology [e.g. 1]. This is corroborated by preliminary EMP dating of two monazite populations, which can be characterized as low-Y and high-Y bearing. High-Y rims are common on low-Y cores of matrix monazite but are absent from crystals present as inclusions in garnet, and are interpreted as representing growth during decompression-driven garnet breakdown. Initial results suggest that this rim growth occurred < 10 Myrs (and possibly closer to 5 Myrs) after prograde growth of the low-Y monazite cores.

The constrained pressure-temperature history, including rapid exhumation and an almost complete lack of retrogressive reaction (other than slight garnet breakdown to Mg-rich talc and kyanite) indicates possible mechanisms for burial, heating and exhumation. Likely exhumation rates approach rapid plate tectonic velocities, indicating that erosion was not a major controlling factor. Furthermore, thermodynamic models suggest that the Dora Maira sample had a density of ~ 3.2 g/cm^3 at 110 km depth, implying that despite the relatively small volume of preserved whiteschist material, buoyant exhumation back along a subduction channel remains a feasible mechanism.

Storage conditions of the silicic magmas preceding major plinian eruptions of Santorini volcano

ANITA CADOUX[1*], BRUNO SCAILLET[1], ETIENNE DELOULE[2] AND TIM DRUITT[3]

[1]Institut des Sciences de la Terre d'Orléans, UMR 7327, Orléans, France, acadoux@cnrs-orleans.fr (* presenting author), bscaille@cnrs-orleans.fr

[2]Centre de Recherches Pétrographiques et Géochimiques, Vandoeuvre-les -Nancy, France, deloule@crpg.cnrs-nancy.fr

[3]Laboratoire Magmas et Volcans, UMR 6524, Clermont-Ferrand, France, T.Druitt@opgc.univ-bpclermont.fr

Magma storage conditions can dramatically change over time at a single volcano and might be in close relationships with stress variations imposed on the crustal plumbing system by the overlying edifice as well as changes in eruptive dynamism. The Santorini volcano (Greece) is an ideal target to unravel these potential relationships. We focused on the silicic products of the four major plinian eruptions of Santorini which occurred since the last 200 ka: the Lower Pumice 1 and 2 rhyodacites, the Cape Riva dacite and the Minoan rhyodacite. In order to precisely define the P, T, fO_2 and volatiles pre-eruptive storage conditions of these silicic magmas, we combined a micro-petrological and geochemical study on natural and experimental products. This study is of particular interest in the context of caldera unrest ongoing at Santorini since July 2011.

Our results indicate pre-eruptive temperatures ranging from ca. 850 to 900°C, and a fO_2 along the FMQ buffer curve (log fO_2 = -12.9 to -13.5) except for the Minoan rhyodacite which displays more oxidizing conditions near the NNO buffer (fO_2 = $10^{-12.8}$). The rhyolitic melt inclusions (MI) of plagioclase and pyroxene phenocrysts are mostly H_2O-rich (~3 to > 6 wt.%). The MI and the matrix glasses are both Cl-rich (~3000-4000 ppm) while F (< 1000 ppm) and S (< 100 ppm) represent minor species. Phase equilibria from crystallization experiments for the four eruptions were established at T = 850-900°C, P = 2-4 kbar, fO_2 ~ FMQ, and XH_2O [= moles of H_2O/ (H_2O+CO_2)] between 1 (i.e., H_2O saturated) and 0.6. Significantly, phase relationships show marked differences between eruptions, outlining the need to establish phase equilibria specific to each composition. While the petrological attributes are broadly reproduced at 2 kbar in the temperature range explored, additional experiments are in progress to explore more oxidizing (~NNO +1) and shallower storage conditions (1 kbar).

Hydro-geochemical impact of CO_2 leakage from CCS on shallow potable aquifers: batch, tank and field scale experiments.

AARON CAHILL[1*], AND RASMUS JAKOBSEN[1]

[1]Technical University of Denmark, Department of Environmental Engineering, aarc@env.dtu.dk (* presenting author)

Investigations regarding the environmental implications resulting from leakage of CO_2 from a geological sequestration site into overlying shallow potable aquifers include; simple laboratory batch experiments [1], reactive transport models [2] and field based studies [3]. However, the value of the methods has not been evaluated in detail and the application of several methods to a single field site has not been made. A 6 month field release experiment will commence in spring 2012 at Vrøgum plantation, Western Denmark and preliminary work has been conducted to aid design. First batch experiments exposing field site sediment to CO_2, followed by a sediment flow tank experiment injecting CO_2 continuously were conducted. Finally, in a pilot field injection 45 kg of food grade CO_2 was injected at 10 m depth over 48 hours and the effects on water chemistry observed. The results from each method are compared to assess suitability and relevance to geochemical process understanding and risk assessment.

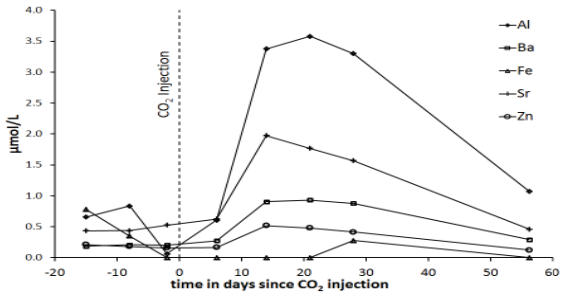

Figure 1: Trace metal concentrations measured 1.0 m down flow of injection point in field pilot experiment.

Results and Conclusion

Batch, tank and pilot injection results all indicate a release of sorbed major and trace elements as well as a release from dissolving silicate minerals. Results also indicate that the risks to water resources from a short term leak from CCS into shallow, overlying, silicate based aquifers (such as the Vrøgum site) are minimal. Some elements approach or exceed guideline values but none of these are particularly toxic or beyond the scope of normal water treatment. Sorption of released elements and accumulation of other elements was observed in the tank and field injections, inferring that a large scale, long lasting leak may develop a CO_2 charged plume or front carrying elements exceeding guideline values for major and trace elements. Differrences in the results from batch and flow based experiments were observed (both for element concentrations and physico chemical parameters) indicating that batch experiments do not accurately indicate the risks to water resources from CCS leakage.

Spatial variability in ocean redox conditions during early Cambrian

CHUNFANG CAI[1*], LEI XIANG[1], YUYANG YUAN[1], LIANQI JIA[1] AND TIANKAI WANG[1]

[1]Institute of Geology and Geophysics, CAS, Beijing, P R China, cai_cf@mail.iggcas.ac.cn (* presenting author)

Lower Cambrian black shales have extensively been considered as euxinic sediments. However, recent studies suggest that euxinic conditions may have been over-estimated and ferruginous-dominated deep water and a statified redox stucture may have occurred from 742 to 542Ma [1, 2]. Interestingly, small amounts of samples from the Lower Cambrian in the Songtao section, South China show deposition in a Fe-rich as well as a euxinic enviroment [1]. However, spacial variation for the ocean chemistry during the period is unclear. Here, we analyzed about 300 samples for the total Fe content (FeT) and the abundance of Fe in highly reactive mineral species (FeHR): pyrite, Fe(III) oxides, magnetite and carbonate minerals, using the standard method [1]. These samples were collected from Lower Cambrian black shales of age about 526 to 510Ma [3] and chert and samll amounts of limestones of age about 542 to 526Ma from eight sections in South China with depositional environments ranging from inner shelf, outer shelf, slope and basin.

The results show that all the anlyzed samples except one have FeHR/FeT>0.22, indicating all deposition in an anoxic enviorment. All the chert and limestone and most of the black shale samples have FePy/FeHR<0.7, suggestive of an anoxic, Fe-rich enviorment. Only a few black shales from inner shelf at Shatan section, out shelf at Muyangxiang section and isolated topographic highs within the basin facies at Zhalagou and Tianzhu sections have FePy/FeHR>0.8, a product of a euxinic condition. Black shales and cherts from basin facies at Lijiatuo and Siduping sections show a characteristic of a ferruginous condition, however, a few euxinic sediments were found in the basin facies from Songtao section. Thus, it is very likely for a statified redox ocean to occur during early Cambrian, similar to Ediacaran ocean, as proposed by Li et al. (2010) [2].

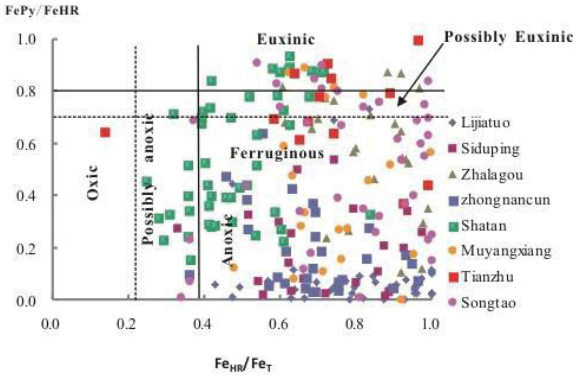

Figure 1: Relationship between FePy/FeHR and FeHR/FeT ratio

Geochemistry of mafic to felsic sequences in the SW border of Ossa-Morena-Zone (OMZ), Portugal

RITA CALDEIRA[1,2*] AND LUISA RIBEIRO[1,3]

[1] LNEG – UGCG, National Laboratory of Energy and Geology, Dept. Geology and Geol. Mapping, Portugal, rita.caldeira@lneg.pt (* presenting author)
[2]CeGul – Geology Center, Faculty of Science,Lisbon University, Portugal.
[3]Geoscience Center, Coimbra University, Portugal

The Beja Igneous Complex (Portugal), located at the SW margin of the Ossa-Morena-Zone (OMZ) in the SW Iberian Variscides, comprises three main units: the LGS - Beja Layered Gabbroic Sequence (gabbros and anorthosites), the CAC - Cuba-Alvito Complex (gabros, diorites and quartzodiorites) and the BPC - Baleizão Porphyry Complex (rhyolites, dacites and granophyries). This Carboniferous Complex has been attributed to a volcanic continental arc related to the closure of a back-arc basin. We studied mafic to felsic outcrops occuring at the Torrão - Alvito – Alcáçovas regions, that have been included by some authors in the CAC and in the BPC.

From the geochemical and mineralogical points of view the studied rocks are sub-alkaline ranging from tholeiitic (Torrão) to calc-alkaline (Alvito - Alcáçovas). The most relevant geochemical features (e.g. TiO2 < 1.9 %, Nb/Y < 0.31, La/Nb > 2, LILE/HFSE enrichment patterns and Nb, Ta, Ti, P negative anomalies) are distinctive of orogenic signature, typical of a subduction zone related continental arc. Beside the tholeitic character of Torrão samples, evidenced by trace element ratios and clionopyroxene composition disciminative plots, they show some other distinctive features i.e. they don't fall in the same liquid line of descend as the others and their normalized REE patterns show lower LREE/MREE than MREE/HREE [$(La/Sm)_N$ = 1.36 and $(Sm/Yb)_N$ = 2.31) while the Alvito – Alcaçovas samples have $(La/Sm)_N$ = 2.41 and 3.39 $(Sm/Yb)_N$ = 1.80 and 1.47. The Alvito – Alcaçovas observed compositional variations are consistent with fractional crystallization + crustal contamination/assimilation evolution from intermediate magmas to the acid magmas that originated the dacites and rhyolites. The integration of these results with other already published for the units of the Beja Massif, geographic information and known stratigraphic/geochronologic information suggest that the Torrão gabbros cannot be included in the same geodynamic stage as those of the CAC. Instead, given their geochemical afinity, they are closer to a earlier stage attributed to Beja Layered Gabbroic Sequence. The Alvito gabbrodiorites and Alcaçovas porphyries are respectively associated with the CAC and the BPC, resulting from a latter period of the Ossa-Morena southwest margin evolution related to a subduction zone linked to the closure of an open basin (South-Portuguese Zone)

Abstract

Stable isotope signatures of Zn have shown great promise in elucidating changes in uptake and translocation mechanisms of this metal in plants during environmental changes [1] [2]. Here this potential was tested by investigating the effect of high Zn concentrations on the isotopic fractionation patterns of *Phragmites australis* (Cav.) Trin. ex Steud [3]. Plants were grown for 40 d in a nutritive solution containing 3.2 mM (sufficient) or 2 mM (toxic) Zn. The Zn isotopic composition of roots, rhizomes, shoots, and leaves was analysed. Stems and leaves were sampled at different heights to evaluate the effect of long-distance transport on Zn fractionation. During Zn sufficiency, roots, rhizomes, and shoots were isotopically heavy ($\delta^{66}Zn_{JMCLyon}$ = 0.2‰) while the youngest leaves were isotopically light (–0.5‰). During Zn excess, roots were still isotopically heavier ($\delta^{66}Zn$ = 0.5‰) and the rest of the plant was isotopically light (up to –0.5‰).

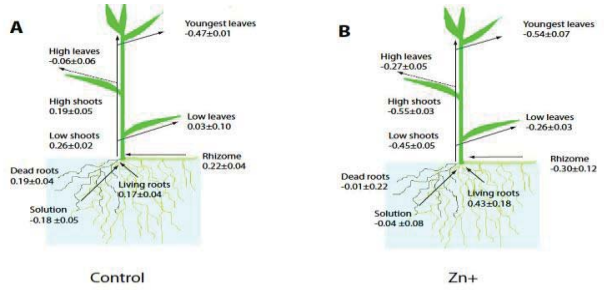

Figure: Isotopic signature of the studied plant sections compared to solutions.

Conclusion

The enrichment of heavy isotopes at the roots was attributed to Zn uptake mediated by transporter proteins under Zn-sufficient conditions and to chelation and compartmentation in Zn excess. The isotopically lighter Zn in shoots and leaves is consistent with long-distance root to shoot transport. The tolerance response of *P. australis* increased the range of Zn fractionation within the plant and with respect to the environment

Interaction of Pb with calcite (104) surface in the presence of EDTA

E. CALLAGON[1*], S.S. LEE[2], P. FENTER[2], K.L. NAGY[1] AND N.C. STURCHIO[1]

[1]University of Illinois at Chicago, Earth and Environmental Sciences, Chicago, Illinois 60607, ecalla4@uic.edu (* presenting author); klnagy@uic.edu; sturchio@uic.edu

[2]Argonne National Laboratory, Chemical Sciences and Engineering, Argonne, Illinois 60439 fenter@anl.gov; sslee@anl.gov

The incorporation of metals in calcite is important for understanding many geological and environmental processes but is still incompletely understood. Calcite (104) cleavage surfaces were reacted with Pb-EDTA aqueous solution (0.09 mM Pb, 0.11 mM EDTA, 0.5 mM Ca, pH 8.35) at room temperature for times ranging from minutes to hours. Freshly cleaved calcite was placed in a flow-through cell, and reacted first with calcite-saturated solution and then Pb-EDTA solution, both at 0.3 mL/min. In situ synchrotron XR measurements revealed evidence for incorporation of Pb into the calcite lattice as well as the formation of cerrusite ($PbCO_3$) with its (021) plane oriented parallel to calcite (104). The reacted calcite was further studied ex situ by atomic force microscopy (AFM) and optical microscopy. AFM imaging of the reacted surface outside the X-ray beam footprint showed narrow overgrowths atop steps and sparse precipitates on terraces (Fig. 1a). Different behavior was seen within the X-ray beam footprint; it contained abundant trapezoidal-and hexagonal-shaped precipitates oriented mainly along a single crystallographic direction, which is consistent with heteroepitaxial cerussite (021) overgrowths (Figs. 1b and 2). X-ray microfluorescence spectroscopy showed that the trapezoidal growth islands are Pb-rich. Features similar to those in Fig. 1a were observed by AFM in separate ex situ experiments without exposure to X-rays. These observations suggest that the X-ray beam enhanced precipitation even at bulk-undersaturated conditions with respect to cerussite (log SI = -2.3), possibly by photolytic destabilization of the Pb-$EDTA^{2-}$ solution complex.

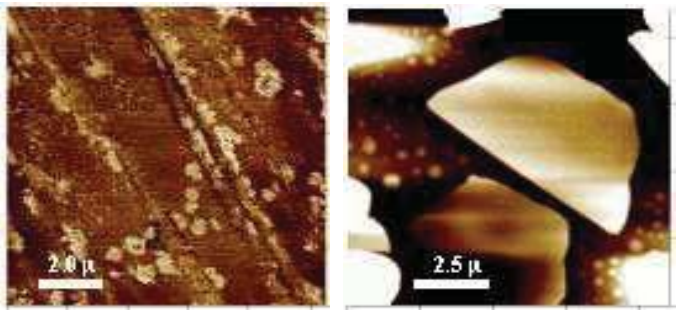

Figure 1: AFM images of the reacted calcite surface. (a) phase contrast image outside the X-ray beam footprint; (b) height image of an area within the X-ray beam footprint (*z*-scale: 100 nm).

Figure 2: The reacted calcite surface imaged within the X-ray beam footprint, observed under reflected light microscopy. Cerussite occurs as trapezoidal precipitates showing euhedral (021) growth face.

Understanding the mechanisms that govern the mobility of elements in rocks and minerals is critical to unravelling the tectonothermal evolution of orogenic belts. The redistribution by diffusion of elements in a system is considered to be extremely sluggish under dry, static conditions, such that reequilibration will not take place even though temperatures far exceed commonly assumed closure temperatures over long periods of time. Here we consider the general question of what physicochemical factors (such as dry vs wet and deformed vs undeformed) control mobility of isotopes in a system (i.e., rock-scale, mineral-scale).

In the Musgrave Block, central Australia the Nulchara charnockite outcrops as a low angle sheet over the Michell Nob Granite. Mutally intrusive relationships and indistinguishable U/Pb ages on zircon of ~1070 Ma in both rock-types indicates that the two magmas crystallized at the same time. Consequently, both rock types have experienced exactly the same thermal and deformational events. The region was subsequently deformed at upper-greenschist to amphibolite facies conditions during the Petermann Orogeny (~550 Ma). The Michell Nob granite is foliated and shows recrystallization/neocrystallization/mylonitic textures. The charnockite does not have a foliation, but exhibits recrystallization/neocrystallization textures that may have formed during cooling.

In the Michell Nob granite, zircon and titanite did not respond to deformation and metamorphism, and the U/Pb analyses yield the emplacement age. ^{147}Sm/^{143}Nd ratios on metamorphic garnet and whole rock suggest that this isotopic system did not equilibrate under these conditions. The apparent ^{40}Ar/^{39}Ar ages of hornblende and biotite are older than the emplacement age, suggesting the presence of excess Ar. This excess Ar is attributed to a relatively high partial pressure of Ar owing to release of radiogenic Ar during recrystallisation of K-feldspar. The Rb/Sr system is partially equilibrated, with the outcome on the age dependent on the biotite. In the charnockite, magmatic amphibole gives a ^{40}Ar/^{39}Ar age that is similar to the U/Pb zircon age and records the age of crystallization. Biotite and K-feldspar give ages that are considerably younger but older than the age of the Petermann Orogeny.

The isotopic results suggest that high-strain deformation at upper-greenschist to amphibolite facies conditions will not necessarily equilibrate the different isotopic systems to give a consistent age. In addition, we show that Ar is mobile in rocks that are relatively dry and undeformed, which has implications for diffusion rates and for determining the duration of thermal events.

Lu-Hf isotope study of mafic and ultra mafic plutonic rocks, Grenville province

Erwan Cambrai[1,2*], Marc Constantin[2] and Christophe Hémond[1]

[1] Laboratoire Domaines Océaniques, UMR6538 UBO-CNRS, Université de Brest, Brest, France.
erwan.cambrai@univ-brest.fr (* presenting author)
[2] Dept. Géologie et Génie Géologique, Université Laval, Québec, QC, Canada

Proterozoic anorthosite suites are common features occurring along the Grenville Province. Still debated, the genesis of these suites is commonly assumed to be linked to lithospheric delamination [1] during or post to collisional and contractional orogenies. A new possible origin that has been proposed is the recycling of juvenile crust [2] in the long-lasting Laurentian convergent margin during the Mesoproterozoic. This crust could be buried into the mantle and/or lower crust, due to subduction processes and later recycled into partial melts that generates AMCG magmatism.

In order to test these hypotheses and to study the magma sources, we determined Lu-Hf, Sm-Nd isotopic ratios, coupled with trace element contents from six sites of anorthosites suites and mafic-ultramafic plutons from the Grenville Province of Québec that range from 1.45 to 1.069 Ga. We also look at plutonic mafic to ultra mafic rocks as possible candidates to represent juvenile crust.

Following the method described by Blichert-Toft [3] we obtained Hf and Lu concentrations using isotope dilution on MC-ICP-MS and TIMS; they range from 0.037 to 14.56 ppm and from 0.003 to 0.989 ppm respectively. We also measured ^{176}Hf/^{177}Hf ratios ranging from 0.282123 to 0.282936, displaying various trends from apparently mantle derived material, to possible crustal contamination with less radiogenic materials. Anorthosite ^{176}Hf/^{177}Hf ratios range from 0.282373 to 0.282490. For these samples, εHf(t) values are between +9.77 and +1.48, what shows possible crustal contamination for anorthosite genesis. Plutonic mafic and ultramafic rocks ^{176}Hf/^{177}Hf ratios range from 0.282123 to 0.282942 and present εHf(t) values between +10.21 and +2.76. They display different trends for each sites, from mantle derived material to possible mixing with crustal-like source. Model ages were calculated for each samples. Except for one case, anorthosites model ages tend to be older than known crystallisation ages by nearly four hundred million years. For plutonic mafic to ultramafic rocks, some samples present juvenile crust characteristic with calculated model ages close to crystallisation age by nearly one or two hundred million years. These results could be explained by incorporation of a less radiogenic component such as melting of the inferior crust by hot asthenosphere in the case of lithospheric delamination, or burying of juvenile crust in a subduction-like environment.

Clumped isotope calibration using modern brachiopods: Implications for reconstructions of temperature and the oxygen isotopic composition of seawater

ROSEMARIE E. CAME[1*], ALEXANDER M. BEACH[1], UWE BRAND[2], AND HAGIT P. AFFEK[3]

[1]Department of Earth Sciences, The University of New Hampshire, Durham, New Hampshire, 03824-3589 U.S.A., Rosemarie.Came@unh.edu (* presenting author)
[2]Department of Earth Sciences, Brock University, St. Catharines, Ontario L2S 3A1 Canada, uwe.brand@brocku.ca
[3]Department of Geology and Geophysics, Yale University, New Haven, Connecticut 06520-8109 U.S.A., hagit.affek@yale.edu

Reconstructions using the isotopic compositions ($^{87}Sr/^{86}Sr$, $\delta^{13}C$, $\delta^{18}O$) of fossil brachiopods have provided fundamental insights into the evolution of the Earth's seawater over the course of the Phanerozoic (e.g. Veizer *et al*. [1]). However, the interpretation of oxygen isotopic reconstructions is complicated by the fact that the $\delta^{18}O$ of carbonate is a function of both temperature and the oxygen isotopic composition of the water ($\delta^{18}O_{sw}$) in which the carbonate grew. The carbonate clumped isotope (Δ_{47}) paleothermometer, which is based on the temperature-dependent ordering of ^{13}C and ^{18}O atoms into bonds with each other in the carbonate mineral lattice, provides a means to isolate the temperature and $\delta^{18}O_{sw}$ signals because Δ_{47} is independent of the isotopic composition of the water in which the carbonate grew [2].

Our clumped isotope calibration is based on 7 specimens of modern brachiopods spanning a temperature range of 1-29°C. Sample locations and depths were carefully selected in order to minimize the effects of seasonal temperature variability. Three replicate analyses were preformed for each sample. Our results indicate that brachiopod carbonate shows a relationship of Δ_{47} to temperature that is similar to the previously published inorganic calcite relationship [2]. However, the new brachiopod calibration does yield different temperatures at the extremes of the calibration temperature range, and may be more consistent with the inorganic calcite relationship of Zaarur *et al.* [3].

In addition, the results of our ongoing investigation into the isotopic heterogeneities within single brachiopod shells (primary versus secondary calcite layers) will be presented and discussed.

WHAT DETRITAL ZIRCONS TELL US ABOUT GROWTH OF THE CONTINENTAL CRUST

IAN CAMPBELL[1*], JAMES GILL[2], TSUYOSHI IIZUKA[3] and CHALOTTE ALLEN[4]

[1]The Australian National University, Canberra, Australia, Ian.Campbell@anu.edu.au (* presenting author)
[2]University of California, Santa Cruz, USA, gillord@ucsc.edu
[3]University of Tokyo, Tokyo, Japan, iizuka@eps.s.u-tokyo.ac.jp
[4]The Australian National University, Canberra, Australia, Charlotte.Allen@anu.edu.au

Zircons provide the only evidence for Earth having a crust older than 4.0 Ga but how extensive was that crust? If it was not extensive when did the continental crust start to form, what was its rate of growth, was growth continuous or episodic and what was time interval between formation of primitive continental crust and remelting of that primitive crust to form stable, cratonic crust? To answer these questions we have analyzed 1500 detrital zircons from the World's major rivers for Lu-Hf, U-Th-Pb and O isotopes. The Lu-Hf system gives a model age for the time at which continental crust that melted to form the granitic magma from which the zircon crystallized separated from the mantle, the U-Th-Pb system dates the crustal melting event and O isotopes can be used to determine whether the crustal source region included a significant sedimentary component. Continents that have been covered include Europe, Russia, North America, Africa and Australia. If we confine our discussion to 500 zircons with mantle-like O isotopic values (between 4.25 and 6.25) to eliminate zircons that cystallized from a hybrid source (e.g. zircons from S-type granites) the maximum model age observed is 4150 Ma and there is little evidence of growth of the continental crust starting before 4.0 Ga. This conclusion is in agreement with Nd model ages for Earth's oldest sediments, and with observation that there in no known preserved continental crust older than that age. However six of the eight model ages that exceed 4.0 Ga have been extrapolated over two billion years from their U/Pb age and uncertainty in the Lu/Hf ratio used in the calculations make the reliability of these ages questionable. We conclude that there is no unambiguous evidence in our data for growth of the continental crust prior to 4.0 Ga and that significant growth of the continental crust was delayed until 3.5 Ga. Distinct peaks can be recognized in the Hf model age histogram at 400-1100 Ma, 1600-2500 Ma and 3000-3500 Ma but we caution against interpreting this as proof of episodic growth because the peaks differ between continents and because we have yet to analyze zircons from South America, SE Asia and Antarctica for Hf and O isotopes. The U-Pb ages how five distinct peaks that correspond to the five known supercontinent-forming events suggesting that continent-continent collisions are periods of enhanced crustal melting. The time difference between the formation of primitive continental crust, as recorded by the Hf model ages, and remelting of that crust to form cratonic crust, as recorded by the U-Pb age, varies between 0 and 3.8 Gyr and averages 780 Myr.]

Kinetic modeling of microbial Fe(II) oxidation, Fe(III) hydrolysis, and As(III) oxidation in acid waters

KATE M. CAMPBELL [1,*], MICHAEL B. HAY[2], AND D. KIRK NORDSTROM[3]

[1]U.S. Geological Survey, Boulder, CO, USA, kcampbell@usgs.gov (* presenting author)
[2]ARCADIS U.S., Inc., Highlands Ranch, CO, USA, Michael.Hay@arcadis-us.com
[3]U.S. Geological Survey, Boulder, CO, USA., dkn@usgs.gov

Abiotic oxidation of Fe(II) in acidic natural water is slow, but acidophillic Fe(II) oxidizing microorganisms, such as *Acidithiobacillus ferrooxidans*, can rapidly oxidize Fe(II). These organisms play an important role in the oxidative dissolution of pyrite and the mobility of many trace elements, including As, realeased from sulfide mineral deposits. The mobility of As depends on the rates of microbial Fe(II) oxidation, abiotic Fe(III) hydrolysis, mineral precipitation, sorption, and photochemical Fe(III) reduction causing As(III) oxidation. Biogeochemical predictions for acidic, Fe(II)-rich natural waters require a coupled biotic-abiotic model that can capture these processes.

A series of batch experiments were conducted at four inital Fe(II) concentrations (10-159 mM) and four inital pH values (1.5-3.0) in the absence of As. A strain of *A. ferrooxidans* isolated from acid rock drainage was used. At least three main reactions can be delineated: microbial Fe(II) oxidation with pH increase, Fe(III) hydrolysis with a pH decrease, and mineral precipitation with pH decrease. Mineral precipitation and Fe(III) hydrolysis were constrained in separate batch experiemnts. Dissolved Fe(II) data were fit with a Monod expression, using parameters optimized by coupling the geochemical modeling code PHREEQC to UCODE, a least squares fitting code. PHREEQC was then used to incorporate microbial Fe(II) oxidation kinetics, Fe(III) hydrolysis kinetics, and mineral precipitation into a simulation of the batch experiments. The Monod expression captures the kinetics of Fe(II) oxidation over the range of pH and inital Fe conentrations. Even in a relatively simple system, the model requires a complex interplay of kinetic and equilibiurm geochemistry.

Rates of abiotic As(III) oxidation were measured as a function of Fe(III) to As molar ratio (0.1-10,000) under a simulated natural light source in the absecence of microorganisms. This reaction is driven by the photoreduction of Fe(III) causing oxidation of As(III) [1 and references therein]. The effect of pH and concentration on reaction rate was also measured. As(III) oxidation proceeds faster at higher Fe(III) concentrations, in an approximately log-linear manner with respect to Fe:As ratio, and is faster at higher pH values.

Microbial Fe(II) oxidation experiments were conducted in the presence of As(III) and light, and the experimental results were modeled using the PHREEQC code. The model was used to evaluate our understanding of coupled biotic/abiotic processes, especially the ability to incorporate kinetic expressions into biogeogeochemical models.

Does Tl/Pb in basalts record low pressure degassing behaviour?

DANTE CANIL [1*]

[1]University of Victoria, Victoria, Canada, dcanil@uvic.ca (* presenting author)

Abstract

Thallium and lead are both incompatible in crystals involved in melting and crystallization of basalts but are fluid-compatible during low pressure degassing of magmas, and occur in considerable concentrations in volcanic aerosols. A compilation of crystalline and glassy basalts (n=628) from mid-ocean riddges (MORs), ocean islands (OIBs), arcs (ARCs) and continental (CONs) settings show sub-parallel but offset arrays of Tl-Pb covariation as a function of eruptive style, irrespective of geologic setting. Specifically, at a given Tl content, all subaqeously erupted basalts, whether from the OIB or ARC settings, glassy or crystalline, contain 5 to 10 times less Pb compared to subaerially equivalents.

Both Tl and Pb have a Kd fluid/melt of between 5 and 10, and Kd Tl/Pb descreases with Cl in the fluid, with Pb preferring Cl-rich fluids. Preferential Pb loss observed in subaqeous rocks could be due to degassing of Cl-rich fluids compared to subaerially erupted magmas, but the variability in Cl in natural basalts is not large enough to affect the change in Tl/Pb observed. Another possibility is that the lower pressure of degassing of subaerial magmas relative to subaqueous examples, leads to lower H_2S/SO_2 in the fluid and causes much higher compatibility of Tl relative to Pb in the fluid, and decreased Tl/Pb in a degassed magma. If fluid-melt partitioning for Tl and Pb can be experimentally calibrated at presures below 2000 bars, the Tl/Pb ratio of basalts could potentially serve as a record of their degassing pressure.

Conclusion

Both Tl and Pb are geochemically similar but the ratio of these metals in erupted basalts differs with eruption mode, and is potentially a record of degassing pressure and fluid composition.

Psychrophiles at the Seafloor: Temperature Response of the Microbial N Cycle in Arctic Fjord Sediments

ANDY CANION[1*], JOEL E. KOSTKA[2], AND PATRICK CHANTON[2]

[1]Earth,Ocean, and Atmos. Science Dept., Florida State University, Tallahassee, FL, acanion@fsu.edu (* presenting author)
[2]Department of Biology, Georgia Institute of Technology, Atlanta, GA, joel.kostka@biology.gatech.edu

The response of the microbial N cycle in polar environments to climate change will depend on the metabolic potential of microbial communities. This research addresses the temperature response of nitrate/nitrite respiration activity and the coupling of the C and N cycles in Arctic fjord (Svalbard) sediments at two sites, Kongsfjorden and Smeerenbergfjorden, with contrasting organic carbon contents of 0.3% and 1.45%, respectively. Rates of denitrification and anammox were determined in anaerobic slurries from -1°C to 40°C with and without the addition of organic carbon substrates. Kongsfjorden sediments showed a lower temperature optimum for anammox (10-20°C) than denitrification (25°C). Smeerenbergfjorden showed similar potential rates of denitrification across a temperature range from 5°C to 30°C, and anammox rates were highest at 26°C. A long term (weeks) temperature shift experiment was performed with Kongsfjorden sediment at 4°C and 25°C to determine structure-function relationships of the microbial communities. Sediments maintained at 4°C exhibited decreased rates of denitrification and increased anammox rates. Sediments exposed to warming (25°C) showed a shift in the optimal denitrification rate to 35°C, a loss of anammox activity, and a change in microbial community composition. Cold sediments amended with carbon substrates maintained the same temperature optima for NO_3^- respiration but showed a pronounced increase in microbial community diversity. Our results indicate a tight interaction between temperature and organic carbon in controlling rates of microbial N cycling that is linked to shifts in microbial community structure in permanently cold environments.

^{17}O anomaly of tropospheric CO_2 fluxes from soil, leaf and ocean

XIAOBIN CAO[1*], YUN LIU[1]

[1]STATE KEY LABORATORY OF ORE DEPOSIT GEOCHEMISTRY, INSTITUTE OF GEOCHEMISTRY, CHINESE ACADEMY OF SCIENCES, GUIYANG, CHINA, LIUYUN@VIP.GYIG.AC.CN (* presenting author)

^{17}O anomaly, a new potential tracer, may supply additional information about the sources and sinks of CO_2. Previous works focused on troposphere-stratosphere CO_2 exchange, which were resulted from the limited understanding of ^{17}O anomaly mechanisms and the lack of precise analytical methods. Recently, a new analytical technique can precisely determine $\Delta^{17}O$ of CO_2,[1] which may change the scenario of this field. It has been expected for a long time that the study of ^{17}O anomaly of CO_2 can be just like those of small ^{17}O anomaly of meteoric waters.(eg, [2]) In this work, we will present theoretical estimates of $\Delta^{17}O$ of CO_2 fluxes from soil, leaf and ocean.

To estimate $\Delta^{17}O$ of CO_2 fluxes from soil and leaf, previous models are used.([3], [4]) Equilibrium theta value (i.e., $\ln^{17}\alpha/\ln^{18}\alpha$) for CO_2-H_2O exchange is taken from [5]. Kinetic theta value for the CO_2 diffusion process is calculated from kinetic theory of gases.(e.g., [6]) CO_2 flux from ocean is assumed to be in equilibrium. The results show that $\Delta^{17}O$ of CO_2 fluxes from different sources are different and the differences are on the order of 0.1 per mil, in the scope that recent techniques can precisely distinguish. Using $\Delta^{17}O$ of tropospheric CO_2, a lot of information could be obtained. The ^{17}O anomalies are temperature and other properties dependent, which could be used to refine or re-check previous models, providing new chance to build more reasonable CO_2 flux models.

Ionization of H_2O – saturated CO_2 at PT conditions relevant to CCS

RYAN M. CAPOBIANCO[1*], MIROSLAW S. GRUSZKIEWICZ[2], ROBERT J. BODNAR[1], J. DONALD RIMSTIDT[1]

[1]Department of Geosciences, Virginia Tech, Blacksburg, USA, rcapobi@vt.edu (* presenting author)

[2]Oak Ridge National Laboratory, Oak Ridge, USA, gruszkiewicz@ornl.gov

Recent studies have shown that mineral carbonation reactions proceed rapidly in the presence of CO_2 – rich ("supercritical") H_2O – CO_2 fluids at temperatures and pressures relevant to Carbon Capture and Storage (CCS) [1][2]. These earlier studies suggest that reactions are occurring on the mineral surface (or in a thin film of aqueous fluid), rather than as dissolution – precipitation mediated by the bulk fluid, as is the case in aqueous geochemistry. This has important implications for CCS in saline aquifers, as the CO_2 – rich phase is positively buoyant with respect to existing brine and will be the fluid in contact with cap rock. Reactions between the CO_2 – rich phase and the cap rock can enhance storage security (if carbonate minerals form) or degrade security (if the fluid corrodes the cap rock). It is well known that in aqueous solutions, H_2O and CO_2 react to form H_2CO_3 which ionizes and promotes dissolution – precipitation reactions. If significant ionization occurs in CO_2 – rich fluids under geologically relevant conditions, understanding reactions between H_2O – saturated CO_2 and mineral phases present in the aquifer will be important when assessing risk associated with CCS.

When ionization occurs in a fluid, such as due to dissociation of H_2CO_3, it allows the fluid to conduct electricity. The conductivity of the fluid is related to the concentration of ions, their charge, solvation, and the physical properties of the fluid. In this study we measure the conductivity of H_2O – saturated CO_2 solutions from 25 to 200°C and 7.39 to 20 MPa using a flow-through conductivity cell. Flow conductivity experiments reduce error associated with sorption to the walls of the cell and accumulation of impurities. Combined with a low cell constant (0.03/cm) we are able to detect conductivity on the order of pS to nS/cm.

In this study we show that conductivity of H_2O – saturated CO_2 does not exceed 3nS/cm from 25-200°C and 7.39 to 20MPa. These conductivity values are comparable to "dry" CO_2 (< 3ppmw H_2O), and indicate that little or no ionization is occurring. In addition, we show that there is no detectable relationship between H_2O content and conductivity from < 1ppmw H_2O to saturation. We conclude that at these conditions "wet" CO_2 has no significant ability to ionize.

Seasonal and inter-annual variations in emerging groundwater mine pollution: Essential background information for acid mine drainage management and remediation

MANUEL A. CARABALLO[1,2*], FRANCISCO MACÍAS[2], JOSÉ MIGUEL NIETO[2], CARLOS AYORA[3] AND MICHAEL F. HOCHELLA, JR.[1]

[2] Geology Department, University of Huelva, Campus "El Carmen", E-21071 Huelva, Spain.

[3] Institute of Environmental Assessment and Water Research, CSIC, Jordi Girona 18, E-08034 Barcelona, Spain.

Design and development of water resources management and restoration strategies requires a deep understanding not only of the specific characteristic of the pollution affecting the water environment but specially of the possible short and long term cycles affecting the intensity of the pollution. The acid mine drainage (AMD) emerging from the adit of Mina Esperanza (Iberian Pyrite Belt, SW Spain) was selected as a typical AMD groundwater effluent from a sulfide mining district influenced by a dry (Mediterranean) climate. This point AMD discharge was monitored for more than four years to reveal the effect of seasonal and inter-annual weather changes in the water flow rate and pollutant concentration. Three well differentiated polluting stages were observed corresponding to: 1) stable low flow rate and high metals concentration, 2) increasing-decreasing cycle of both high to extreme metals concentration and flow rate, and 3) increasing-decreasing cycle of flow rate but steady high metals concentration. The specific processes and mechanism involved in the generation of these three stages (pyrite dissolution, evaporitic salts precipitation-redisolution and pluviometric inter-annual fluctuations) can be understood on the basis of the water chemistry and statistical analyses performed. Despite the almost negligible seasonal variations observed in the AMD pollution, the important variability observed in the inter-annual periods strongly recommends long-period AMD monitoring as essential background information for water resources management. This knowledge is being shown to be critical to efficiently perform environmental impact studies in these specific areas (sulfide mining and dry climates) and subsequently to design efficacious remediation strategies.

Urban soil-dust interactions: improving urban risk models

RAQUEL CARDOSO[1*], KEVIN TAYLOR[2], JIANQUAN CHENG[1], AND NEIL BREWARD[3]

[1]Manchester Metropolitan University, School of Science and the Environment, raquel.cardoso@stu.mmu.ac.uk (* presenting author), j.cheng@mmu.ac.uk

[2]University of Manchester, School of Earth, Atmospheric and Environmental Sciences, kevin.taylor@manchester.ac.uk

[3]British Geological Survey, nbr@bgs.ac.uk.

Introduction

Road deposited sediments (RDS) carry a high loading of potentially harmful elements (PHE). Another environmental media that is a likely source of PHE in urban areas is soil. PHE present in these media may cause deleterious human health effects due to close proximity to the receptors; furthermore, urban agglomerations tend to grow exponentially and so does the importance of RDS and soil characterization and monitoring. The aim of this research is to explore the spatial, geochemical and mineralogical linkages, and produce novel mineralogical data on the PHE/particulate relationships within and between soils and RDS.

Results and Conclusion(s)

Geochemical datasets are composed of 144 RDS and 300 soil samples, collected across 75 Km^2 of Manchester urban centre. PHE maximum and average concentrations, determined by XRF, are generally higher in soils than in RDS. Geographic information systems (GIS) allowed the spatial detection of contamination hotspots for these media, where PHE concentrations (namely for Cr, Ni, Cu, Zn, Pb and Cd) were in excess of the regional 90th percentile. Spatial analysis pointed to localised contamination sources as main influences on RDS composition, which vary considerably over short distances. However, spatial distribution of PHE in soil highlighted four broader areas with systematically high concentrations. Principal component analysis (PCA) has evidenced important PHE associations both for soils and RDS. PCA of grain size data obtained by laser diffractometry revealed that, in RDS, the 63-125µm fraction might act as hosts for PHE. SEM-EDS analysis supported this observation, but the source(s) of these grains still needs further investigation - they have also been observed in soil samples from the same area.

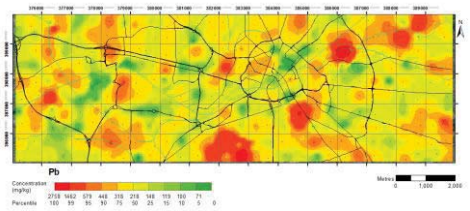

Figure 1: Interpolated surface for lead in Manchester soils.

This detailed geochemical and mineralogical characterization of both soil and RDS, as well as their spatial associations, allow a better understanding of PHE dynamics in urban systems and add vital knowledge on the risks posed to human populations by PHE exposure.

Icelandic zircon: Illuminating juvenile silicic crust construction

[5] Memorial U., Earth Sciences, St. John's, NL, Canada, c.fisher@mun.ca, jhanchar@mun.ca

Iceland's crust (thick, juvenile, silicic and mafic, zircon bearing, with an elevated geothermal gradient) resembles what is visualized for the early (Hadean-Archean) crust, whose physical record exists only in detrital zircon. It is tempting to postulate that Icelandic crust construction is an analogue for early-Earth processes. We explore this hypothesis using trace elements (SHRIMP) and O (SIMS) and Hf (LA-MC-ICPMS) isotopes to characterize zircon from 15 samples (active and ancient volcanoes, intrusions, sandstones, river sands) spanning Iceland's range of ages and tectonic settings.

Our Icelandic "protocontinental" zircons exhibit setting-specific variability, but together share elemental and isotopic characteristics that clarify silicic petrogenesis in this type of environment. They define a narrow range of compositions, overlapping with zircon from ocean islands and, notably, Alid Volcanic Center (continental-oceanic transitional rift, Eritrea); their compositions are largely distinct from continental, MORB, arc, and Hadean zircon (e.g., on plots of U/Yb vs Y, Yb/Nb vs U/Yb). Icelandic zircons are typically ~3x richer (~15 vs 5 ppm) and more variable in Ti than Hadean-Archean zircons, suggesting higher crystallization temperatures. Their range of $\delta^{18}O$ (~0 to +3‰ on-rift, ~+3 to +5‰ off-rift, to -6‰ hydrothermal-like) is very low by global standards, and significantly lower than reported Hadean-Archean values (~4.5-7.5‰). Icelandic zircon ε_{Hf} typically ranges from +10 to +17 (lowest off-rift, highest on), spanning reported values for Icelandic basalt. Extremely low ε_{Hf} of +5 for zircon from Askja 1875 AD pumice (host pumice ε_{Hf} +14) suggests that Icelandic rhyolite might not all be truly juvenile; ancient crust may influence petrogenesis, in discrete locations.

Our data set, while not precluding petrogenetic similarities between Icelandic and early-Earth silicic magmas, demonstrates differences in zircon that call into question a closely similar origin.

Wiring the cell wall: Surface multiheme *c*-type cytochromes from *Thermincola potens* and implications for dissimilatory metal reduction by Gram-positive bacteria

HANS K. CARLSON[1,2], ANTHONY T. IAVARONE[3], AMITA GORUR[7], BOON SIANG YEO[6], ROSALIE TRAN[4,8], RYAN A. MELNYK[1], RICHARD A. MATHIES[4,8], MANFRED AUER[2,7] AND JOHN D. COATES[1,2,5]

Background

Almost nothing is known about the mechanisms of dissimilatory metal reduction by Gram-positive bacteria, although they have been shown to be the dominant species in some environments. Thermincola potens strain JR was isolated from the anode of a microbial fuel cell inoculated with anaerobic digester sludge and operated at 55 °C. Preliminary characterization revealed that T. potens coupled acetate oxidation to the reduction of hydrous ferric oxides (HFO) or an analog of the redox active components of humic substances, anthraquinone-2,6-disulfonate (AQDS). The genome of T. potens was recently sequenced, and the abundance of multiheme c-type cytochromes (MHCs) is unusual for a Gram-positive bacterium.

Results and Conclusions

We present evidence from trypsin shaving LC-MS/MS experiments and surface-enhanced Raman spectroscopy (SERS) that indicates the expression of a number of MHCs during T. potens growth on either HFO or AQDS and that several MHCs are localized to the cell wall or cell surface of T. potens. Furthermore, one of the MHCs can be extracted from cells with low pH or denaturants suggesting a loose association with the cell wall or cell surface. Electron microscopy does not reveal an S-layer, and the precipitation of silver metal on the cell surface is inhibited by cyanide, supporting the involvement of surface-localized redox-active heme proteins in dissimilatory metal reduction. These results are the first direct evidence for cell-wall associated cytochromes and MHC involvement in conducting electrons across the cell envelope of a Gram-positive bacterium.

Early Earth differentiation: Before and after Earth formation

R.W. CARLSON[1*], M. BOYET[2], , M. JACKSON[3], J. O'NEIL[2], L. QIN[4]

An increasingly long list of isotopic differences between Earth and most types of chondritic meteorites is straining the traditional model of a bulk Earth composition that has chondritic abundances of the refractory lithophile elements. Some isotopic differences (e.g. Cr, Mo, Ba) reflect an imperfect mix of the various nucleosynthetic contributions to the Solar nebula. Oxygen isotope differences between Earth and meteorites appear to reflect photochemically induced isotope variation in the nebula with differential sampling of volatile and refractory components by meteorites and terrestrial planets. Both causes of isotope variation point to chemical variability in the Solar nebula that was inherited by the terrestrial planets. The composition of the bulk-silicate-Earth predicted from the difference in $^{142}Nd/^{144}Nd$ between Earth and chondrites is most consistent with the loss of a component produced by low-pressure melting. Compared to chondritic Earth models, the calculated non-chondritic Earth composition has 30-35% lower concentrations of heat producing elements (U, Th, K), eliminating the need for ^{40}Ar retention in the mantle, and implying that incompatible element depleted material is the volumetrically dominant mantle component.

Variability in the relative abundance of daughter products (^{142}Nd, ^{182}W) of short-lived nuclides in Archean/Hadean rocks points to preservation of chemical heterogeneity within Earth's interior that was created by differentiation events occurring prior to 4.3-4.4 Ga. The declining ^{142}Nd variability between 3.8 and 3.5 Ga must reflect mixing within the silicate mantle. While this explanation might also apply to the recent discovery of ^{182}W variability, another option is that the W isotopic variability reflects addition of siderophile elements to Earth's mantle by continued late accretion. The composition of Hadean crust exposed in the Nuvvuagittuq greenstone belt and the inferred composition of the host rocks of the western Australia Hadean zircons point to the beginning of crust forming processes similar to those acting through the Archean within 100-200 Ma of Earth formation.

Kinetics of garnet nucleation: Inferences from natural occurrences

WILLIAM D. CARLSON[1*], ERIC D. KELLY[1], RICHARD A. KETCHAM[1]

[1]Department of Geological Sciences, University of Texas at Austin, Austin, Texas 78712 USA, wcarlson@mail.utexas.edu (* presenting author)

Recent assessments of nucleation and growth of garnet in metamorphic rocks [1-3] invoke divergent controlling mechanisms, and make widely contrasting predictions for nucleation kinetics that are sharply differentiated by the sizes of the thermal intervals over which nucleation is envisioned to extend. Tests of these predictions against chemical and textural features in natural occurrences favor a mechanism in which diffusive impediments to equilibration produce protracted nucleation that extends across a large fraction of the crystallization history.

A set of 371 centered radial concentration profiles on central sections (located by HRXCT) and 468 central compositions for individual garnet crystals in a single sample from the Picuris Range (New Mexico, USA) [4] can be explained only if nucleation of new crystals continued throughout nearly the entire period of garnet crystallization. Mutual consistency among Fe, Mg, and Mn concentrations documents establishment of rock-wide chemical equilibrium for these elements, which allows one to use, for example, Mn content as a proxy for time. A strong correlation exists between crystal size and central Mn content, and central Mn contents in progressively smaller crystals match Mn concentrations in progressively more rimward portions of larger crystals. In these and other rocks, further evidence of protracted nucleation arises when quantitative textural analysis reveals spatial ordering of crystal centers, consistent with suppression of nucleation in diffusionally depleted zones surrounding pre-existing crystals. Such effects have been documented in a suite of 13 garnetiferous pelitic and mafic rocks spanning a wide range of metamorphic conditions.

These chemical and textural observations require that nucleation of garnet is commonly essentially continuous throughout nearly all of its crystallization history: nucleation commonly spans a broad thermal interval (several tens of degrees) and is thus characterized by substantial thermal overstepping and significant departures from chemical equilibrium. The observations are consistent with numerical models of diffusion-controlled nucleation and growth [3] that replicate measured size-composition-isolation correlations, plus spatial ordering and other key textural features; such models require that nucleation intervals span 50-100 °C or more. The observations run strongly counter to the predictions of models that invoke interface-limited precipitation control [2] or reactant-dissolution-limited control [1], for which thermal intervals of nucleation are calculated to be very narrow, ~1 °C or < ~6 °C respectively.

In one exceptional case, chemical data indicate that nucleation was restricted to a short period near the beginning of garnet crystallization [5], but textural measures show that early site-saturation — rather than non-diffusional controls — was responsible.

Biological controls on Mn oxide ore formation in east Tennessee, USA

SARAH K. CARMICHAEL*, CRYSTAL G. WILSON, MICHAEL RASH, AND JOSHUA FEIERSTEIN

Appalachian State University, Boone, NC, USA, carmichaelsk@appstate.edu (* presenting author)

Field Relationships

Mn oxide ore deposits are commonly found as discrete and disseminated deposits below the middle Ordovician unconformity throughout the Valley and Ridge from GA to VA. Deposits in the Cambrian Erwin, Shady, and Rome Formations in northeast TN are associated with brecciated jasperoid and residual clays of the Shady dolomite and are exposed in the hanging wall of northeast trending thrust faults juxtaposed atop Erwin Formation quartzites. Ore formation postdates jasperoid replacement and occurs primarily as matrix material in jasperoid breccias and as vug infillings with minor occurrences along faults and bedding planes.

Mineralogy and Crystal Morphology

Mn oxides in these ores exhibit a variety of morphologies: loose pellets enclosed in geodes, botryoidal nodules, dendrites and shrubs, drusy coatings on geode interiors, and massive porous and laminated ore with interbedded laminae of Mn oxides and Fe oxyhydroxides. X-ray diffraction (XRD), and scanning and transmission electron microscopy (SEM, TEM) indicate that the shrubs, pellets, and laminae are composed of columnar crystals of a cryptomelane-hollandite solid solution, and are associated with filaments of goethite nodules that form a draped net-like structure. Botryoidal nodules are composed of sheets of romanechite exhibiting stromatolitic layering. The dendritic and drusy Mn oxides are composed of nanoscale acicular cryptomelane needles radiating from irregular chains and interconnected clumps of clay spheres. The dendrites and drusy are microporous with imprints of gas bubbles. The shrubs and laminae resemble stalactites with crystals radiating out from nucleation sites in increasing sizes, and are partially encased by ropes of gravity-draped goethite filaments. Nucleation sites consist of irregular sheets, encrusted ropes, and networked filament structures. TEM and XRD analysis indicate that individual Mn and Fe oxide crystals around the nucleation sites are highly ordered, yet on the μm scale they exhibit unusual morphologies commonly associated with biological mineralization [1,2,3]. Fluid inclusion observations in the jasperoid matrix indicate fluid temperatures < 120°C for the region, which does not rule out biological associations.

Conclusions and Continuing Work

Due to the scale and shape of of the nucleation sites, it is likely that small Mn oxide crystals nucleated on negatively charged biological particles (such as extracellular polymeric substances), allowing for abiotic crystal growth, and were not deposited directly on cell surfaces as primary, poorly crystalline biominerals. $^{40}Ar/^{39}Ar$ dating of cryptomelane will constrain the timing of ore emplacement and allow paleoreconstruction of regional sources of ore fluids.

The lithospheric mantle is characterized by pressure ranges from ~ 2.0 and ~ 7.7 GPa and a specific mineralogy and composition. This region can be re-hydrated and re-enriched in incompatible elements (*e.g.* potassium) through subduction processes that bring pelagic material, composed of clay minerals and other phyllosilicates, together with the hydrated subducted oceanic slab. A mass transfer from the subducted slab plus sediments into the mantle wedge occurs primarily through the release of aqueous fluids produced by devolatilization of hydrated minerals. In this context, smectite stands out as one of the most important minerals responsible for re-enriching the lithospheric mantle with water and incompatible elements when its structure is destabilized. By pressure and temperature increasing smectite can lose its interlayer water, at the same time that it transforms into a mixed-layer Illite-Smectite, followed by illite crystallization. In this condition of dehydration, and with increasing burial, reactions evolve in transforming illite to phengite, a variety of muscovite which plays an important role as host of potassium in subducted oceanic crust. In this work, we verified the structural and compositional behavior of K saturated smectite under pressure from 2.5 to 4.0 GPa and at different temperatures (400ºC to 700ºC). . X-ray diffraction, scanning electron microscopy (SEM), infrared spectroscopy (FTIR) and transmission electron microscopy (TEM) results suggest that under the pressure of 2.5GPa, which is about 75km depth in the mantle, and at around 500ºC smectite transforms into phengite, while under the pressure of 4.0GPa, equivalent to 120km depth, the same transformation occurs at 400ºC. These results contribute significantly to understanding how pelagic sediment dehydration occurs in a subduction process, as well as the behavior of smectite under the influence of increasing pressure and temperature.

Structural evolution of the retrowedge, SE Canadian Cordillera

SHARON D. CARR[1*] & PHILIP S. SIMONY[2]

[1]Carleton University, Ottawa Carleton Geoscience Centre, Department of Earth Sciences, scarr@earthsci.carleton.ca
[2] University of Calgary Department of Geoscience, pssimony@ucalgary.ca

In the southern Canadian segment of the Cordilleran orogen, a Middle Jurassic "small cold accretionary orogen [1]" evolved into a doubly vergent, "warm medium-sized orogen [1]" during Cretaceous to Eocene oblique convergence. In some orogens (e.g. Appalachians, Caledonides, Himalaya) a megathrust sheet or crystalline sheet with basal shear zone overrode the foreland obscuring the relationships between coeval Internal and External structures. However, in the ~400 km wide, east-verging, retrowedge of the southern Canadian Cordillera, the Internal zone is situated to the rear of the External zone preserving evidence of structural and kinematic linkages. The External Rocky Mountains and Foothills comprise three major east-verging, Late Cretaceous to Eocene, thin-skinned, piggyback thrust and fold systems, with ~180 km of shortening, that root westward into a basal décollement. The Western Internal zone is characterized by tracts of metamorphic rocks and metamorphic core complexes (e.g. Kettle, Okanagan, Priest River and Valhalla), some of which are basement-cored domes (e.g. Frenchman Cap, Thor-Odin, and Spokane). They have a downward-younging progression of Late Cretaceous to Eocene metamorphism and deformation in infrastructural flow zones characterized by transposition foliation, migmatites, flow folds and 1-7 km thick shear zones. Nested between the External and Western Internal zones is a relict ~100-200 km wide Early Cretaceous orogen, that predated emplacement of ca. 100 Ma plutons. The geology and architecture of the Western Internal and External zones can be explained by progressive development of major Late Cretaceous to Eocene shear zone systems in the Internal zone that can be directly linked with coeval thrust and fold systems in the External zone. The linkage was via Late Cretaceous activation and Late Cretaceous to Early Eocene reactivation of the 150-200 km-wide central portion of the Rocky Mountain basal décollement that lies beneath and translated the intervening Early Cretaceous orogen. During orogenesis, the craton was progressively underthrusting the developing retrowedge. Thickening in the retrowedge insulated the underlying rocks of the incipient Internal zone, thus resulting in a mechanism of progressive heating, weakening and localization of the basal shear zone. At the base of the wedge, cooler stiffer rocks lay to the east of the Internal zone, at each stage, acting as an indentor. Thus, the development of a basal shear zone was coupled with flow of the hot mass of the Internal zone up and over an indentor, strain softening of it, and incorporation of it into the wedge in successive stages. Our general model is consistent with those of Beaumont et al. (2010) demonstrating the lateral transition from stiff cool crust to hotter weaker crust where the stiff cool crust acted as an indentor, with development of a ramp at the edge of the indentor, and flow up and over the ramp. In the latest stages of Early Eocene shortening, extensional shear zone systems were localized on the margins of tectonothermal culminations. Motion of deep-seated décollements beneath some of these culminations may have contributed to their doming. Crustal shortening ended at ca. 52 Ma due to a change in tectonic setting to that of a transtensional tectonic regime, coinciding with the end of thrusting in the External thrust belt and with crustal-scale extension in the Western Internal zone.

Geochemical evidence for complex preeruption configuration of a silicic magma chamber associated with Los Humeros caldera, Mexico

GERARDO CARRASCO-NÚÑEZ [1*], MICHAEL BRANNEY[2], MICHAEL MCCURRY[3], AND MICHAEL NORRY[2]

[1] *Centro de Geociencias, Universidad Nacional Autónoma de México, Querétaro, Mexico.* gerardoc@geociencias.unam.mx

The >15 km^3 late Pleistocene Zaragoza ignimbrite from Los Humeros caldera volcano in central Mexico shows complex (rhyodacite-andesite-rhyodacite) compositional zoning, including mingled and rare mixed pumice (dacite-D). Petrographic and microprobe analyses of coexisting glass and phenocrysts provides evidence of crystal-liquid equilibrium and disequilibrium conditions in multiple types of magmas at the time of eruption. Highly resorbed calcic plagiocase (to An_{82}) mantled by more sodic plagioclase suggests that pre-eruptive mixing between andesitic and plagioclase-bearing basaltic magma was followed by equilibrium crystallization within the resultant hybrid magma. A broad co-genetic relationship between the rhyodacite and basaltic andesite-trachyandesite magmas is indicated by overlapping Nd-, Sr- and Pb-isotopes, major- and trace-element covariation patterns, and the association in space and time. Differences in phenocryst chemistries indicate that the andesite-trachyandesite (A-TA) magma was at least 80˚C hotter than the rhyodacite (RD) magma at the time of the eruption. We propose a model (Fig. 1) where the ignimbrite eruption started tapping rhyodacite and then andesite from a zoned magma chamber. This was followed by a complex syn-eruptive mechanical mixing between a fairly uniform reservoir of rhyodacite, with a pre-eruptive heterogeneous (hybridized) mafic reservoir formed from andesites and andesite-trachyandesites, possibly in the form of semi-connected high-melt lenses within a partially consolidated crystal mush. Episodic replenishment of basaltic magmas occurs periodically.

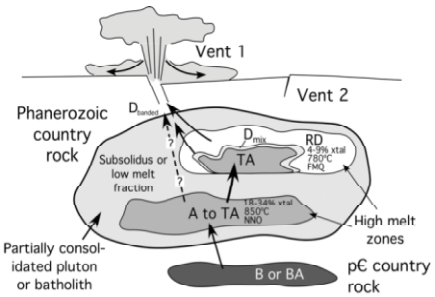

Figure 1: This shows our preferred pre-eruption magma reservoir model for the Zaragoza ignimbrite.

Lead, Cadmium and Copper concentrations and Lead isotopic distribution in seawater, sediments and coral reefs in Kuwait

Objective and Methods

The objective of this study was to reconstruct detailed input chronologies of trace metals in the Kuwaiti marine environment, influenced by the Shatt al-Arab River's load, using water, sediment cores and corals. Pb, Cd and Cu concentrations in seawater and sediments were determined by plasma mass spectrometry using isotope dilution for seawater and Indium internal standardization for "Graney leach" sediment extracts. Pb isotopic distributions in seawater and sediments were determined using multicollector magnetic sector plasma mass spectrometry after anion exchange purification of Pb.

Results and Discussion

Pb, Cd and Cu concentrations in seawater are high in the northern stations, including Kuwait Bay, Awhah and south of Bubiyan Island. They show combined anthropogenic and riverine sources, while waters near two coral reefs near Kubar and Qaruh islands show high Pb, but low Cd and Cu. Surface sediment samples show metal enrichments in Kuwait Bay as expected for elements with anthropogenic enhancements; the 206/207Pb isotope data shows a large range, hinting to a mix of natural and leaded gasoline sources, or other sources, with a negative correlation of 206/207Pb in sediments vs. Pb in seawater and a decreasing trend into Kuwait Bay.

Analyses of the concentration and isotope distribution of Pb in the upper ~60-cm sediment strata and on porite corals are in progress.

General Geology and Mineralization

Sierra Gorda nature reserve is the central part of the East Sierra Madre (Mother Range) of east Mexico. The Sierra Gorda is mostly composed by a highly deformed sequence of Mesozoic Carbonate sedimentary rocks. The Zuluaga Jurrassic formation host various hydrothermal deposits, which include Sn mantos, polymetallic sulfide veins and other irregular bodies [1]. There have been reconigzed some Eocene to Oligocene igneous intrusive bodies (granitoides stocks), crosscuting all the sedimentary sequence and developing mineralized metamorphic halos and hydrothermal veins, mantos, snd skarn bodies (stibine, cinabar, realgar, chalcopyrite, galena, sphalerite, Ag minerals with some Au and As) [2]. Exploitation of these mineralized bodies have left behind millions of tons of mine waste materials scattered in the nature preserve. These waste materials have released to the environemnt (soil and water) heavy metals (Cd, Cr, Co, Cu, Ni, Pb, Hg and Zn), and metalloids (As and Sb).

Environmental Geochemistry

We select three mining zones in the Sierra Gorda nature preserve for chemical analisis on the mine waste material, sediments, soil, water and some plants to assess the mobility, dispersion and geochemical controls of heavy metals and metalloids in the environment. Preliminary results show that mine tailings have up to 7 gr/Kg of As, 1 gr/Kg of Cu, 5 gr/Kg of Zn and 3 gr/Kg of Pb. River sediments concentrations of As and metals (maximum) are as follow: As = 2.5 gr/kg, Cu = 0.146 g/Kg, Zn = 1 g/Kg, and Pb = 0.117 g/Kg. For agricultural soils (small patches of land along river terraces) the As and metals concentrations are: As = 0.117 g/kg, Cu = 0.022 g/kg, Zn = 0.087 g/kg, and Pb = 0.037 g/kg. For surface water (seasonal mountain creeks) the As and metals concentrations are: As = 0.05 mg/l; Cu = 0.01 mg/l; Pb <0.017 mg/l, and Zn = 0.01 mg/l. We are processing different vegetation to determine bioacumulation of As and metals in different parts of the plants and in different zones of the mining area (affected by mine tailings, and no-affected by mine tailings). The ultimate goal is to understand the geochemical controls of As and heavy metals in this environemnet.

Session 9e : from a durable ressource to its environmental impact

The oldest economic uranium deposits on Earth are the quartz pebble conglomerate containing detrical uraninite from the Dominion Group (3074 ± 6 Ma) and the Witwatersrand Supergroup (2970 to 2714 Ma) on the Kaapvaal craton in South Africa. A reducing atmosphere before 2.2 Ga allowed uraninite to be stable on Earth's surface. We investigte the magmatic source of the uraninite; the ubiquitous Archaean TTG suite (trondhjemite-totalite-granodiorite) having uranium concentrations (about 2 ppm) insufficient to permit uraninite cristallization, the only posible source is ca. 3.1 Ga, incompatible elements-enriched, granitic batholiths such as the Mpuluzi and Heerenveen batholiths located to the South of the Barberton Greenstone Belt of South Africa

The Heerenveen and Mpuluzi batholith belong to the 3105 Ma granodiorite-monzogranite-syenogranite GMS suite intruding paleoarchaean TTG plutons. These two batholiths are made of different facies belonging to different phases of emplacement. Early sheeted leucogranites are followed by the intrusion of a large core of porphyritic granite, then by the intrusion of diverse facies in the border shear zones of both batholiths.

Although the average U composition of either batholiths is low (3 and 6 ppm for Heerenveen and Mpuluzi resp.), late phases emplacing in shear zones are significantly richer. However, they show a similar U/Th ratio than the bulk of the intrusions. On the other hand, a few samples show uranium concentrations up to 25 ppm, with Th/U ratios below 1, compatible with uraninite cristallization. Radiometric maps and analysis show that all these samples are located inside the shear zones; however in details the distribution of these spots is independant of lithologies. The size of these high uranium concentration zones is about 100 meters and can be located in later phases of intrusion as well as in earlier phases. This suggests that redistribution of incompatible elements and fractionation of U relative to Th occurred after emplacement of the granitoids and independantly of it.

Microscopic studies confirm that the primary uranium-bearing minerals such as monazite, xenotime and thorite are partially or totally altered, uranium-rich phases being secondary minerals such as brannerite and uraninite. Primary monazite have been altered by calcic fluids, and replaced by apatite and thorite; REE from the monazite form allanite and residual thorite, while uranium is partially incorporated into secondary thorite and partially liberated into the fluid. In ilmenite, uranium is concentrated in altered crystals (up to 6% wt UO_2), showing that ilmenite was altered by uranium-enriched fluids.

Conclusion

Two different processes seem to explain the uranium concentrations: (1) a magmatic process which concentrate uranium and thorium in the later intrusion phases and (2) a second process, calcic fluids associated to the shear-zones which alter primary accessory minerals and preferentially concentrate uranium in small zones independent of the different intrusion lithologies.

Distribution and Speciation of Arsenic in Poultry Particulate Emissions

SHANNON E CARTER[1*], DONALD L SPARKS[2], ANA MARIA RULE[3], RYAN TAPPERO[4] AND ERIC BENSON[5]

[1]University of Delaware, Newark, United States, Shanncar @udel.edu (* presenting author)

The use of organo-arsenicals such as roxarsone in poultry production is quite common. These compounds are primarily used as anticoccidials, as growth promoters, and to increase feed efficiency. Such usage has raised a variety of environmental concerns such as the accumulation of arsenic in poultry excrement and the release of arsenic into air, soil and water resources. Confined animal feeding operations (CAFOs), such as broiler poultry houses, are sources for airborne particulate matter (PM) emissions and have become major environmental and human health concerns. Many growers and their families are the primary operators of these CAFO facilities, and can spend anywhere from 25-45 hours per week working on the farm. Farm workers who average as little as two hours per day inside of a CAFO may develop acute and chronic respiratory diseases associated with the long term exposure to the particulate matter. Studies have indicated that there is a presence of toxic metals and metalloids, such as arsenic found in the poultry litter; however, it is not well known whether the re-suspended PM from these poultry houses carries such toxic contaminants, which could be harmful to human health. This presentation will focus on the chemistry and metal(loid) speciation of airborne emissions of both $PM_{2.5}$ and PM_{10} from confined broiler operations. The samples were analyzed using traditional wet chemistry techniques, such as inductively coupled plasma-mass spectrometry (ICP-MS) to determine total heavy metal and metalloid concentrations. More advanced, state-of-the-art, synchrotron-based spectroscopic and microscopic techniques, such as SEM-EDX were applied to determine arsenic and other metal speciation and distribution, and thus shed light on the potential toxicity. The results of this research suggest that arsenic concentrations vary depending upon location, size fraction, and period of growout cycle. In addition, u-XANES results suggest that the arsenic present in both PM_{10} and $PM_{2.5}$ fractions can be in organic and inorganic forms, and is widely distributed across the filtered samples of the particulate matter.

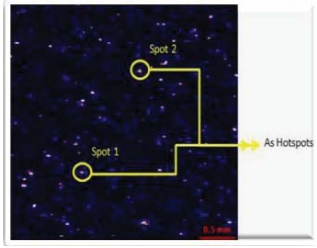

Figure: 3mm x 3mm micro X-ray fluorescence (m-XRF) map of As from a PM10 sample. The bright "hot" spots indicate an area where there is higher intensity of As present.

On overview of the deep carbon cycle and its isotope heterogeneity

Carbon is massively exchanged between the Earth's surface and the deepest part of the mantle so that, on billion years time-scales, is at, or close to, steady state (= amounts and isotope compositions of C being degassed and subducted being balanced). This is best evidenced by constant C-isotope compositions, over nearly 3.5 Gy, in both sediments (typically 20% organic matter, 80% carbonates with δ^{13}C-values of -25 and 0‰ respectively) and mantle-derived samples (MORB, OIB, diamonds, carbonatites, carbonates from kimberlite) averaging $\delta^{13}C \sim -4\pm1$‰. This can also be inferred from the short modern residence time of surface carbon, close to 1.5 Gy. The implication is that modern recycled carbon flux equals degassed carbon flux at about 2×10^{12} mol/y.

Owing to mantle carbon steady-state, it is unlikely that mantle (= *cycled*) and primordial (= *uncycled yet)* carbon would display distinct isotopic, although longer residence time of mantle carbon, ca. 4-6 Gy, suggests that such a primordial C-reservoir might exist. Our best estimate, based upon diamonds having the most primordial (= *lowest*) N-isotope compositions, indicates a primordial C-isotope composition close to -3.5‰. The size of the primordial carbon reservoir remains however elusive.

If subducted carbon has a $\delta^{13}C_{average}$~-4‰, it is originally both chemically and isotopically heterogeneous; so there is some chance that some deep mantle domains would record a subduction-related heterogeneity. Such a heterogeneity cannot however be inferred from mid-ocean ridge or ocean island basalts; the C-isotope variability mostly reflect degassing processes (= lowering residual δ^{13}C). This is best illustrated by relationships with degassing proxies (e.g. $^{40}He/^{40}Ar^{*}$) but not with those tracing mantle volatile heterogeneity (e.g. H_2O/Ce, D/H or δ^{34}S-ratios). So, if any, mid-ocean ridge or ocean-island basalts bear very small C-isotope heterogeneity.

Many authors ascribe low δ^{13}C-diamonds (typically in the range of -15 to -25‰) to mantle carbon isotopic *heterogeneity* related either to subduction or to be primordial. Coupled ^{34,33}S, N and C-isotope systematics suggest however that most relate to high-temperature fractionation, occurring at depths (typically 250-150 km), prior to diamond precipitation.

Yet, several diamond populations (from komatiites in French Guyana and from Jericho kimberlite in Northern Slave with δ^{13}C-modes ~-28 ‰ and -38‰ respectively) are unique and difficult to interpret in the light of heterogeneity being either primordial, subducted or mantle-related (i.e. there are only rare sediments with δ^{13}C as low as -40‰). Together with diamonds from the transition-zone (from 300 to 660 km depth), there is still the possibility that mantle domains with odd C-isotope characteristics indeed exist. If correct, this would have very strong implications when considering sedimentary C-isotope excursions associated with the emplacement of large igneous provinces: their C-budget would not need to be close to the *canonical* mantle δ^{13}C of -4‰.

GEOCHEMICAL AND TEXTURAL CHARACTERIZATION OF FRESH WATER MICROBIALITES OF LAGUNA, BACALAR, MEXICO

SET CASTRO-CONTRERAS[1*], ERNESTO PECOITS[1], NATALIE R. AUBET[1], DANIEL PETRASH[1], MURRAY K. GINGRAS[1], KURT O. KONHAUSER[1]

[1]University of Alberta, Edmonton, Canada, sicastro@ualberta.ca (* presenting author)

Microbialites are amongst the oldest direct evidence of life [1]. Understanding how they are formed and the biosignatures they may disclose is important in understanding the evolution of early life on Earth. Microbialites reached their peak during the Proterozoic (>542 Ma) and drastically declined thereafter. The cause of which has been attributed to either grazing and/or burrowing by metazoans [2], or to changes in ocean chemistry leading to a drop in [CO_3^{2-}] [3]. The recent discovery of rare, freshwater endolithic microbialites in Laguna Bacalar, Mexico offers a unique opportunity to test the interaction between burrowing and grazing organisms, calcium carbonate precipitation, and microbialite growth. The Bacalar microbialites vary from centimetre- to metre-sized structures. The larger of these show two distinct layer types: (a) stromatolitic layers composed of millimetre-thick laminae of cyanobacterial cells encrusted in a low Mg-calcite matrix, and (b) thrombolitic, centimetre-thick layers of rounded micritic peloids, randomly distributed in microsparite cement. In contrast, the smaller microbialites are always laminated with a stromatolitic fabric. We observe that unlike stromatolitic layers, thrombolitic layers occur during a period of higher sediment and contain a lower abundance of biolimiting trace elements (e.g., Mn, Mg, Fe). This suggests that the rapidity of such migration (due to cementation) leads to an increase in binding/trapping and the resulting thrombolitic texture. Additionally, microbialites and sediment have a similar C- and O-isotopic signature, unlike those of associated gastropods and bivalves, suggesting no vital effect and the preservation of an environmental signature. In conclusion, while the rate of microbialite growth is largely a function of CO_3^{2-} ion saturation, the texture is especially dependant on accretion rate. Furthermore, the variability of the trace element concentrations is highly dependant on texture dependant. The very coexistence of these thriving microbialites with grazing and burrowing organisms implies that these do not inhibit growth and, therefore, suggest that the decline in microbialite abundance and diversity during the Phanerozoic was likely due to other factors.

Benthic Oxygen Uptake rates measured on deep-water coral reef by Eddy Covariance (EC)

Deep-water coral reefs are unique biodiversity hotspots that are vulnerable to future environmental changes in response to climate change or fishing activities [1]. Accurately assessing the coral reef community metabolism is needed to ensure a suitable monitoring and management of these areas, but traditional methods are inadequate to map the complex 3D structure of these reefs.

Therefore the non-invasive EC technique has been used to measure in situ benthic respiration rates of a deep-water coral reef ecosystem and surrounding sponge-beds in the Træna Deep (Norway). EC measurements were contrasted with on-board oxygen incubations of living coral and bare sediments.

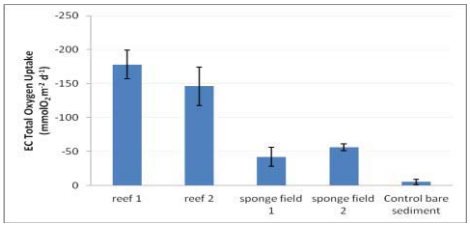

Figure 1: EC Total Oxygen Uptake rates (TOU, $mmolO_2\ m^{-2}\ d^{-1}$) at the Traena Deep site in June 2011.

Deep-water coral reefs: active benthic ecosystems

The Traena deep-water coral reefs have benthic oxygen consumption rates that are comparable to coastal benthic systems (TOU > 50 $mmolO_2\ m^{-2}\ d^{-1}$) and 35 times higher than bare sediments at comparable depth. If such high consumption rates are a common feature, deep water coral reefs are likely to play an important role in regional carbon cycles and need to be accounted for in global carbon budgets.

What caused the 2.4 Ga rise of oxygen?

DAVID C. CATLING[1*], KEVIN J. ZAHNLE[2], MARK W. CLAIRE[3]

[1]University of Washington, Seattle, USA, dcatling@uw.edu (*presenting author)
[2]NASA Ames Research Center, Moffett Field, CA, USA, kevin.j.zahnle@nasa.gov
[3]University of East Anglia, Norwich, UK, M.Claire@uea.ac.uk

The Great Oxidiation Event (GOE) was an increase in O_2 levels from <1 ppm to 0.2-2% at ~2.45-2.22 Ga. How it happened is still debatable. One idea is that the GOE ensued when oxygenic photosynthesis originated [1]. But evidence suggests that oxygenic photosynthesis considerably predates the GOE, e.g., from redox-sensitive metals, stromatolites, organic carbon derived from methanotrophs, and biomarkers [2]. Instead, reductants plausibly cleared the late Archean air of O_2. Most hypotheses explain the delay by suggesting that O_2 sources took time to overwhelm O_2 sinks.

The O_2 source, organic carbon (C_{org}) burial, may have slowly increased to cause the GOE [3]. But the noisy $\delta^{13}C$ record may not allow for such a change [4], while the decomposition of C_{org} in the ~10^8 yr geologic cycle destroys O_2 gains from C_{org} burial. Also, inventories show that continents have excess oxygen, not excess C_{org} [5]. An alternative is that O_2 could have risen if the sink from volcanic reducing gases declined. Many ideas have focused on a shift in mantle or seafloor reductant fluxes [4], including appeals to changes in subaerial vs. submarine gases [6, 7]. But for this idea to work, the surface still has to export net reductant to the mantle, which is itself initially reduced.

Oxidation of *other* planetary or satellite surfaces is universally attributed to the escape of hydrogen. This accounts for Mars' redness and tenuous O_2 atmospheres on Europa, Ganymede, and Rhea. Earth's pre-GOE atmosphere was enriched in CH_4 and H_2 and prone to hydrogen escape at rates that must have produced large irreversible oxidation. If continents grew until ~3-2 Ga, they would have accumulated excess oxygen in minerals. Atmospheric O_2 would have become more stable by application of Le Chatelier's principle to the surface environment of the whole Earth.

Conclusions: Overall, rapid escape of hydrogen to space from the pre-GOE atmosphere should have gradually oxidized the Earth, accompanied by falling atmospheric CH_4 levels. The disappearance of S isotope mass independent fractionation at 2.4 Ga is best explained by the collapse of CH_4 as marine sulfate levels grew and methanotrophy kicked in [8]. The "tipping point" for flooding the atmosphere with O_2 was when the flux of O_2 from the burial of organic carbon exceeded O_2 losses. Glaciations during 2.45-2.22 Ga suggest oscillations in atmospheric composition until a new O_2 balance with oxidative weathering was established.

Reconstructing impact basins from *ex situ* shocked zircon

AARON J. CAVOSIE[1,*], HENRI A. RADOVAN[1], DESMOND E. MOSER[2], IVAN BARKER[2], JOE WOODEN[3], KOUKI KITAJIMA[4], JOHN W. VALLEY[4]

Meteorite impacts have played a critical role in the evolution of Earth and the terrestrial planets. Large impacts cause profound geomorphic changes of the crust, the concentration of economic metals, and have been correlated to climate change and biological extinctions. Despite the importance of impact cratering to a variety of disciplines, the terrestrial impact record is poorly known. On Earth, most impact structures have been removed by erosion or burial; only 180 impact structures have been confirmed, and none from the Archean when impact rates were higher. To locate Earth's missing impact record, and to build a tool for extraterrestrial impact chronology, we present a method to identify evidence of eroded impact craters through the identification of detrital (*ex situ*) shocked minerals.

We describe a detrital shocked zircon collected in modern sediment in the Vaal River basin at the Vredefort Dome in South Africa, one of Earth's largest known impact structures. Detailed isotopic, elemental (U-Th-Pb, $\delta^{18}O$, REE), and microstructural (CL, BSE, EBSD) analysis reveals that the detrital grain comprises a single mineral record of the giant impact basin. Multiple shock microstructures, including planar fractures (PFs) and granular texture, occur in different domains distinguished by CL zoning and U-Pb age, and allow the determination of the age of the source terrain and timing of impact. EBSD analysis documents the presence of shock-induced microtwins in one PF orientation. Oxygen isotopes ($\delta^{18}O$) and trace elements (REE, Th, U, Pb) record the variable response of an evolved granitoid zircon to extreme conditions during and after impact.

Modeling the source of this zircon yields the following impact basin reconstruction. The target rocks were comprised of 3161±71 Ma felsic granitoid; the impact crater thus formed on an Archean craton. U-Pb ages of granules record a Proterozoic impact at 1974±74 Ma. The impact created a >5 km diameter complex crater, as evidenced by the presence of PFs. PFs and microtwins require pressures >20 GPa; granular texture requires higher pressure, ~50 GPa. The two billion year time lag indicated by the presence of a detrital shocked zircon from a ca. 2 Gyr old impact in modern sediments suggests either that the impact structure may have been considerably larger than 5 km and eroded, or that the structure escaped early erosion due to burial and was later exposed. Thus with the exception of original crater size, many significant aspects of the Vredefort impact are accurately recorded in this grain. This method of impact basin reconstruction from single grains is well-suited for studies of lunar impacts, and also for other sample return missions where the quantity of sample is limited.

An early Ediacaran cap carbonate sequence in east central Brazil

FABRÍCIO CAXITO[1*], GALEN P. HALVERSON[2], ROSS STEVENSON[3], ALEXANDRE UHLEIN[1]

[1]UFMG, Belo Horizonte, Brazil, boni@ufmg.br (*presenting author)

[3]UQAM, Sciences de la terre et de l'atmosphère and GEOTOP, Montréal, Canada, stevenson.ross@uqam.ca

Introduction

The Sete Lagoas Formation is a 200 m thick carbonate unit sitting atop glacially-related diamictites (Jequitaí Formation) at the São Francisco craton, east central Brazil. It is currently recognized as a typical Neoproterozoic cap carbonate, and most authors prefer a mid-Cryogenian (post-Sturtian) age for it, based mainly on Pb-Pb data. Recently, however, Ediacaran zircons have been recovered from the middle portion of the Sete Lagoas Formation, constraining the deposition of its upper half to be younger than 610 Ma[1]. These conflicting results underline the need for further research on the assignment of a relative age for the Sete Lagoas cap carbonate.

Materials and Methods

We present lithostratigraphic and C, O and Sr isotopic data from a 127-m section of the Sete Lagoas Formation near Correntina, Bahia. In addition, sixty-five carbonate clasts from four separate diamictite occurences were sampled for C and O isotopic analysis.

Results and Conclusions

A 1.5 m thick layer of pink laminated dolomite marks the base of the Sete Lagoas Formation at Correntina ($\delta^{13}C$: -3.8 to -4.2‰; $\delta^{18}O$: -4.5 to -5.1‰). It is overlain by 55 meters of reddish laminated limestone with $\delta^{13}C$ values of about -5‰, jumping abruptly to around -0.5‰ at the middle of the section and remaining nearly constant upwards. The thin pink dolostone unit at the base of the section, preserving decreasing-upwards $\delta^{13}C$, is nearly identical to basal Ediacaran cap dolostones globally. The $^{87}Sr/^{86}Sr$ values obtained from high Sr carbonates (above 1000 ppm), around 0.7076, are also consistent with deposition during the early Ediacaran. The carbonate clasts display similar ranges of $\delta^{13}C$ (-6.7 to +2.6‰), except for the meter thick Carrancas Formation, which yielded pale dolostone clasts with $\delta^{13}C$ in a small range between -4.2 and -3.4‰, and $\delta^{18}O$ around -6.5‰. These could be derived from the cap dolostone unit itself, in which case the Carrancas Formation would represent resedimented basal Sete Lagoas Formation, implying that cap carbonate sections sitting atop it are incomplete. The base-truncated sections have confused previous attempts to assign a relative age for the Sete Lagoas cap carbonate. The combination of available lithostratigraphic, isotopic and geochronological data strongly supports the interpretation of an early Ediacaran age for the Sete Lagoas Formation. This new interpretation profoundly impacts the current views of Neoproterozoic history and sedimentation within the São Francisco craton.

An absorption method for porewater characterization in low permeability sedimentary rocks

MAGDA CELEJEWSKI[1*], TOM AL[1], IAN CLARK[2], AND JENNIFER MCKELVIE[3]

[1]Earth Sciences, University of New Brunswick, Fredericton, New Brunswick, Canada, m.celejewski@unb.ca, tal@unb.ca (*presenting author)
[2]Earth Sciences, University of Ottawa, Ottawa, Ontario, Canada, idclark@uottawa.ca
[3]Nuclear Waste Management Organization, Toronto, Ontario, Canada, jmckelvie@nwmo.ca

Determination of porewater geochemistry in low-permeability, low-porosity rocks is problematic given small fluid volumes and difficulty associated with extracting representative samples. Several techniques are available including crush and leach, vacuum distillation and forced advective displacement. However, these methods are not always successful and can be subject to error arising from the estimate of matrix porosities. The purpose of this study is to explore a new innovative method for characterization of representative pore fluids in clay rich rocks. The method involves the extraction of pore fluids using absorption into hydrophyllic membranes. From preliminary experiments, scanning electron microscope (SEM) images and energy-dispersive x-ray spectroscopy (EDS) analyses confirm that the method successfully extracts porewater and associated solutes. Absorbed water was determined gravimetrically and the solute masses were quantified by x-ray fluorescence (XRF).

Interim experimental results have been compared with porewater compositions derived using the crush and leach technique. The gravimetric water-content analyses are subject to large errors, which carry through to porewater concentrations. However, when the extracted solute masses for major elements (Na, Mg, K, Ca, Br and Sr) are normalized to Cl mass, data from the absorption method display higher precision than data from the crush and leach technique. The Cl normalized elemental masses from the two extraction methods compare well for Sr and Ca, but K:Cl and Mg:Cl ratios obtained with the crush and leach method are higher than from the absorption method, while Br:Cl and Na:Cl ratios are lower.

Continuing research and development aims to refine the technique by investigating preferential ion sorption and reversibility of ion leaching, improving water-content measurements using near-infrared spectroscopy, and testing other analytical methods such as neutron activation analysis. With refinement of the water-content and solute analytical methods, the technique holds promise for characterizing porewater geochemistry occurring in low-permeability, low porosity rocks.

Heavy metal sequestration in nanoporous minerals

AARON J. CELESTIAN[1*], MICHAEL POWERS[1], AND SHELBY RADER[1]

[1]Advanced Materials Institute, Dept. of Geography & Geology, Western Kentucky University, USA aaron.celestian@wku.edu (* presenting author), michael.powers509@topper.wku.edu, and shelby.rader684@topper.wku.edu

Introduction

The nanoporous minerals sitinakite (sodium titanium silicate hydrate) and umbite (potassium zirconium silicate hydrate) are a pair of highly selective, fast ion conductor that are being tested for targeted removal of cesium and strontium from high level waste solutions [1]. In addition to their environmental applications, titanium silicates, and similar zirconium and yttrium silicates, have many technological uses including battery materials, hydrogen storage, and rare earth and transition element catalysts for gasses and petrochemicals [2]. Sitinakite and umbite are stable under a wide range of pressure, temperature, and chemical conditions making them potential host materials to perform selective chemistries in extreme environments. We are determining the fundamental structural properties governing ion selectivity in these unique minerals with emphasis toward understanding their energy related applications.

Results and Discussion

The studied materials exhibit multiple ion exchange steps that serve to enhance ion selectivity, and these steps are controlled by the host crystalline framework as well as the chemistry and hydration state of the native and ion exchanged compounds. To determine the exchange mechanisms, we collected high resolution in situ Raman spectroscopy, X-ray diffraction and computational data to capture the ion exchange processes from the natural forms, to the enhanced hydrogen form, and finally to the heavy metal exchanged structure.

The results from these ion exchange studies (using Y, Eu, Gd, Cu, Ni, Cs, Sr) indicates that a range of exchange dynamics exsist within a single host mineral. Specifically in sitinakite the exchange dynamics are sigificanly different for each REE tested (Y, Gd, Eu). This was somewhat suprising as all three elements possess the same valance charge, similar ionic radii (±0.05Å), and similar hydration states in aqeous solutions (CN=8-9). TGA/DSC curves for before and after exchange states showed significant variation in nanopore H_2O capacities, indicating that the hydration states of the element and valence electron conduction have an effect on the sequestion mechansims and pathways through the porous host structure. The selectivity hypothesis concerning the effects of internal hydration and valence electron conduction has been previously proposed [3,4], however the mechanisms of framework conformational changes, presence of intermediate structural states, and diffusion pathways have only been reported for a handful of materials and is the main area of focus for this study.

Implementing Stable Isotope Fractionation of Two Elements in Reactive Transport Models to Validate Novel Assessment Methods for Biodegradation in Aquifers

FLORIAN CENTLER*AND MARTIN THULLNER

Helmholtz Centre for Environmental Research - UFZ, Leipzig, Germany, florian.centler@ufz.de (* presenting author), martin.thullner@ufz.de

Compound-specific stable isotope analysis has been established as a viable method to detect and quantify *in situ* biodegradation. Even the identification of dominant degradation pathways is possible if stable isotope data of two elements are combined in the so-called two-dimensional isotope analysis. These assessment methods can be applied at field sites where degradation occurs via a single dominating pathway that does not change qualitatively over space. If spatially varying redox conditions lead to multiple degradation pathways, each associated with a different zone along a groundwater flow path, the application of current stable isotope based methods is not straigth forward. For such conditions, novel analytically derived concepts are presented which allow the use of two-dimensional isotope analysis for estimating the share of two competeing degradation pathways on overall degradation at a specific location as well as along a given flow path interval. In order to test these novel estimates, reactive transport simulations implementing a generic benzene plume/degradation scenario with aerobic and anaerobic degradation as exemplary degradation pathways were performed using the numerical model GeoSysBRNS [1]. Simulations considered besides biochemical reactions also the associated concurrent fractionation of both carbon and hydrogen isotopes. Resulting isotope signatures were used to estimate pathway contributions which were then compared to actual contributions calculated from simulated reaction rates. Estimates were very accurate for one-dimensional plume scenarios. For two-dimensional plume scenarios, estimates for pathway specific contributions to overall biodegradation were most accurate along the center of the plume, but lost accuracy towards the fringe, where transversal mixing processes were shown not only to affect contaminant concentration but also associated stable isotope signatures [2]. Total estimates could be significantly improved if additional observation points were taken into account along the flow path. Reactive transport models that incorporate the concurrent fractionation of two elements are helpful in validating and testing novel assessment methods based on two-dimensional stable isotope data and can also be applied to field sites where two-dimensional isotope data are available, improving the expressive power of the model by considering the concurrent fractionation of two elements as an additional process parameter.

Nanogranites in anatectic metapelites: building up the database

BERNARDO CESARE[1*], SILVIO FERRERO[1], OMAR BARTOLI[2], ANTONIO ACOSTA-VIGIL[3], ALICE TURINA[1], STEFANO POLI[4], TANYA EWING[5] AND ROBERT BODNAR[6]

[6]Dept of Geosciences, Virginia Tech, Blacksburg, VA, USA; email: rjb@vt.edu

Nanogranites are inclusions of former anatectic melt trapped within peritectic minerals, particularly garnet, and crystallized to a cryptocrystalline aggregate of quartz, feldspars and micas. After their recent discovery[1] in the khondalites of the KKB (India), nanogranites have been found in numerous localities worldwide and, with their appropriate characterization and analysis can provide the missing information on the composition of natural anatectic melts before they undergo modification processes. We report the main results of the study of *nanogranites* in the Ronda migmatites, and preliminary results from migmatites in the Ivrea Zone (Italy) and Kaligandaki (Himalaya). Successful experimental rehomogenization of the inclusions to a glass allows the analysis of major elements and H_2O contents of the natural anatectic melts. Despite being all leucogranitic, the compositions generally plot away from those of *minimum melts*. Systematic differences occur among samples, particularly concerning Qtz-Ab-Or relationships. The analysis of H2O in the rehomogenized inclusions demonstrates that nanogranites preserve the primary fluid contents and that melts produced at Ronda were mainly H_2O-undersaturated even at low degree of melting. Since H_2O is one of the main parameters determining melt viscosities and, in turn, the strength of partially melted rocks, the characterization of the fluid contents of *nanogranites* will allow more realistic constraints to the rheological behaviour of the deep crust, and to the timescales of melt extraction from it.

[5]CPRM, Salvador, Bahia, Brazil, augusto.pedreira@terra.com.br

Introduction. The Rio Pardo Basin and Rio Preto Belt surround, respectively, the southeastern and northwestern portions of the São Francisco Craton, eastern Brazil. We examined the possibility that carbonates of the Serra do Paraíso Formation (Rio Pardo Basin) that overly diamictite/arkose of Panelinha Formation or basement, and those of the São Desiderio Formation (Rio Preto Belt) that covers the Canabravinha Formation, represent Neoproterozoic cap carbonates.

In the Serra do Paraíso Formation, the $\delta^{13}C$ values for carbonates with stromatolites at Serra do Paraíso Farm are ~ -5‰ and upsection values jump to around +9‰ towards the top of this formation.

In the Rio Preto Belt, representative sections of São Desiderio Formation have the following $\delta^{13}C$ values: at the Mineração do Oeste Quarry, limestones show $\delta^{13}C$ values from +1.2 to +2.2‰ in the first 16m changing abruptly upsection to values between +10 and +12‰ in organic matter-rich limestones. At Sítio Rio Grande, limestones show values from +13.5 to +15‰ in the first 30m, and from +14 to +16‰ upsection, in organic matter-rich limestones.

Carbonates from Serra do Paraíso Formation display negative Ce anomaly values in the base of the formation and positive values upsection, as an indication that the depoitional environment passed from anoxic into oxic conditions. Their positive Eu anomalies roby resulted from influence of hot exhalation of hydrothermal fluids. Carbonates from the São Desidério Formation exhibit just positive Ce anomaly values, indicating an anoxic environment, and display negative Eu anomaly values that suggest reducer environment.

Hg values have been used as a proxy of volcanism intensity and CO_2 buildup during Snowball Earth events. Hg contents in cap carbonates are usually over 10 times higher than background values (<1 $ng.g^{-1}$) [1], in Serra do Paraíso Formation Hg values is 0.92 in the base changing upsection to 10.64$ng.g^{-1}$.suporting the idea of mantle-origin for the CO_2 in cap carbonates, transferred to the atmosphere by volcanism.The values of $^{87}Sr/^{86}Sr$ for carbonates of both formations vary from 0.707584 to 0.708061, compatible with a depositional age bracketing the end of Cryogenian (Marinoan) glaciation.

Conclusions. Our current data set is compatible with the hypothesis that Serra do Paraíso and São Desidério formations represent two cap carbonates.

Biogeochemical Mn cycling and its influence on the water column Mn concentrations in the Southwestern East/Japan Sea

CHA, HYUN JU[1*], AND CHOI MAN SIK[2]

[1]Chungnam National University/Research Institute of Marine Sciences, , Daejeon, Republic Of Korea hcha80@chol.com (* presenting author)

[2]Chungnam National University/Department of Oceanography/Graduate School of Analytical Science and Technology, Daejeon, Republic Of Korea, mschoi@cnu.ac.kr

Abstract

Biogeochemical cycling of Mn was studied for the southwestern East/Japan Sea for the upper part of sediments collected from 1995 through 2007. The sites cover continental shelf, continental slope and deep basin areas (the Ulleung Basin ~ 2300 meter deep). From the profiles of dissolved Mn concentrations in porewater, we found that intensive redox-cycling of Mn occurring in the upper layer of sediments over the study area. From the vertical profiles of dissolved Mn in porewater and particulate Mn in iron-oxyhydroxide phase of sediment, we calculated benthic fluxes of dissolved Mn and accumulation rates of particulate Mn in sediment that varied significantly between sedimentological settings. Accumulation rates of particulate Mn in the oxyhydroxide phase increased with water depth of sampling site. On the contrary benthic fluxes of dissolved Mn decreased with water depth of each site despite of the high sediment accumulation rate and high organic carbon concentrations of the continental margin areas. The authors related this phenomena to the concentrations of water column Mn concentrations showing downward increase below 1000m water depths and concluded that there may be a horizontal transport of dissolved and/or colloidal Mn from the continental slope to the basin.

Modelling of U-series nuclides in regoliths and the recovering of weathering propagation rates

F. CHABAUX[1]*, E. PELT[1], E. BLAES[1], R. DI CHIARA-ROUPERT[1]

[1]LHYGES, Université de Strasbourg/EOST, CNRS, France (*correspondence: fchabaux@unistra.fr)

The interest of U-series nuclides as tracers and chronometers of weathering processes results from the dual property of the nuclides to be fractionated during water-rock interactions and to have radioactive periods of the same order of magnitude as the time constants of many weathering processes. The development of U-series nuclides for investigating weathering processes is quite recent, and was significantly stimulated by the analytical improvement made over the last decades in measuring the ^{238}U series nuclides with intermediate half-lives (i.e., ^{234}U-^{230}Th-^{226}Ra) (1-5).

Here it is proposed to present some recent results obtained with the analysis of U-series nuclides in weathering profiles to determine rates of soils processes. We will especially highlight how a simple modelling of u-series nuclides based on mathematical formalism assuming a continuous gain and loss of the different U-series nuclides within a weathering profile allow ones to recover propagation rates of weathering front within the regolith. The limitations of this approach and the future developments required to progress in this topic will be also discussed.

Intrinsic and Extrinsic Factors Governing Development of Time-Dependant Leaching/Depth Thresholds in Hawaiian Soils

OLIVER A. CHADWICK[1]

[1]University of California, Santa Barbara, USA, oac@geog.ucsb.edu

Sampling and Methods

Soils have been sampled across the Hawaiian Islands guided by state factor theory which dictate sampling along near orthogonal gradients of climate and time. Hawaii has strong gradients of both and due to the intersection of island topography and the dominant NE tradewinds, climate patterns have been quite stable over the last 4 my. In particular, climate gradients ranging from <500 mm to >3000 mm have been sampled on 10 ky, 150 ky, 400 ky, and 4000 ky lava flows. Soils were sampled to depth of backhoe and/or auger refusal and analysed for total element composition, soil physico-chemical exchange, mineralogical and plant nutrient properties.

Results and Conclusions

We observed distinct thersholds in soil depth and soil chemical properties that become more strongly expressed over time and that are expressed at rainfall values that decline from about 1800 mm at 10 ky, to 1300 mm at 150 ky, 1000 mm at 400 ky and 800 mm at 4000 ky. Below the threshold soil depth is a meter or less on the yonger flows and increases to between 3 and 4 m on the oldest flow. Above the threshold soil depth is between 1 and 2 m on the youngest flows increasing to about > 5 m on the intermediate age flows and to as much as 20 m on the oldest flow. Nutrient status as indexed by the fraction of non-hydrolizing cations sorbed to soil exchange complex changes strongly across the threshold but the difference varies according to flow age. Young and intermediate age flows show very strong differences whereas the oldest flows are quite depleted in cations even below the threshold. The observed thresholds are very sharp occurring over spatial distance of a km or less and over a rainfall distance of a few hundred mm. Although they are strongly expressed, the processes associated with formation of the thresholds are complex and are a response to both intrinsic and extrinsic variables. The dominant control of threshold location is related to the balance of rainfall and evapotranspiration. Where the latter predominates leaching and weathering depths are limited. Increasing amounts of rainfall lead to increased pore volumes of water which enhances both weathering depth and cation removal. However even at low rainfall occasional extreme wetting events serve to slowly deepen weathering depths and remove ions. Thus over time the threshold is expressed at lower rainfall values. On Hawaiiain shield surface erosion is quite low which allows these thresholds to be expressed in ways that might not occur in most landscapes.

Element impurities as time scale in otoliths of wild Prussian carp (*Carassius gibelio*): Implications for past environmental reconstructions

XINNA CHAI[1*], MING LI[2], SHENGHONG HU[1], ZHAOCHU HU[2] AND LANLAN JIN[1]

[1] State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Wuhan 430074, China, chaixinna@gmail.com (* presenting author)

[2] State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China, liming19820426@163.com

Otoliths are paired structures composed of biogenic calcium carbonate in teleost fish inner ears [1]. Otoliths accrete new crystalline and protein material on to their exterior surface daily throughout fish's life, incorporating minor and trace elements, and are not re-metabolized once deposited [2]. These element impurities, which represent less than 1% of the otolith weight, provide a chemical chronology over the entire life of a fish. The combination of laser ablation with inductively coupled plasma mass spectroscopy (LA-ICPMS) is a powerful tool for determination of trace elements or elemental ratios and has wide applications in otolith section analysis providing message in a specific life-history period or changes in long periods of time. Otolith annuli, opaque and translucent zones in otolith, relate to fish age due to seasonal variation in the diurnal process of the deposition of the calcareous, crystalline structure and protein matrix. Hence spatial otolith chemistry usually is match to fish age using otolith annuli as temporal references. From the combination of optical and chemical characteristics of fish otoliths, it have been used to reconstruct the sequence of environmental changes experienced by a fish throughout its life and to relate these changes to when they occurred [3]. Here, we analyzed concentration profiles of element impurities in wild Prussian carp otoliths by LA-ICPMS. The periodic distribution of normalized ratios of Mg, Sr, Mn to Ca were appeared along the otolith growth axes. The high value of ratios were corresponding to the opaque zones and the low value corresponding to the translucent ones. A series of experiments were undertaken to verify the consistency of the elemental vibration and otolith annuli with a pair of otolith, different sampling strategy with antero-posterior and dorso-ventral direction, and different otolith with the visible or invisible annuli. These element impurities, distributing in otoliths with periodical fluctuations, can be used for fish age determination and time scale for past environmental reconstructions.

Effect of abiotic environment on biogeochemical response of arctic sediments : a multivariate analysis

GWÉNAËLLE CHAILLOU[1], HEIKE LINK[2] AND PHILIPPE ARCHAMBAULT[3]

[1] Canada Research Chair in the Geochemistry of Coastal Hydrogeosystems Department of biology, Chimistry, Geography, Université du Québec à Rimouski, Rimouski, Canada, gwenaelle_chaillou@uqar.ca

[2]Institut des Sciences de la Mer, Université du Québec à Rimouski, Rimouski, Canada, heike.link@uqar.ca

[3]Institut des Sciences de la Mer, Université du Québec à Rimouski, Rimouski, Canada, philippe_archmbault@uqar.ca

The effects of global changes on Arctic Ocean biogeochemical cycles are difficult to predict given the complex web of physical, biological and chemical interactions that act in this system. It is clear, however, that the flux of organic matter to coastal Arctic sediment will be considerably altered. In this context, understanding how the benthic biogeochemical fluxes of arctic sediment are controlled by organic carbon fluxes is essential.

To examine the effect of abiotic environment on benthic nutrient and metabolite exchanges, we measured fluxes of dissolved oxygen, nitrate, nitrite, ammonia, soluble reactive phosphate and silicate at the sediment-water interface of nine stations located in the souheastern Beaufort Sea in water depth from 45m to 580m. We focussed on abiotic parameters that characterize the quality of the organic matter that reaches the seafloor (e.g. Chla, phaeopigment, $\delta^{13}C_{org}$, C/N_{tot}, $\delta^{13}C$ on lipids, particulate organic carbon fluxes) and others that characterize the surficial sedimentary environment (e.g. overlying dissolved oxygen concentration, salinity, temperature, surficial Fe and Mn concentrations, surficial porosity). In this communication, after a presentation of the spatial distribution of the measured fluxes, we will use a multivariate approach enabling simultaneous evaluation of several variables. The biogeochemical response pattern will be evaluated with ordination by non-metric multidimensional scaling (nMDS) and principal components (PCA). The relationship between multivariate biogeochemical fluxes and abiotic parameters will also examine using distance-based multivariate multiple regression using the DISTLM routine. The model will be built using a forward selection of abiotic parameters tested on individual fluxes using a mutiple regression analysis. Most of these tests are still in progress.

We will show that multivariate approach is efficiant to reveal hidden relationships between samples and that it can be used to improve our knowledge on coastal environments.

Mass-independent sulfur isotopic fractionation in VUV photodissociation of H_2S: implications for meteorite data

SUBRATA CHAKRABORTY[1*], RYAN DAVIS[1], TERESA L. JACKSON[1], MUSAHID AHMED[2], AND M. H. THIEMENS[1]

[1]Department of Chemistry and Biochemistry, University of California, San Diego, La Jolla, California 92093-0356, subrata@ucsd.edu (* presenting author)

[2]Lawrence Berkeley National Laboratory, 1 Cyclotron Road, Berkeley, CA 94720, mahmed@lbl.gov

Introduction

Mass-independent sulfur isotopic compositions have been observed in chondritic chondrules and organics [1-2] and bulk achondritic meteorites [3-4]. Sulfonic acid extracts from Murchison also displayed a significant ^{33}S anomaly and it was suggested that methanesulfonic acid could have resulted from gas-phase ultraviolet irradiation of a precursor, carbon disulfide [2]. Stellar nucleosynthesis and cosmic ray spallation have been ruled out as the cause of the observed $\Delta^{33}S$ anomaly [3]. Photochemical reactions in the early solar nebula was inferred to be a leading process to generate mass independent sulfur composition.

UV photolysis of SO_2, H_2S and CS_2 with $\geq$ 180 nm photons have been carried out in the laboratory to understand the isotope effect in photolysis of sulfur bearing molecules [5-7]. Here we present S-isotope data from VUV photodissociation (using Chemical Dynamics Beamline at the ALS synchrotron) of H_2S.

Results and Discussion

H_2S photolysis was carried out at four different synchrotron bands centred at 90, 121.6, 139.1, and 157.6 nm at various pressures in a differentially pumped chamber. Elemental sulfur produced in all these experiments was collected and converted to SF_6 to measure the isotope ratios (e.g., $^{33}S/^{32}S$, $^{34}S/^{32}S$, and $^{36}S/^{32}S$). Among four different synchrotron bands used, 121.6 nm photolysis products show significant mass-independent fractionations both in $\Delta^{33}S$ and $\Delta^{36}S$ with a $\Delta^{36}S/\Delta^{33}S$ ratio of -3 ‰.

H_2S is one of the major sulfur-bearing species in the gas-phase of the solar nebula. Photodissociation of H_2S by Lyman-alpha (121 nm) lines from solar radiation could change the isotopic composition of this major sulfur reservoir. The observed meteoritic sulfur isotopic anomaly, especially those measured in organics may be due to the isotope shift of this precursor sulfur reservoir due to photochemistry. The complete results and a full discussion will be presented at the conference.

MA and the ALS are supported by the Director, Office of Energy Res., U. S. Dept. of Energy (Contract No. DE-AC02-05CH11231).

Glacial-Interglacial boron isotope changes in the deep North Atlantic

THOMAS B. CHALK[1*], GAVIN L. FOSTER[1], AND PAUL A. WILSON[1]

[1]Ocean and Earth Sciences, National Oceanography Centre Southampton, University of Southampton Waterfront Campus, Southampton, United Kingdom, (* presenting author) t.chalk@noc.soton.ac.uk

Despite many decades of research, the causes of the well documented pCO_2 changes that accompany, and partly drive, glacial-interglacial climate cycles remains elusive. The speed with which these changes take place points to the importance of changes in storage of carbon in the deep ocean , but the mechanisms involved remain uncertain. Recent modelling studies have suggested the volume of bottom water of southern origin that bathes the abyss may play a crucial role ("the standing volume effect"; Brovkin et al. 2011[1]; Skinner et al. 2009[2]).

Here we investigate this phenomenon by producing boron isotope records of epibenthic foraminifera, *Cibicidoides wuellerstorfi,* at three North Atlantic sites ([I]ODP 980, 1308 and 1313) from Marine Isotope stage six to the Holocene. These sites effectively form a depth profile from 2100 to 3900m. At these northern latitude sites, changes in the ocean storage of carbon, and in particularly northerly excursions of corrosive southern sourced water, are expected to be seen as changes in water column profile of the carbonate system parameters pH and $CO_3^=$ which can be reconstructed by changes in $\delta^{11}B$ and B/Ca in epibenthic foraminifera (Rae et al. 2011[3], Yu and Elderfield 2008[4]). Our chosen sites therefore are a sensitive monitor of the "standing volume effect" and by comparing our results to records of atmospheric CO_2 we will gain new insight into the role of this phenomenon in driving glacial-interglacial CO_2 change.

Direct magmatic input in geothermal systems of the Taupo Volcanic Zone

ISABELLE CHAMBEFORT[1*], ANDREW RAE[1] AND GREG BIGNALL[1]

[1]GNS Science, Wairakei Research Centre, Private Bag 2000, Taupo, New Zealand, i.chambefort@gns.cri.nz (* presenting author).

In the last 20 years, insights on the content and behaviour of volatile constituents in magmas, particularly from melt inclusion studies, have enhanced our understanding of hydrothermal fluid-magma interactions, and volatile transfer from magma to active hydrothermal systems. Exsolved fluids from magmatic sources contribute to the evolution of geothermal systems, by influencing fluid (reservoir) chemistry and associated hydrothermal alteration.

Geothermal systems of the Taupo Volcanic Zone (TVZ), New Zealand, are large convective cells of heated, primarily meteoric-derived waters. CO_2, Cl, B and N contents in TVZ well discharges indicate magmatic fluids are present in small proportion, but until now no direct, unequivocal evidence of magmatic fluid input or magmatic-derived hydrothermal minerals have been identified.

Secondary (alteration) minerals can point to magmatic, meteoric or mixed fluid origins, and processes (e.g. boiling, fluid mixing) within active geothermal systems. In the future, tracking a magmatic fluid signature in geothermal systems is expected to be an important consideration for establishing the spatial distribution of deep-seated magma bodies in the TVZ and for potential delineation of green-field geothermal systems with resource potential. New oxygen and sulphur stable isotope analyses of anhydrite in drillcore from ~2000 mVD (vertical depth) within the Rotokawa Geothermal Field exhibit an arc-related magmatic-hydrothermal signature, similar to anhydrite from the Ladolam epithermal gold depost (Lihir, Papua New Guinea, [1]) or Butte porphyry-copper deposit (Montana, USA [2]). Isotopic compositions of the Rotokawa anhydrite are $\delta^{18}O_{anh}$ = +13.9 to +17.9 (± 0.5‰, with one anhydrite of $\delta^{18}O$= 0.4‰), and $\delta^{34}S_{anh}$ +10.1 to +13.0 (± 0.5‰). The calculated sulphur isotopic composition of H_2S in equilibrium with the Rotokawa anhydrite are -4 to -9‰, whilst $\delta^{34}S_{H2Sg}$ in well discharges range between +4.1 and +4.8‰. The trace element composition of the Rotokawa anhydrite (e.g. Sr content up to 5000 ppm) also show similarities with inferred magmatic-derived anhydrite seen elsehwere (e.g. at Ladolam).

The trace element and isotopic compositions of Rotokawa anhydrite both point to sulphate in the hydrothermal system having a magmatic origin. In contrast, chemical analysis of discharge Rotokawa well fluids cannot have precipitated the anhydrite seen in core samples from >2000 mVD in several Rotokawa wells. We suggest that the anhydrite observed in Rotokawa core samples formed in equilibrium with magmatic-derived, low pH, sulphate-rich fluids, at some time during the the evolution of the hydrothermal-magmatic system, as a result of magmatic degassing. This study provides the first direct evidence of magmatic fluid input to the otherwise dilute, meteoric-dominated, low-salinity geothermal systems of the TVZ, and is expected to impact future deep geothermal exploration strategies.

[6]St. Petersburg State University, St. Petersburg, Russia, khudoley@AH3549.spb.edu

We report an *in-situ* method to date micro-baddeleyite grains whose exposed dimensions are less than 20 μm in length using secondary ion mass spectrometry (SIMS) U-Pb isotopic analysis [1,2]. We've successfully dated grains as small as 3 microns using the CAMECA *ims*1270 at UCLA. The method is ideal for samples that contain baddeleyite crystals that are too small to separate physically, such as fine-grained tholeiitic dikes and lavas, or samples that are too rare and precious to crush for mineral separation, such as meteorites, drill cores and samples from remote regions. Baddeleyite is common as a magmatic phase in tholeiitic and (less commonly) alkaline mafic rocks where it is not known to nucleate metamorphically, thus baddeleyite dates can generally be regarded as magmatic ages. We have occasionally documented zircon overgrowths on baddeleyite, however. The method requires only portions of polished thin sections and is relatively non-destructive, as it preserves the analyzed sections largely intact and still suitable for additional types of analyses. X-ray mapping, energy-dispersive spectrometry and backscattered electron imaging (BSE) are used to locate and image the grains and have added benefits of identifying alteration-free grains, armoring relationships, and mineral growth mechanisms. Coexisting zircons can also be dated in the same sections, if present, and often yield metamorphic ages. Analytical precision is practically limited by presence of common Pb (e.g., present at grain boundaries or crystal imperfections), and can be enhanced by averaging multiple crystal analyses. From our experience, precisions obtained by averaging 8 to 10 spot analyses range from 0.5 to 1% for $^{207}Pb/^{206}Pb$ dates from rocks that are >1000 Ma, and 3 to 8% for $^{238}U/^{206}Pb$ dates from Paleozoic to Mesozoic rocks. Recent case studies include lunar, Martian and eucritic meteorites, tholeiitic dikes and sills from 2.7 Ga to 0.4 Ga, Mesoproterozoic volcanic rocks and Caribbean intrusive rocks.

CHALLENGES OF CELL-MINERAL CONTACT DURING MINERAL FORMATION AND DISSOLUTION BY FE AND S-OXIDIZING BACTERIA

CLARA S. CHAN[1*], THOMAS E. HANSON[2], JENNIFER HIRAS[2], KEVIN A. CABANISS[2] AND JEFFREY BRODZINSKI[3]

[1]Dept. of Geological Sciences, University of Delaware, Newark, DE, USA, cschan@udel.edu (* presenting author)
[2]School of Marine Science and Policy, University of Delaware, Newark, DE, USA, tehanson@udel.edu

Microbial Fe and S redox transformations commonly involve mineral formation and dissolution, which presents challenges due to spatial issues. During mineralization, cell-mineral contact is ideally minimized to prevent encrustation. During dissolution, cell access to mineral surfaces can be limiting. We are studying mineral dynamics and cell-mineral interfaces in chemolithotrophic Fe oxidizers and phototrophic S-oxidizers. The Fe-oxidizers cultured from Rifle, CO groundwater produce Fe oxyhydroxides; the phototroph *Chlorobaculum tepidum*, a well-characterized model organism with a genetic system, oxidizes sulfide to solid elemental S(0) and once sulfide is exhausted, oxidizes the S(0) to sulfate. Real time dynamics of cell-mineral interactions are observed by time lapse light microscopy of live cultures. Higher resolution images are obtained by scanning and transmission electron microscopy, including cryo-techniques to preserve delicate cell-mineral spatial relationships. *C. tepidum* appears to require biogenic S(0) for growth and direct cell contact with S(0) during dissolution, but only a subset of cells appear to be firmly attached. Current efforts are aimed at dissecting the molecular components mediating cell-S(0) interactions in *C. tepidum* using a variety of microscopic, proteomic, and analytical chemistry tools.

Global Mercury Pollution and Seafood Safety

LAURIE H.M. CHAN

University of Ottawa, CAREG, Biology, Ottawa, Canada, laurie.chan@uottawa.ca

Mercury is a global pollutant and there is strong evidence that the emission will increase by 50% in 2050. The major source of mercury is from the emission of fuel fossil burning power plants. Mercury accumulates along the aquatic food chain and can reach high levels in fish and shellfish. Mercury is a known neurotoxicant that is particularly harmful to fetal brain development. However, fish and shellfish are widely available food that provides many nutrients, particularly the n-3 polyunsaturated fatty acids (n-3 PUFAs), to many populations globally and there are benefits linked to brain and visual system development in infants and reduced risk for certain forms of heart disease. In this talk, we will review the current state of knowledge including results of our ongoing research in this area. We will also discuss the national and international efforts on regulation policy and public health messages on benefits and risks associated with fish consumption (1).

Fate, Transport, and Deposition of Gold Nanoparticles in Porous Media

MATTHEW Y. CHAN[1*], MATTHEW S. HULL[1], JASON C. JONES[2], AND PETER J. VIKESLAND[1]

[1]Department of Civil and Environmental Engineering, Virginia Tech, Blacksburg VA 24061, USA, mychan@vt.edu (* presenting author)

[2]Department of Materials Science and Engineering, Virginia Tech, Blacksburg VA 24061, USA

Over the past two decades, there has been a steady increase in the application of nanomaterials and nanotechnology.[1] Gold-nanoparticles (AuNP) show significant potential in cancer treatment, drug delivery, self-assembling constructs, chemical analytical techniques and many more.[2] As the utilization and manufacture of AuNP increase it is important to understand the fate of these materials once they are released to the environment. In this work, we sought to investigate the fate, transport and stability of AuNP discharged to groundwater environments.

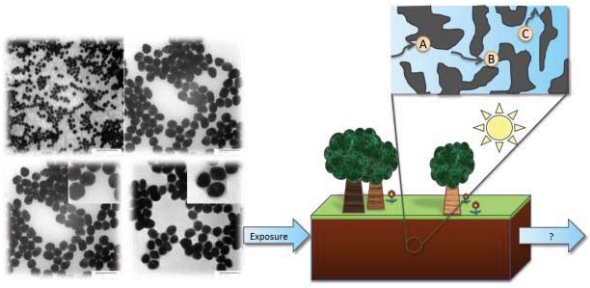

Figure 1: Exposure of AuNP to groundwater environment. There can be many possibilities for the fate of AuNP once released. For example: A) Adsorped by sediment; B) Fitrated and retained by pores; C) Unhindered transport.

AuNP transport in groundwater is heavily influenced by the intrinsic properties of the nanoparticles and the external parameters of the environment. Batch experimental data indicated that 15 nm AuNP coated by bovine serum albumin (BSA-AuNP) was more stable under high ionic strength conditions compared to citrate-coated AuNP (Cit-AuNP) of similar size. It was expected that the stability of these AuNP would be replicated in column studies. Column experiments with varying monovalent and divalent ion concentrations using both types of AuNP yielded breakthrough curves that both adhere and deviate from this hypothesis. BSA-AuNP was found to be more stable relative to Cit-AuNP during flow in the presence of increasing concentrations of $CaCl_2$, but the opposite occurred with an increase in NaCl concentration. Colloidal filtration theory (CFT) fails to predict and explain this discrepancy.

Mercury isotope fractionation during aqueous photo-reduction of methylmercury in presence of dissolved organic matter

PRIYANKA CHANDAN[1] , SANGHAMITRA GHOSH[1] AND BRIDGET A. BERGQUIST[1*]

[1]Department of Geology, University of Toronto, 22 Russell Street, Toronto, Ontario, M5S 3B1, Canada
(*correspondence: bergquist@geology.utoronto.ca)

Monomethylmercury (MMHg) is a globally persistent toxin that bioaccumulates in aquatic ecosystems. The photo-degradation of MMHg in freshwater systems is a significant pathway for the destruction of MMHg from surface waters and is considered an important sink in aqueous systems, which limits MMHg availability to biota. Quantifying this sink for MMHg is challenging, and it was suggested that natural fractionation of Hg isotopes might be useful in both understanding and quantifying this pathway [1]. In order to use this new tool, the isotopic fractionation factors associated with MMHg photo-degradation need to be characterized along with the variability that might be induced by environmental factors (i.e. type and amount of organic matter, light intensity and wavelength).

In a previous study, aqueous photo-reduction of MMHg in the presence of dissolved organic matter (DOM) was shown to display both mass dependent (MDF) and mass-independent (MIF) fractionation of Hg isotopes with the odd isotopes (^{199}Hg and ^{201}Hg) being preferentially retained in the reactant [1]. The observation of large MIF signatures (>0.5‰) is likely due to magnetic isotope effect (MIE), which is expressed during radical pair photochemistry. It was also observed that the magnitude and extent of MIF was different for two concentrations of DOM. Since these experiments were carried out on different days in natural sunlight, which likely had different solar intensity and frequency, it was unclear whether the variability in MIF was due to varying DOM concentrations or the variability in solar radiation.

We investigated the effects of different types and amounts of DOM on the isotope fractionation of Hg isotopes during aqueous photo-reduction of MMHg to assess if MIF signatures can be used to track photo-degradation of MMHg in natural waters. From experiments conducted with different amounts of reduced organic sulfur (S_{red}-DOM), it appears that MIF during photo-reduction may be dependent on whether MMHg is dominantly bound to S_{red}-DOM. Similar fractionation factors were observed for experiments where S_{red}-DOM was in far excess of MMHg, while significantly lower fractionation factors were observed with lower S_{red}-DOM. We also characterized the signature of MIF (i.e. $\Delta^{199}Hg/\Delta^{201}Hg$) during MMHg photo-degradation to assess if it was similar in different matrices. The experimental $\Delta^{199}Hg/\Delta^{201}Hg$ ratio for all the MMHg-DOM experiments was 1.39±0.06 (2SE). However, we observed that the experimental slope is slightly but statistically different than the slope observed in freshwater fish.

Anomalous zircon Ce^{4+}/Ce^{3+} ratios from early Jurassic plutons in Yukon: implications for porphyry exploration

JOHN B. CHAPMAN[1*], SIMON E. JACKSON[1] AND JAMES J. RYAN[2]

[1]Geological Survey of Canada, Ottawa, Ontario, Canada, john.chapman@nrcan-rncan.gc.ca (* presenting author); simon.jackson@nrcan-rncan.gc.ca
[2]Geological Survey of Canada, Vancouver, British Columbia, Canada, jim.ryan@nrcan-rncan.gc.ca

Studies suggest that a genetic link exists between oxidized magmas and porphyry-style Cu (±Au±Mo) mineralization.[1] However, many indicators of magmatic redox state – such as whole-rock Fe^{3+}/Fe^{2+} ratio – can be reset during both hydrothermal alteration and surficial weathering. Zircon ($ZrSiO_4$) is an abundant accessory mineral in granitoids, and is both refractory and resistant to alteration. Cerium commonly shows anomalously high concentrations within zircon, due to its stable +4 oxidation state and preferential incorporation of the Ce^{4+} ion over Ce^{3+}. The magnitude of this substitution should correlate with the Ce^{4+}/Ce^{3+} ratio in the parent magma, and as such can be used as a qualitative proxy for oxidation state.[2] In this study, we determined zircon Ce^{4+}/Ce^{3+} ratios for a suite of late Triassic to Jurassic granitoid intrusions from southern and western Yukon, Canada, including mineralised and host rocks of the Minto Cu-Au mine, and for mid- to late-Cretaceous intrusive phases associated with the Casino Cu-Mo-Au deposit.

Results for the Casino samples show that the major mineralising intrusive breccia phases have average zircon Ce^{4+}/Ce^{3+} values of 200-350, and peak values approaching 500, in contrast to mid-Cretaceous host granitoid rocks which have average values of 50-100 and peak values <250. Both sets of observations fit previously published models for the identification of Cu prospective intrusive rocks.[2,3] Hence, it appears possible to use zircon Ce^{4+}/Ce^{3+} ratios for exploration fingerprinting within the Cretaceous of the Yukon.

The 'Carmacks Copper Belt' (CCB) of western central Yukon includes the Minto Cu-Au mine, the Carmacks Copper deposit, and several smaller Cu±Au occurrences and showings. Both the Minto and Carmacks Copper deposits are hosted within the Triassic-Jurassic plutonic rocks of the Granite Mountain batholith, part of a regionally extensive suite of plutonic rocks of similar age and composition. The Triassic-Jurassic samples appear to fall into two distinct groupings: those with modal zircon Ce^{4+}/Ce^{3+} values >700, and those with values <600. The regionally extensive nature of these elevated Ce^{4+}/Ce^{3+} values may reflect the petrogenesis of these plutonic rocks, and as such need to be better understood before reliable prospectivity indicators can be defined. In contrast to the Cretaceous suite, all early CCB samples analysed have zircon Ce^{4+}/Ce^{3+} ratios greater than the previously published prospectivity threshold values.[2,3] However, Granite Mountain samples have higher apparent oxidation state, so the broad relationship to mineralisation established for the Cretaceous suite is maintained.

MOLYBDENUM SEQUESTRATION IN SULFIDIC SEDIMENTS: XAFS EVIDENCE FOR MO REDUCTION

ANTHONY CHAPPAZ[1,*], TAIS W. DAHL[2], JEFFREY P. FITTS[3] AND TIMOTHY W. LYONS[4]

[1] Institute for Great Lakes Research, Dept. of Chemistry and Dept. of Earth and Atmospheric Sciences, Central Michigan University, Mount Pleasant, MI 48859, USA

[4] Dept. of Earth Sciences, University of California – Riverside, CA 92521, USA

Molybdenum (Mo) has attracted attention as a paleoredox proxy particular because of its isotopic behavior and concentration relationships in sediments [1,2]. Much of this strength lies with the specifics of Mo redox behavior. In oxygenated water, Mo occurs dominantly as unreactive molybdate ($Mo^{VI}O_4^{2-}$). When sulfide appears under in the sediments or water column, sulfur substitutes progressively for oxygen in MoO_4^{2-}, leading to reactive tetrathiomolybdate ($Mo^{VI}S_4^{2-}$) by way of transient intermediates ($Mo^{VI}O_xS_{4-x}^{2-}$) [3]. However, the post-thiomolybdate steps and the ultimate Mo host in sulfidic sediments remain unclear and thus compromise its strength as a redox proxy.

We used x-ray absorption fine structure spectroscopy (XAFS) to determine the oxidation state and molecular coordination environment of solid phase Mo in sediments deposited under a permanently sulfidic (euxinic) water column. Samples were taken from a 9 meter drill core from Lake Cadagno representing the last ten thousand years of deposition.

Our data provide unequivocal evidence for Mo reduction in the sulfidic water column and/or in the sediments. We identified two types of spectral patterns. Type 1 samples contain primarily Mo^{IV} bonded exclusively to sulfur atoms; Type 2 samples contain mainly Mo^{VI} bonded to both oxygen and sulfur atoms.

Based on experiments, we argue that Mo^{VI}-O-S compounds have been oxidized after collection. These Type 2 compounds compare to spectra previously reported for black shales and thiomolybdate adsorption experiments on Fe-sulfides [4,5] and suggest that oxygen exposure might have altered these samples too.

Mo^{IV}-S compounds are found in both modern and ancient sediments indicating that Mo has not experienced diagenetic alteration over the last ~10,000 years. These Type 1compounds show many similarities with the Mo-Fe-S cubane structure. Finally, our results support a model involving post-thiomolybdate reactions wherein the Mo^{VI} reduction proceeds via reactions with with zero-valent sulfur (S_8) [6].

We conclude that Mo-XAFS is a powerful way to study the geochemical details of the Mo burial pathway and enhance our ability to infer ancient environmental conditions from the sedimentary rock record. Further, the post-thiomolybdate reduction may exert isotope fractionation that could affect the Mo isotope composition in euxinic sediments.

Number density considerations in the dispersion-dissolution behavior of engineered silver nanomaterials

Background

With the acquisition of new technologies, the U.S. Army is now required to consider the environmental implications of fielding new nanomaterial-based technologies in theater and as part of warfighter training. To this end, the U.S. Army Engineer Research & Development Center (ERDC) has expended considerable effort and resources into quantifying the environmental fate of nanomaterials. Here is presented our work on the dispersion-dissolution processes associated with silver nanoparticle dispersions under simulated environmental conditions.

Methods

Long-term dispersion studies were conducted either by shaking or stirring nanomaterial suspensions under laboratory-controlled conditions. Systems were sampled periodically with time and analyzed for multiple dispersion and dissolution endpoints.

Results & Discussion

Our results demonstrate that the dissolution processes were coupled to the solid-phase dispersion characteristics. We note that such linkages are often apparent in the scientific literature yet not explicitly explained because this behavior is almost invariably considered in terms of particle mass concentrations. Instead, these relationships are preferably viewed through considering the change in the suspension number density. The number density parameter is (i) inversely related to the size distribution of the dispersion and (ii) shifts by several orders of magnitude with small changes in particle size at the nano-scale. Experimental results show that an increase in dissolved Ag concentration observed over a two-week period correlated with the increase in the number density of silver nanoparticle dispersions. This relationship was only apparent as long as the suspension remained in a sub-saturation mode. This latter observation is important as at the nanoscale, where the nearly two-order magnitude length difference in our current analytical technologies blurs the classical definitions between particles and dissolved solutes. We reason that the relationship to nanoparticle dissolution and particle surface area commonly portrayed in the scientific literature is mathematically fortuitous but mechanistically inaccurate. Here, we discuss number density in terms of implications for ecosystem effects described in eco-toxicology literature.

In situ monitoring for studying the seasonal pattern of dissolved oxygen in a sandy beach of the Aquitaine coast (France)

CELINE CHARBONNIER[1*], PIERRE ANSCHUTZ[1], BRUNO DEFLANDRE[1], DOMINIQUE POIRIER[1], STEPHANE BUJAN[1] AND PASCAL LECROART[1]

[1]Université de Bordeaux, CNRS, UMR 5805 EPOC, Talence, France, *c.charbonnier@epoc.u-bordeaux1.fr

Despite low concentrations of organic matter and associated reactive compounds, sandy sediments of tidal beaches are now considered as biogeochemical bioreactor [1]. Tidal beaches are affected by an intense advective transport of seawater during each tide: during floods, seawater penetrates sandy sediments, bringing dissolved oxygen and marine organic matter in the pore space. The aim of this study is to determine how dissolved oxygen evolves in pore waters along the year and how this evolution is linked to physical forcing such as tide and swell. Autonomous sensors were buried into sediment during 3 to 14 days on the Truc Vert beach (Aquitaine, France) every 3 months. Dissolved oxygen concentration (measured with Aanderaa optodes and NKE data loggers), temperature, salinity and pressure were recorded with a high frequency (from 2 to 10 minutes) at the top of the water table (30-50 cm below sediment surface). The data showed that dissolved oxygen depletions occurred in pore waters and that the intensity of these depletions varied seasonally. Indeed, dissolved oxygen concentration was influenced by the intensity of coastal planktonic primary production. Plankton from the near coastal ocean is the main source of organic matter entering sands. Degradation of this organic matter by respiration processes in the sediment significantly decreased the dissolved oxygen concentration in the pore waters. Strong depletions of dissolved oxygen were observed during spring, with some anoxic events. Furthermore, high frequency recordings highlighted the strong influence of tidal forcing on the benthic dynamic of dissolved oxygen in sands. Swell breaking generated episodic rises in the dissolved oxygen concentration during ebb tides. This in situ study demonstrated how physical (tide and swell) and biogeochemical (respiration) processes may control dissolved oxygen dynamics in intertidal sandy beaches.

Evaluating meteorites using LA-ICPMS: 'Lovina' test case

CHRISTOPHER R.J. CHARLES[1*], PHIL J.A. MCCAUSLAND[2], ROBERTA L. FLEMMING[2] AND DONALD W. DAVIS[1].

[1]Jack Satterly Geochronology Laboratory Dept. Geology, Univ. of Toronto, Toronto, Canada (*christopher.charles@utoronto.ca).
[2]Dept. Earth Sciences, Univ. of Western Ontario, London, Canada.

'Lovina' was found on a beach in Bali, Indonesia in January, 1981 appearing as a football-sized 8.2 kg weathered iron. Lovina was originally classified as an ungrouped ataxite on the basis of petrography and geochemistry [1,2] but was found to have virtually no record of exposure to cosmic rays [3] so its meteoritic status was in question. Here we measure the Pb isotopic composition (IC) of troilite nodules in Lovina in an effort to determine its source.

Pb and U isotopes were analyzed in 10 randomly chosen troilite nodules on a Lovina polished thin-section, by a VG PQ ExCell ICP-MS and UP-213 laser ablation system. Data were acquired on 100 um spots at 70% power and 10Hz. Surface Pb was ablated off each nodule by rastering 4x over an area larger than the spots (raster 4-5 'lines' spaced 30 um apart at 70%, 10 Hz at 120 um/sec speed). Mass fractionation for Pb (~1%) was corrected based on NIST-610.

No U was detected in any of the trolite nodules. 207Pb/206Pb ratios (Figure 1) for all 10 analyses fall in the range expected for modern terrestrial Pb [4-7] and are distinctly below the primordial CDT Pb composition of meteoritic troilite [8]. We conclude that the Pb in Lovina troilite is consistent with a terrestrial source. Lovina's origin remains unclear, but it does not appear to be a meteorite. Despite the relatively poor precision of LA-ICPMS, this rapid and cheap technique may also be useful for identifying meteoritic phases most amenable to U-Pb geochronology.

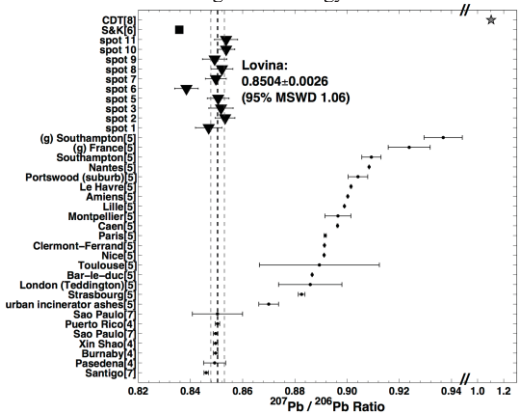

Figure 1: Pb IC of Lovina troilite nodules (triangles) compared to [6], terrestrial airborne particulates and gasoline (g) Pb sources [4,5,7] and Canyon Diablo Troilite (CDT) [8]. Note the break and change in $^{207}Pb/^{206}Pb$ axis scale for plotted CDT.

Redox oscillation impact on natural and engineered biogeochemical systems

L. CHARLET[1,2].

[1]ISTerre, University of Grenoble, B. P. 53, 38041 Grenoble, France.
[2]Institut Universitaire de France, Paris, France

Many systems fluctuate from oxic to anoxic conditions, in an oscillatory way. Systems becoming seasonally anoxic include irrigated, phreatic- or engineered-flooded soils, seasonally stratified lakes, urban waste sewage pipe and floodplain, macrophyte water treatment plant, and engineered low activity nuclear waste disposal. Conversely, lake "sediments", swamp and peat-bog become oxic "soils" upon urbanization, desertification or agriculture expansion, while anoxic sedimentary formation and aquifers turn oxic upon groundwater over-abstraction or fracking fluid intrusion.

Many reactions in these systems do not reach thermodynamic equilibrium and physical/chemical diffusion, electron transfer kinetics, and solid (e.g. carbonate, sulphide, metallic) phase nucleation control, together with microorganisms, the transitory states of these system. To conduct field work and experimental, analytical or spectroscopic investigation on these systems is a challenge which will be discussed, together with the "natural attenuation"- or release - of toxic elements (such as As, Hg, Se, U..) [1, 2]. (Bio)chemical models of redox oscillatory systems must include a combination of fast reversible reactions (e.g. aqueous and surface complexation equilibria), surface- or microbially- mediated redox kinetic reactions and slow irreversible adsorption/co-precipitation [3]. They should be included in risk assessment and system management of former military or mine sites, waste storage facilities, "green" waste water treatment, floodplains and urban development [4].

Mantle-seawater exchanges contribute significantly to the hydrothermal fluxes at slow-spreading ridges. The emplacement of serpentinized mantle at all ultramafic-hosted hydrothermal systems discovered along the slow-spreading Mid-Atlantic Ridge (MAR) where tectonic extension dominates over magmatic construction is a common feature leading to the production of hydrogen and hydrocarbons. To understand the processes controlling the gas generation in ultramafic-hosted active fields, field data including the chemical composition of plumes and fluids are necessary to constraint experimental studies and modeling. The chemical composition of fluids from ultramafic-hosted hydrothermal fields (Rainbow, 36°14'N, Lost City, 30°N, Logatchev I and II, 14°45'N; Ashadze I and II, 12°58'N), all located along the MAR [1] is compared here. Like basalt-hosted fluids, the ultramafic-hosted fluids are controlled by phase-separation. But everywhere H_2 content is extraordinarily enriched in low or high chlorinity phases, demonstrating that the serpentinization process is mainly responsible for hydrogen production. As a consequence of the high reducing power of these systems, isotopic measurements of light hydrocarbons (C_1 to C_4) show that abiogenic hydrocarbons are generated by catalytic Fischer-Tropsch type reaction, considering their isotopic pattern, which is opposite to that for thermogenically-produced hydrocarbons. From plume and fluid data, H_2 and CH_4 fluxes may be calculated. For example, the total hydrogen discharge Φ_{H2} is found to be between 2.5 to 7.5 millions standard cubic meters per year for the Rainbow single site. Based on Rainbow $H_2/^3He$ and ^3He/heat ratios, the global H_2 and CH_4 fluxes for slow-spreading ridges are estimated to be 89 x 10^9 and 8 x 10^9 mol/year, respectively.

Noble gases and halogens in the oceanic crust

D. CHAVRIT[1]*, R. BURGESS[1], B. WESTON[1], L. ABBOTT[1], D. TEAGLE[2], C.J. BALLENTINE[1]

[1]S.E.A.E.S., University of Manchester, Manchester, UK (*deborah.chavrit@manchester.ac.uk)

[2]National Oceanography Centre, University of Southampton, Southampton, UK

Recent studies showed that seawater-derived noble gases and halogens can be recycled into the mantle during the subduction of the oceanic crust [1, 2, 3]. To better understand how this signature is acquired and thus can be preserved, we determined the heavy noble gas (^{36}Ar, ^{84}Kr, ^{130}Xe) and halogen (Cl, Br, I) concentrations in the pre-subducted materiel represented by altered MORB (IODP sites 504, 896, 1256 in the Pacific ocean). The measurements were obtained from samples irradiated via neutron activation, by the release of noble gases in vacuo step crushing (N=18) and followed by in vacuo step heating (N=11).

The ^{130}Xe/^{36}Ar ratios are on average 2 times higher for the heating data (13±5.10^{-4}) than for the crushing data (5.0±4.8.10^{-4}) for similar ^{84}Kr/^{36}Ar (0.05±0.01 and 0.04±0.02 respectively). Thus, the fluid phase is interpreted to be a mixture of air and seawater (± sediments) whereas the solid phases contain an additional altered MORB noble gas component.

An average of ~90% of the halogens are contained in the solid phases and are comparable to the levels present in unaltered MORB glasses. The bulk rock Br/Cl ratio is ~constant (1.05±0.45.10^{-3}) but is 30% lower than in unaltered MORB. In more detail, the Br/Cl ratios of the fluid phases are higher than the seawater's ratio (1.54.10^{-3}) and lower than seawater in the solid phases. The I/Cl ratios vary by 4 orders of magnitude for both the fluid and the solid phases (from 5.5.10^{-7} to 9.03.10^{-3}). The halogen ratios of the fluid phases can thus be explained by a mixing of seawater and sediment or marine pore fluid components. In contrast, the lower Br/Cl value of the altered oceanic crust is mainly attributed to the addition of Cl during the alteration process on the seafloor.

For both halogens and heavy noble gases, we observe different partitioning between the fluid phase and the solid phase. While the fluid phases are more likely a mixing between seawater and a sediment/marine pore fluid signature component, the solid phases define an altered MORB signature. Halogens seem to be a powerful tool to trace the seawater and marine pore fluid signature in rocks and the budget of these elements that is potentially available to be delivered to mantle during subduction.

Zircon as a probe of oxygen fugacity: observations and limitations from natural samples

CYRIL CHELLE-MICHOU[1*], MASSIMO CHIARADIA[1], KALIN KOUZMANOV[1] AND JÖRN F. WOTZLAW[1]

[1]Section of Earth and Environmental Sciences, University of Geneva, 1205 Geneva, Switzerland, cyril.chelle-michou@unige.ch (*presenting author)

Ongoing experiments on zircon crystallization confirm the idea that Ce, Eu and Th/U in zircon are sensitive to the oxygen fugacity (fO_2) of the melt from which it crystalizes [1]. At high oxidation states zircons will display a prominent positive Ce anomaly and none or only a weak negative Eu anomaly that are attributed to the predominance of Ce^{4+} over Ce^{3+} and Eu^{3+} over Eu^{2+}, respectively.

The accurate determination of the Ce anomaly is often problematic due to the low La and Pr concentrations in zircon and possible contamination of the signal during LA-ICP-MS analyses by small LREE-rich mineral inclusions. Alternatively, the Ce^{4+}/Ce^{3+} ratio can be calculated by using the more enriched REEs, from Nd to Lu, together with Zr, Hf and Th [2]. This ratio can be used to infer the relative oxidation state of magmas if a representative population of zircons for each sample is available.. The method is based on the assumption that zircons are in equilibrium with their host rock. If xenocrystic and/or antecrystic zircons are present, the calculated Ce^{4+}/Ce^{3+} ratio may then be inaccurate. Xenocrysts will alter the trace element budget of the whole rock that had never been available in the magma and then affect the calculated Ce^{4+}/Ce^{3+} value of the neoformed zircons. Antecrystic zircons (that cannot be differentiated from autocrysts unless high-precision dating can be done) may have crystallized in a magma of different composition from the rock they are found in. Their relative effect was investigated by numerical simulations on a dataset from dated zircons (by LA-ICP-MS) of the Eocene-Oligocene calc-alkaline Coroccohuayco magmatic suite in southern Peru, associated with porphyry and skarn copper mineralization.

Results show that the effect of xenocrystic zircons on the calculated Ce^{4+}/Ce^{3+} is very limited. Values obtained on antecrystic zircons can be inaccurate if the melt from which they crystallized has a significantly more fractionated REE pattern than the rock they are finally found in. The absolute zircon Ce^{4+}/Ce^{3+} ratio was also found to be very sensitive, by almost one order of magnitude, to the number of REEs used for its calculation. The Ce anomaly does not necessarily correlate with Ce^{4+}/Ce^{3+}. Nevertheless, the interpretations of the Ce^{4+}/Ce^{3+} ratio calculated using different REEs and of the Ce anomaly are very similar, if a representative number of zircons per sample is available. In our dataset, the zircon Eu anomaly was found to correlate with the bulk rock Eu anomaly and not with the zircon Ce^{4+}/Ce^{3+}, suggesting a first order control by the primary melt composition. The zircon/rock partition coefficient of the Th/U ratio decreases systematically with increasing zircon Ce^{4+}/Ce^{3+} values (i.e., fO_2). This supports the idea that U can also occur as U^{5+} and/or U^{6+} in magmas, altering the relative partitioning of Th and U.

Unusual fractionation of both odd and even Hg isotopes in precipitation

JIUBIN CHEN[1,2*], HOLGER HINTELMANN[2], XINBIN FENG[1] AND BRIAN DIMOCK[2]

[1]State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Science, Guiyang, China. jiubinchen@vip.gyig.ac.cn (* presenting author)

[2]Chemistry Department, Trent University, 1600 West Bank Drive, Peterborough, Ontario, K9J7B8, Canada.

Preliminary studies have demonstrated both mass-dependent fractionation (MDF) and mass-independent fractionation (MIF) of Hg isotopes in the environment and the potential for their application in biochemistry and geochemistry. Though atmospheric deposition is a primary pathway by which Hg enters earth surface ecosystem, little has been reported on Hg isotopes in precipitation.

In order to examine Hg isotopic composition in precipitation, rainwater and snow samples were collected in Peterborough (Ontario, Canada) in 2010. Hg isotopic compositions were determined after Hg pre-concentration using the method developed by Chen et al. (2010). All precipitation samples displayed significant MDF (δ^{202}Hg between -0.02‰ and -1.48‰) and MIF of odd isotopes (Δ^{199}Hg varying from -0.29‰ to 1.13‰). We reported here, for the first time, a seasonal variation of even Hg isotope MIF (Δ^{200}Hg). Our results suggest that photo-reduction in droplets or on the surface layer of snow crystals induce odd Hg isotope anomalies determined in precipitation samples, while mass independent fractionation of even Hg isotopes is likely triggered by elemental Hg oxidation occurring on aerosol or solid surface in the tropopause. Though more research is required to fully understand the behaviour of Hg isotopes in the atmosphere, the striking seasonal variation of even Hg MIF (and with temperature) may provide useful information for meteorological research and related climate studies and help in monitoring atmospheric Hg transportation.

The analysis of solution-ICP-MS of rare earth elements of carbonate minerals in carbonate rocks

LINYING CHEN, CHONGYING LI AND DUOFU CHEN*

CAS Key Laboratory of Marginal Sea Geology, South China Sea Institute of Oceanology, Chinese Academy of Sciences, Guangzhou, China, cdf@gig.ac.cn

The trace elements of carbonate minerals in carbonate rocks, especially rare earth elements (REEs), are the best parameters to trace the redox conditions of the sedimentary environment. However, because the REE contents of carbonate minerals are much lower than that of terrigenous clays, a small quantity of clays dissolved will affect true redox implication. Therefore, to conduct an analytical method to get the true REE contents of carbonate minerals deposited in marine environment without the contamination from terrigenous clays is very important.

At the present time, the analytical methods of REEs of carbonate minerals in carbonate rocks mainly are solution-ICP-MS and LA-ICP-MS. In solution-ICP-MS method, hydrochloric acid, nitric acid and acetic acid are usually used. Hydrochloric acid and nitric acid could dissolve all carbonate minerals in carbonate rocks and also possibly parts of non-carbonate minerals, which disturb the analysis results. Although using acetic acid can avoid the interference of non-carbonate minerals, it probably could not completely dissolve the carbonate minerals in carbonate rocks, the results also could not be true. In LA-ICP-MS analysis, carbonate minerals was ablated by laser beam firstly, and then evaporation was directly carried into ICP-MS, which could be the most effective method for REE analysis of carbonate minerals without clays. But, because the diameter of laser beam is too large to avoid tiny clays which usually occur in carbonate minerals, LA-ICP-MS also has uncertainty.

Here we use 5% CH_3COOH, 5% HCl, 2% and 5% HNO_3 to dissolve powder samples split from one carbonate rock for 0.5, 1, 2, 3, 6 and 24 hours, respectively. The XRD analysis results show that there is no calcite in insoluble residues after acid dissolution suggesting that calcite was completely dissolved. The ICP-AES analysis results of acid dissolved solution indicate that small quantities of clays were dissolved. These dissolved clays result in an increase of REE contents, but do not affect Eu/Eu*, LaN/YbN and Gd/Gd*. The obvious positive relation between Al_2O_3 and Ce/Ce* in acid dissolved solutions suggests that the dissolved clays did affect the Ce/Ce* values of carbonate minerals to a certain degree.

Comparing results under different acid dissolution, we could conclude that the appropriate conditions for REE analysis of carbonate minerals in carbonate rocks is 0.5-1g samples reacting with 5% CH_3COOH for 1 hour, which decrease the influence of clays on Ce/Ce* values to the lowest. As for HNO_3 dissolution, the acid with concentration <2% should be used to react with 0.2g power sample for <30 min. And for 5% HCl dissolution, the reacting time should be <30 min with 0.2-1g sample. The Ce/Ce* values obtained from HCl and HNO_3 dissolutions could still be used to trace sedimentary environment, but will be higher about 0.1 than that from CH_3COOH dissolution.

Investigating biogeochemical alteration of oil sand tailings: Field vs. laboratory studies

M. CHEN[1], M. GOETZ[1], N. LOICK[1] AND C. WEISENER[1]

[1]Great Lakes Environmental Research Institute, University of Windsor, Windsor, Canada, weisener@uwindsor.ca

Introduction

The oil sands deposits in Northern Alberta are one of the largest oil reserves in the world, containing an estimated 2.5 trillion barrels of recoverable bitumen held in a mineral matrix consisting of sand, clay and water. The current practice is to store the tailings in large settling basins, to allow the solids to settle out by gravity forming a denser unconsolidated mass termed fluid fine tailings (FFT). FFT is transferred from settling basins into the mined-out pits, being proposed for a series of end pit lakes, a strategy for sustainable environments being evaluated in the Fort McMurray region. As these end pit lakes (EPL) evolve, significant changes in the physicochemical properties, microbiology and geochemistry can occur affecting both the volume and quality of the intended water cap. To date little information exists on the biogeochemical nature (redox mediated reactions) of the FFT product prior to deposition. Our research program is investigating both the chemistry and the microbial community structure within core samples collected from oil sands tailings basins. To compliment and confirm predictive models there is a need for detailed systematic studies bridging the physical (mineralogy) and chemical (redox chemistry abiotic vs. biotic; cycling of Fe and S) gradients observed for samples collected.

Results/Conclusions

Detailed studies in our group have shown that chemical and biological mechanisms play a role in controlling diffusivity, O_2, HS^-, NO_x gradients which may be linked to sulfur and Fe (II/III) cycling during initial settling under aerobic and anaerobic conditions [1, 2]. To validate these assumptions further investigations have assessed the chemical and secondary mineralization mechanisms that occur in REDOX sensitive microaerophilic zones in both laboratory studies and collected field samples from the settling basins. Data will be presented which support these assumptions from the EPL materials by looking at temporal chages of the materials as well as comparing results from bioreactor-studies and field-samples.

bjorn_sundby@uqar.qc.ca

Redox-sensitive elements (RSEs) are potentially powerful paleo-redox tracers [1]. To realize this potential requires an improved understanding on their geochemical properties and the chemical reactions they participate in during early diagenesis.

We measured the distributions of Fe, Mn, U, Mo, Re, and Cd in solid phase sediment and their porewaters in six cores collected along the Laurentian Trough of the Estuary and Gulf of St. Lawrence and the Eastern Canadian continental shelf. The data were obtained via ICP-MS analysis of porewaters and buffered-ascorbate and 1 N HCl extractible solid phase components. The results are consistent with the conclusions of a previous investigation that the accumulation rates of U, Mo, Re, and Cd are controlled by slow precipitation kinetics [2]. At the most landward station, where the sedimentation rate is highest (~4 mm/yr) and the bottom water dissolved oxygen concentration is lowest (~60 μM), the porewater U, Mo and Re concentrations decrease gradually with depth, supporting diffusion from the bottom water into the sediment. In contrast, porewater U, Mo and Re profiles show little variation with depth in the Gulf and on the continental shelf where the sedimentation rates are lower (0.5-1.5 mm/yr) and the bottom water oxygen concentration is higher (~150 μM). At all stations, the porewater Cd concentration is variable with depth. The extractible solid phase concentrations of Mo, U, Re and Cd increase with depth in all cores. These findings provide a useful test of how RSEs respond to variable overlying water oxygenation and sediment accumulation rates and how their vertical distributions are modified by early diagenetic processes.

Nd & Hf concentrations and isotopic compositions in the Baltic Sea

TIANYU CHEN[1], MARTIN FRANK[1], AND ROLAND STUMPF[1*]

[1] GEOMAR | Helmholtz Centre for Ocean Research Kiel, Wischhofstr.1-3, Kiel, Germany, rstumpf@geomar.de (*presenting author)

Abstract

Within a process study in the framework of the international GEOTRACES program and led by the Institute of Oceanology of the Polish Academy of Sciences (IOPAN) a two-week cruise on the R/V Oceania sailed in November 2011 to investigate the distribution of trace elements and their isotopes in the Baltic Sea. The scientific goals were particularly focused on compiling trace element budgets for the Baltic Sea including in- and outflow, as well as to investigate elemental behavior and isotopic fractionation associated with the redox gradients of the Baltic Sea water column and the permanently anoxic conditions within its deep basins (i.e. Gotland Deep, Landsort Deep).

The Baltic Sea is a shallow, brackish inland sea with an average salinity of ~7 psu in the mixed layer. It is fed by the Bothnian Sea in the north, by the Finland Sea in the east, as well as by numerous rivers from Scandinavia and the Baltic states, and it is drained through the Danish Strait into the North Sea. In the opposite direction, a denser bottom water mass enters the Baltic Sea through deeper channels from the Danish Strait successively filling the deep basins northward. Below 130 m water depth, the water column is permanently anoxic.

Here we present the first combined data set of Nd and Hf concentrations and isotopic compositions for the Baltic Sea. A total of 21 water samples (60L volume per sample) including two water column profiles from the deeper basins were filtered (0.45 μm) and Nd and Hf were extracted and analysed following the accepted GEOTRACES protocols. The distribution patterns of the two elements and their isotopic compositions are compared to hydrographic data and oxygen measurements and provide information on sources and mixing of water masses, as well as on exchange processes with the underlying sediments, which are influenced by the prevailing redox gradients.

Acknowledgements

Very special thanks go to the Institute of Oceanology of the Polish Academy of Sciences (IOPAN) as well as to the crew and science party of the R/V Oceania for making this cruise possible.

Stability of engineered nanoparticles in aqueous environments: measurements and modeling

YONGSHENG CHEN*, WEN ZHANG AND KUNGANG LI

School of Civil and Environmental Engineering, Georgia Institute of Technology, Atlanta, Georgia, 30332; e-mail: yongsheng.chen@ce.gatech.edu

Aqueous stability of engineered nanoparticles (ENPs) plays a crucial role in their environmental fate, transport, bioavailability and biological consequences. ENPs, once disposed into aqueous enviornments, may undergo aggregation and dissolution or ion release. In this study, we systematically investigated aggregation kinetics of serval selected ENPs through assessment of the environmental effects (e.g., ionic strength) and modeling approaches. Particularly, CeO_2, due to its broad industrial applications, was chosen as a model ENP to study the aggregation kinetics under different concentraions and species of electrolyte (K^+ and Ca^{2+}) [1] and natural organic matter (NOM) [2] using time resolved-dynamic light scattering (TR-DLS). Expeirmental results were further evaluated by theoretical models developed on the basis of Extended Derjaguin−Landau−Verwey−Overbeek (EDLVO) theory. Based on the EDLVO theory and the von Smoluchowski's population balance equation, a model accounting for diffusion-limited aggregation (DLA) kinetics was established. Furthermore, a new approach was presented for assessing the attachment efficiency (a measure of relative aggregation kinetics) of ENP aggregation based on the Maxwell-Boltzmann distribution coupled with the DLVO theory [3], which is a first attempt to the best of our knowledge. The modified attachment efficiency equation was proposed and the equation successfully interpreted the effects of ionic strength, NOM, and temperature on aggregation kinetics [3], showing the balanced consideration of interfacial energy and Brownian motion in evaluating the aggregation kinetics of NP dispersions. For chemically reactive ENPs, silver NPs (or AgNPs) was selected to investigate the disolution kinetics and effects of particle size and concentration, and other factors (e.g., aggregation) [4]. An Arrhenius-based equation was developed for the first time to describe and simulate the Ag^+ release kinetics. Oxidative dissolution of AgNPs was accompanied by particle aggregation, which differed in kinetics with or wihtout the presence of disssolved oxygen [5]. The knowledge gained from this research proivdes insight into the aqueous stability of ENPs and using expeirmental and modeling approaches, allowing us to better undertand and predict environmental fate of ENPs at nanoscale.

The Formation and Evolution on the Central Asian Orogenic Belt

YUELONG CHEN[1*], DAPENG LI[1], ZHONG WANG[2], JINBAO LIU[2], CHANGZHENG LIU[3]

[1] China University of Geosciences (Beijing), Faculty of Earth Sciences and Mineral Resources, Beijing, China, chyl@cugb.edu.cn (*presenting author); ldpzhuanyong@163.com

[2] Geological Survey of Inner Mongolia Autonomous Region, Hohhot, China, wzhong61@126.com; nmgljb@126.com

[3] The Fifth Geological Survey of Qinghai Province, Xining, China

Geological Setting

The Central Asian Orogenic Belt (CAOB), one of the largest orogens on the Earth, has attracted numerous geologists and geochemists around the world[1]. It is surrounded by the Siberian craton in the north and by the North China and Tarim cratons in the south and extends from the Ural Mountains in the west to the Pacific coast in the east. The CAOB is considered as an accretion orogen through arc/backarc systems, ophiolites, and microcontinental fragments[2,3]. Although there are many achievements on geodynamic models, accretion rates, Precambrian microcontinents etc., general characters of the CAOB have not been summarized yet.

Methodology

Due to rapid development of SHRIMP and LA-(MC)-ICP-MS techniques, a lot of precise and accurate U-Pb dating and Hf isotopic data of zircons in the CAOB have been accumulated during recent 10 years. We compiled the comprehensive histograms and probability density curves of U-Pb ages and Hf model ages on zircons as well as Nd depleted mantle model ages of whole rocks on the basis of our results and published data.

Results and Conclusions

Although the Hf isotope of a zircon grain represents its composition in a micro-domain, averaged Hf model age (1.39Ga) is almost consistent with that (1.28Ga) of Nd model ages，which are much older than that (571Ma) of zircon U-Pb ages. Collectively, the most intensive magmatic and crustal growth event took place during the Early Palaeozoic and Neoproterozoic periods according to consistent peaks among U-Pb ages and Hf model ages of zircons and Nd model ages. The earliest history can be tracked to ~3.2Ga by U-Pb ages of zircons and Nd model ages, whereas the oldest Hf model age is ~4.3Ga, which indicates that the crustal components of older than 3.2Ga have only been recorded in some zircon grains. The zircons of older than 1.0Ga derived from reworked Precambrian basements of the CAOB, which account for <10% in populations of all zircon U-Pb ages, in contrast to cumulative probability of over 60% in those of Hf and Nd model ages. Therefore, the Mesoproterozoic juvenile crustal components constitute dominant part of CAOB's Precambrain basements, most of which have involved in subsequent intra-crustal magmatisms. The Neoproterozoic is a transition period initiating intensive magmatism in the CAOB. Magmatism arrived at the climax in Palaeozoic, whose cumulative probability possesses 76% in whole range of ages.

Local spatial and scaling modelling for geochemical heterogeneity and anomaly detection

ZHIJUN CHEN[1*] AND QIUMING CHENG[1, 2]

[1]State Key Lab of Geological Processes and Mineral Resources, Faculty of Earth Resources, China University of Geosciences (Wuhan), Wuhan, China, chenzhijuncs@163.com (*presenting author)

[2]Department of Earth and Space Science and Engineering, York University, Toronto, Canada, qiuming@yorku.ca

Regional geochemical mapping with stream sediments provides information on weathering and transport processes and on the presence of contaminants and mineral deposits. Various quantitative methods have been developed in geochemical exploration to separate anomalies associated with mineralization from background reflecting regional geological processes. However, geochemical datasets often show strong heterogeneity in geomorphologically and geologically complex settings. Therefore, anomaly detection methods based on the assumption of homogeneity and stationary are inappropriate. A key change in separating anomalies from background has been from a focus on local singularities rather than the search for global regularities and production of local mappable statistics rather than global summaries. The local spatial and scaling model that combines local singularity analysis and spatial U-statistics introduced is a potential powerful method for geochemical heterogeneity and anomaly detection.

The study area is in the northern part of the Lanping basin, Yunnan province, China. A total of 1172 stream sediment samples were collected at 2 km intervals. Many Pb-Zn-Ag deposits including the Jinding super large Pb-Zn deposit exist in this area.

The scale-invariant property has been observed not only in many geochemical maps but has also proved useful for characterizing variability in maps. Local singularity analysis based on multifractal theory is a powerful tool for characterizing local structural properties of spatial patterns. It uses the local singularity index α to indicate background or anomaly, where $\alpha(x)$ close to 2 represents background with homogeneity, $\alpha(x) > 2$ corresponds to local depletion, and $\alpha(x) < 2$ to anomalous enrichment at the neighborhood $\Omega(x)$. Locally-adaptive detection of the geometrical properties of $\Omega(x)$ (size, shape, and orientation) will obtain better $\alpha(x)$ if patterns are heterogenous at the scale of measurement. A spatial U-statistic can be used not only for geochemical anomaly separation but also for searching anisotropic parameters at arbitrary sample location. Thus, it useful for anisotropic local singularity modelling.

The combined local singularity analysis and spatial U-statistics considers not only concentration values, frequency distributions and spatial correlation, but also geometrical properties of anomalies and scale independence characteristics, which are effective to reveal multi-scale anisotropy and heterogeneity in geochemical exploration data. It can be a useful tool to discover weak anomalies related to buried mineral deposits.

This research was supported by NCFC(40802081), 863 Plan(2009AA06Z110), and the Special Fund for Basic Scientific Research of Central Colleges at China University of Geosciences (Wuhan).

Identification of Transport Pathway and Geographical Source Location of Light Absorbing Species and Co-Pollutants

MENG-DAWN CHENG[1*] AND JOHN M.E. STOREY[1]

[1]Energy and Environmental Directorate, Environmental Sciences Divison, Oak Ridge National Laboratory, Oak Ridge, TN, USA, chengmd@ornl.gov (* Presenting author)

Ground observations of light absorption and aerosol-borne species are analysed and digested in a hybrid receptor-modelling framework called the Potential Source Contribution Function (PSCF)[1]. The analytic method establishes the relevant events based on observations using a number of time-series techniques to separate various frequency components; then the PSCF algorithm computes the probability of the overloading probability of identifiable polluting events for each grid cell in the modelling domain. The calculated probability is then an indication of a grid cell being an emission source of a particular pollutant under investigation. Multiple pollutants and or co-pollutants are used in the combined / joint probability analysis to enhance the identification power. We have analyzed the assembled time-series observations made at Barrow, Alaska for the past 15 years. Similar to many previous data taken at other site such as Alert, NWT, periodic pattern of light absorption, CNC, and other ground aerosol species concentrations were observed. Many data from Barrow are ran off by low-freqency compoent in the timer-series analysis. For those detectable, the correlation between light absorption and black carbon measurements were analyzed to show that there are other light absorption components existing in the Arctic particles. Backward trajectories segregated by season show different transport pathways to the two receptor sites suggesting alternative control strategies. Ongoing PSCF modeling will identify the geographical locations of various pollutants modeled and show the uncertainty of the identification, which will be presented in the conference.

Diffusion in Minerals Relevant to Geochronology

D.J. CHERNIAK[1]*, E.B. WATSON[1]

[1]Department of Earth and Environmental Sciences, Rensselaer Polytechnic Institute, Troy, NY, USA, *chernd@rpi.edu (presenting author)

Understanding diffusion processes in minerals of geochronologic interest is important in interpreting results from geochronological studies and in refinement of thermal histories. Much progress has been made in characterizing diffusion in various systems, and work continues. Diffusivities in minerals may depend on many factors, including the presence of fluids. There is abundant evidence [1] that the presence of water or other hydrous species affects oxygen diffusion in minerals. However, studies of cation diffusion generally indicate little influence of the presence of hydrous species. Hence, while fluids can play a significant role in geochronological systems in facilitating dissolution/precipitation reactions which can result in the resetting of isotopic and chemical signatures, it appears that fluids will have little additional effect on resetting due to volume diffusion within mineral grains at crustal conditions. A summary of relevant diffusion studies will be presented, along with implications of these findings with regard to transport in fluid-present systems.

Diffusion data have long found application in geochronologic studies through the concept of diffusive closure advanced by Dodson [2] and its subsequent refinements [e.g., 3,4]. When considering geologic temperature-time paths, the most important limitation of Dodson's [2] expressions is that they apply strictly to cooling regimes, since many geological processes involve heating of mineral grains that are initially diffusively closed. Thus, in a prograde thermal regime, it is not a question of when closure "sets in" but when a mineral grain "opens up" diffusively. Despite its original intent, Dodson's equation has been used frequently to address closure conditions of minerals during heating, perhaps because simple alternatives are lacking. Sophisticated approaches have been developed to address diffusive loss during heating, but mainly for specific applications; however, Gardes and Montel [5] have recently more generally examined conditions for "opening" and "resetting" in prograde temperature regimes.

In a complementary study, we take a somewhat different approach, using a combination of numerical simulations and mathematics to obtain simple equations with parameters equivalent to those in used in Dodson's equation [2], to evaluate conditions for opening and resetting in prograde T-t regimes. Tests of these equations demonstrate accuracy to within 5°C for the vast majority of measured diffusivities, and within 1° in most cases. In addition, there are essentially no restrictions on grain size or heating rate (up to 2000°C/Myr) that can be used without loss of accuracy. These findings will be presented, with discussion of various parameters considered in the modelling, including linear heating vs. other prograde paths, and the production of radiogenic species.

Diffusion of Neon in Olivine and Quartz

D.J. CHERNIAK[1]*, J.B. THOMAS[1], E.B. WATSON[1]

[1]Department of Earth and Environmental Sciences, Rensselaer Polytechnic Institute, Troy, NY, USA, *chernd@rpi.edu (presenting author)

Diffusion of neon has been characterized in olivine and quartz. Polished, oriented slabs of olivine (synthetic forsterite and natural Fe-bearing olivine) and synthetic quartz were implanted with ^{22}Ne at 100 keV with a dose of $5x10^{15}/cm^2$. Experiments on the implanted olivine and quartz were run in 1-atm furnaces, with ^{22}Ne distributions in samples following diffusion anneals measured by Nuclear Reaction Analysis using the reaction $^{22}Ne(p,\gamma)^{23}Na$.

For diffusion in synthetic forsterite, for transport parallel to the b-axis, we obtain the following Arrhenius relation over the temperature range 500-1000°C:

$D_{forst} = 2.4x10^{-12}exp(-155 \pm 12 \text{ kJ mol}^{-1}/RT) \text{ m}^2\text{sec}^{-1}$.

Diffusion parallel to the c-axis appears similar over the temperature range investigated. Data from "soaking" experiments on forsterite, in which ^{20}Ne was diffused into samples during anneals in cold-seal vessels pressurized with neon, are in generally good agreement with results from the ^{22}Ne implantation experiments. Work is currently underway on measurements of Ne diffusion in a natural Fe-bearing olivine.

The Ne diffusivities for olivine measured in this work are roughly two orders of magnitude slower than those obtained by Futagami et al. [1], who measured Ne diffusion in synthetic forsterite by outgassing ^{20}Ne implanted samples.

Activation energies for Ne diffusion are comparable to those recently measured for helium diffusion in olivine [2], but diffusion of Ne is about 5 orders of magnitude slower than He diffusion.

For quartz, we obtain the following Arrhenius relation over the temperature range 450-1000°C for Ne diffusion parallel to the c-axis:

$D_{qtz} = 1.3x10^{-14}exp(-112 \pm 15 \text{ kJ mol}^{-1}/RT) \text{ m}^2\text{sec}^{-1}$.

Ne diffusion normal to the c-axis appears similar. As with olivine, data from "soaking" experiments using pressurized ^{20}Ne are in generally good agreement with the ion implantation results. However, these diffusivities are about 10 orders of magnitude slower than the values for diffusion of ^{21}Ne in quartz from outgassing experiments reported by Shuster and Farley [3].

Our data suggest that both quartz and olivine may be moderately retentive of neon; for example, 500 micron radius grains of quartz and olivine would experience only 5% loss of Ne in 1 Myr at 320°C and 395°C, respectively, and negligible Ne losses at surface temperatures over times on order of the age of the earth.

The transient rheology of crystallizing magmas

MAGDALENA ORYAËLLE CHEVREL[1*], LEA J. DE BIASI[1], JONATHAN B. HANSON[1, 2], CORRADO CIMARELLI[1], YAN LAVALLÉE[1], DONALD B. DINGWELL[1]

[2] University of Bristol, Department of Earth Sciences, Bristol, United-Kingdom

Introduction

The viscosity of magmas is a key parameter in magma transport processes and volcanic eruptions. In nature, magmas are transient. Changes in P-T conditions force the magma to chemically and physically evolve, resolving a transient viscosity of the melt (e.g., 10^{-1} to 10^{14} Pa s), overprinted by the complex rheological effects of the suspended fraction (crystals and bubbles). Such a dynamic understanding of transient rheology escapes our ability to fully assess the extent of volcanic hazards (e.g., lava flow reach out). To date, rheological studies provide a static view on individual contributions (e.g., chemical composition of the interstitial liquid [1] vs physical effects of the suspended phases [2,3]), without consideration of the feedback involved in the thermodynamic process underlying the evolution of the magmatic system. Alternatively, thermodynamic calculators (e.g., MELTS [4]) provide a static view of mineral assemblage equilibrium, disregarding kinetic information on the physical evolution of the system during crystallization. Here, we assess the adequacy of combining rheological, petrologic and thermodynamic models in a transient system (such as lava flow dynamics) by comparing their outcome to dynamic rheological experiments on crystallizing and flowing natural melts with various (andesitic to basaltic) compositions.

Methodology and results

We optimized previous experimental methods [5,6] for the concentric cylinder apparatus to measure the dynamic apparent viscosity of a magmatic suspension undergoing cooling and crystallization. The spindle is left in situ during quenching of the experimental products, to preserve the complete developed texture of the sample. Experiments are carried out in air or under controlled oxygen fugacity in order to avoid extensive oxide crystallization. Below the liquidus we record a transient evolution of the system; when crystals nucleate and when crystals grow. Thermodynamic equilibration is then reached after some hours. With each further cooling increment equally complex rheological response (overprint by non-Newtonian behavior) is observed. Quantification of the evolving mineralogical assemblage as well as the crystal fraction and distribution reveal that the steady state flow conditions are reached upon completion of crystallization at equilibrium (under a given T increments). Comparatively, the apparent viscosity at each investigated temperature is calculated as a function of the crystallization sequences (via MELTS), the residual liquid composition (via GRD calculator [1]) and the characteristics of the solid fraction [2,3], presenting the discrepancies of employing static models in a dynamic system. Our findings suggest that dynamic models will need to be developed to improve the description of magma transport in our assessment of volcanic hazards.

Hydrodynamic constraints on relationships between different types of U deposits in southern China

GUOXIANG CHI[1], YONGZHANG ZHOU[2]

[1]University of Regina, Department of Geology, Regina, Canada, guoxiang.chi@uregina.ca (* presenting author)
[2]Sun Yat-sen University, Guangdong Provincial Key Lab of Mineral Resources and Geological Processes, zhouyz@mail.sysu.edu.cn

Four types of U deposits (granite-, volcanic-, carbonaceous-siliceous-pelitic-, and sandstone-type) have been documented in southern China [1, 2]. The majority of them were formed in late Cretaceous-Tertiary (K-E) [2, 3], much younger than the host rocks, suggesting that most of them did not form from magmatic (Triassic-Jurassic) fluids [2]. Based on their association with K-E red-bed basins, it was proposed that the U deposits are genetically related to basinal fluids, like Proterozoic unconformity-type [3]. Alternatively, mantle-derived CO_2-rich fluids, in relation to crustal extention during K-E, were held responsible [4]. It remains poorly understood why U deposits were not well developed before Cretaceous.

It is proposed here that the paucity of U mineralization in Jurassic and Triassic is related to the compressional tectonic environment, which resulted in impermeable basement and dominantly upward fluid flow in sedimentary basins (Fig. 1a). Such a hydrodynamic regime limited oxidizing fluids near the surface and reduced the opportunity for them to extract U from granites at depth. In contrast, the extentional tectonic environment in K-E increased the permeability of the basement, resulting in "leaky" basins and infiltration of oxidizing fluids into the basement (Fig. 1b), forming U deposits in various basement rocks including granites.

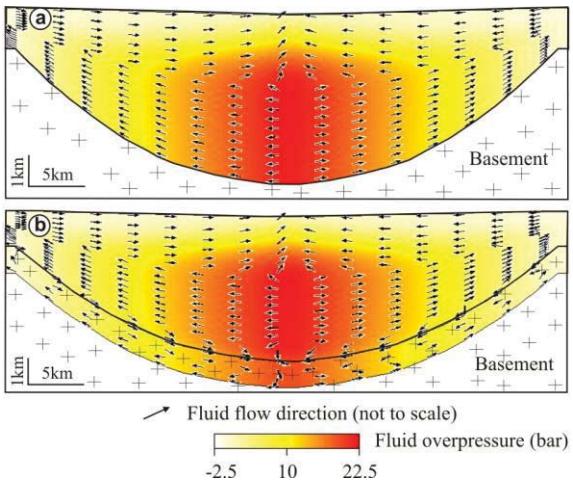

Figure 1: Fluid flow patterns of generic basins in southern China. (a) Triassic-Jurassic model with impermeable basement; (b) Cretaceous-Tertiary model with permeable (upper 1km) basement. Basin 50km wide, 5km deep, duration 100 Ma, 50% sand + 50% shale, topographic relief 250 m, computed with *Basin2*.

CO_2 rich environments under silica confinement

ARIEL A. CHIALVO[1*] , LUKAS VLCEK[2], AND DAVID R. COLE[3]

[1] Oak Ridge National Laboratory, Oak Ridge, TN 37631, U.S.A., chialvoaa@ornl.gov, (* presenting author)
[2] Oak Ridge National Laboratory, Oak Ridge, TN 37631, U.S.A., vlcekl1@ornl.gov
[3] Ohio State University, Columbus, OH 43210, U.S.A., cole.618@osu.edu

A potential approach toward the mitigation of the greenhouse effects of CO_2 release into the atmosphere is based on its geological capture and sequestration, a process that relies on the low hydraulic permeability of caprocks resulting from fluid-substrate interfacial and confinement behaviour. Current studies have mainly focused on the interactions of either water-rich CO_2 or pure CO_2 environments with representative caprock substrates, and the concomitant modeling is based on that assumption, *i.e.*, the impact of the CO_2-contaminants has rarely been addressed. In fact, due to its source, CO_2 always carries small quantities of 'contaminants' including SO_2, N_2, NO_x whose impact in terms of fluid-rock interactions must be considered.

Obviously, the presence of SO_2 in aqueous solution may trigger the formation of sulfurous/sulfuric acids [1], whose immediate consequence is the increase in acidity and the potential for dissolution/precipitation of secondary mineral phases that results in significant changes in substrate porosity and permeability [2]. Unfortunately, thermophysical properties for these mixtures at reservoir conditions are scarce or nonexistent [3], and our microscopic understanding of their interaction with caprock is extremely limited.

For that reason, we carried out a molecular-based study of the behavior of CO_2-rich environments containing common contaminants when in contact with and under severe confinement of silica surfaces, to address fundamental issues, including (a) how the degree of surface hydrophobicity affects the interfacial structure and dynamics, (b) how the overlap of interfacial structures affects the confined fluid composition, and (c) how contaminants affect the preferential adsorption and composition of the interfacial fluid layers.

Adsorption of Humic Acid onto Alumina: Conformational Changes

G. CHILOM[1*], M.M.R. KHALAF[1] AND J. A. RICE [1]
[1]Dept. Chemistry & Biochemistry, South Dakota State University, Brookings, SD 57007, USA, moustafa.khalaf@sdstate.edu, gabriela.chilom@sdstate.edu (* presenting author), james.rice@sdstate.edu

Natural organic matter is a key component of both soils and sediments that is likely to be associated with mineral matter. Natural organic matter - mineral complexes typically represent more than 50% of the organic carbon in a soil and typically more than 70% of the OC in unlithified sediments. The behavior of NOM in the environment is affected by their interactions with minerals due to their possible fractionation and conformational changes. The objective of this study was to investigate these conformational changes and the mechanisms that produce them. The adsorption isotherms of a humic acid as well as its non-amphiphilic and amphiphilic components, onto alumina were determined. The adsorbed and remaining humic acid in solution at both low and high concentration was characterized by solid state NMR and UV spectroscopy. Data suggested that preferential sorption and changes in the mobility of aromatic carbon occur upon adsorption and these changes vary with concentration. Analysis of the data for the amphiphilic fraction of humic acid suggested that surfactant character plays an important role in the adsorption selectivity and conformational changes that occur upon adsorption onto alumina.

Electrochemical study of pyrite oxidation in oxygen-bearing solutions

PAUL CHIRITA[1]*, CRISTINA A. CONSTANTIN[1] AND MICHEL L. SCHLEGEL[2]
[1]University of Craiova, Department of Chemistry, Calea Bucuresti 107I, Craiova Romania, paulxchirita@gmail.com (* presenting author) and cristina_a_constantin@yahoo.com
[2]CEA, DEN/DANS/DPC/SEARS//Laboratory for the Engineering of Surfaces and Lasers, F-91191 Gif-sur-Yvette, France, michel.schlegel@cea.fr

Pyrite (FeS_2) is the most common disulfide mineral. [1,2] Oxidation of FeS_2 in presence of dissolved oxygen results in the release of sulfuric acid and toxic trace metals in acid mine drainage, which is one of the most serious environmental problems. Inspite of this importance, the kinetics and mechanism of electron transfer from pyrite to oxidants are poorly understood. The aim of this study was to investigate the kinetics of FeS_2 interaction with dissolved oxygen using electrochemical techniques.

Electrochemical experiments were performed in a conventional three-electrodes electrochemical cell with a Pt counter electrode and saturated calomel reference electrode. The electrochemical parameters (exchange currents densities, charge transfer resistances, etc) of pyrite oxidation in air-saturated HCl solutions were measured as a function of pH (1.0 to 5.0) at temperatures from 25 to 40°C.

Preliminary analysis of the experimental data indicated that temperature has a notable effect on the rate of pyrite oxidation by dissolved O_2. The values obtained for activation energy decrease from 69 kJ mol^{-1} (at pH 5.0) to 33 kJ mol^{-1} (at pH 1.0), suggesting that pyrite oxidation is controlled by surface reaction at high initial pH, with diffusion of reactants and reaction products between surface and solutions gradually becoming rate-limiting at lower initial pH. The reaction order with respect to $[H^+]$ shows a small decrease from 0.15 at 25°C to 0.09 at 40°C. This variation can be attributed to the decrease of oxygen solubility at greater temperature.

Another important observation is that for oxidation by dissolved oxygen under similar experimental conditions (initial pH and temperature) the exchange currents densities (i_0) measured for pyrite are lower than those measured for iron monosulfide (FeS). For example, at initial pH 3.5 and 30°C temperature, i_0 of FeS oxidation is $1.19 \cdot 10^{-5}$ cm^{-1}, and i_0 of FeS_2 oxidation is $1.48 \cdot 10^{-6}$ cm^{-1}.

The authors greatly appreciate support from IFA-CEA Program (Project C1-04), and Cr.A.C-tin support from the strategic grant POSDRU/CPP107/DMI1.5/S/78421, Project ID 78421 (2010).

Tracers of pollutant sources and transport pathways using stable Cd and Pb isotopes in Ulsan Bay sediments

JUNG-SUN CHAE · MAN SIK CHOI*

Chungnam National University, GRAST, Daejeon, Korea
Kbsi2987@nate.com
mschoi@cnu.ac.kr (*presenting author)

Abstract

Metal sources have been traced by exclusively Pb isotopes in the previous studies. Although Pb isotopes were successfully used for the identification of Pb sources and mixing processes, the explanation for other metals with different geochemical behaviour was restricted. Cd isotopes become a candidate to trace Cd sources and transport pathways because Cd isotopic ratios could be fractionated by high-T processes such as smelting and refinery processes. Evaporated Cd showed depleted isotopic composition while Cd in slags from refinery has heavy isotope enriched composition [1]. This study aimed to apply stable Cd and Pb isotope ratios in Ulsan bay sediments to identify their sources and transport pathways. To do this, firstly we setup the analytical procedures for precise and accurate Cd isotope ratios including chemical separation and instrument measurement steps [2]. And we presented stable Cd and Pb isotope ratios in real sediment samples.

Surface and core sediments were collected at the Ulsan Bay, Korea. After the chemical separation of matrix and interferent metals using AGMP-1 and TRU-spec, Cd and Pb isotope ratios were measured by MC ICP/MS equipped with APEX desolvation system

Cd concentrations in surface sediments ranged from 0.15 ppm to 1.6 ppm, and were the maximum at station close to Onsan industrial complexes and at station close to Jangsaengpo harbor. Offshore stations showed the lowest concentration of Cd. $\epsilon^{114/112}_{NIST}Cd$ in surface sediments showed a little variation and ranged from –4.5 to 0.6. Sediments with the highest concentrations of Cd showed the most depleted (St. 30), non-fractionated (St. 4) and slightly enriched (St. 17). Sediments with the lowest concentration of Cd showed slightly depleted $\epsilon^{114/112}_{NIST}Cd$ values (St. 36 and 7). Although isotopic composition of Cd did not show systematic aerial distribution, it might be suggested that most Cd in Ulsan bay sediments were negatively fractionated except for harbor and ship building plant, which indicates that atmospheric transport are important pathway for Cd in sediments.

Pb concentration in surface sediments ranged from 10 ppm to 215 ppm and was the maximum at station close to Onsan industrial complexes and was the minimum at offshore station. Pb contamination was focused at stations in the southern part of the Ulsan Bay but sediments in the northern parts showed also slightly enriched Pb concentration. 207Pb/206Pb showed the wide range of variation from 0.844 to 0.90. Combining isotope ratio and the inverse of Pb concentration (Fe/Pb), three end-members of Pb sources were identified; that is, the first one is high concentration and highly un-radiogenic Pb which has similar to those in Broken Hill ores, the second is high concentration and radiogenic Pb isotope similar to background value, and the last is background concentration and Pb isotope. In other words, imported ores and local ores were two major pollutant sources.

Characteristic and Leaching behavior of Cd-, Pb-substituted goethite under CO_2

SUNKYUNG CHOI [1*] AND RICK WILKIN[2]

[1]National Research Council Resident Research Associate at the USEPA, National Risk Management Research Laboratory, Ada, USA, choi.sunkyung@epa.gov (*presenting author)
[2]USEPA, National Risk Management Research Laboratory, Ada, USA, wilkin.rick@epa.gov

Introduction and Methods

Transport of CO_2 from deep geological formations to shallow ground-water aquifers may threaten the long-term quality of drinking water resources in locations adjacent to sites of carbon sequestration. Metal transport resulting from potential CO_2 leakage into freshwater aquifers is a major concern accompanying carbon sequestration operations. Acidity resulting from dissolution of leaked CO_2 into aquifer waters may result in release of metals from aquifer minerals. Goethite (α-FeOOH) is one of the most abundant and reactive iron oxides in soils and sediments. Goethite plays an important role in nature controlling the mobility of heavy metals cations as well as certain anions as it possesses a strong affinity to a variety of contaminants in subsurface environments. Natural goethite is usually associated with a number of metals. Heavy metals such as Pb(II) and Cd(II) are common in surface water and groundwater and their transport, toxicity, and bioavailability are mostly impacted by interactions with water and oxide and (oxy)hydroxide surfaces. In this study, we synthesized and characterized metal-substituted (Cd, Pb) goethite[1]. Dissolution experiments were performed with or in the absence of CO_2 and $CaCO_3$ at two different temperatures (room and 60°C). This study provides data from small-scale, short-term tests involving direct release of CO_2 in a system in order to provide constraints on potential migration of metals under CO_2 leaking carbon storage areas.

Petrogenesis of Cenozoic plateau lavas from the Pali Aile Volcanic Filed and Morro Chico Volcano, southern Patagonia in South America

MI KYUNG CHOO[1,2*], MI JUNG LEE[1], JONG IK LEE[1], KYU HAN KIM[2] AND KYE-HUN PARK[3]

[1]Korea Polar Research Institute (KOPRI), Incheon, Korea, mkchoo@kopri.re.kr (* presenting author), mjlee@kopri.re.kr and jilee@kopri.re.kr

[2]Ewha Womans University, Seoul, Korea, kyuhan@ewha.ac.kr

[3]Pukyong National University, Busan, Korea, khpark@pknu.ac.kr

Geochemical and Sr-Nd-Pb isotopic analyses of late Miocene to Quaternary plateau lavas from the Pali Aike Volcanic Field (PAVF) and Morro Chico Volcano (MCV) (52°S) were undertaken to constrain the melting processes and mantle sources that contributed to magma generation and the geodynamic evolution of southernmost Patagonia, South America. The PAVF and MCV lavas are alkaline (PAVF, 45–49 wt% SiO_2; 4.3–5.9 wt% Na_2O+K_2O) and subalkaline (MCV, 50.5–50.8 wt% SiO_2; 4.0–4.4 wt% Na_2O+K_2O), relatively primitive mafic volcanic rocks that have typical intraplate ocean island basalt-like signatures. Incompatible trace element ratios and isotopic ratios of the PAVF and MCV lavas differ from those of the majority of Neogene southern Patagonian slab window lavas in showing more enriched characteristics and are similar to high-μ (HIMU) end-member basalt. The REE melting model suggests that these lavas were produced by low degrees of partial melting of a garnet lherzolite mantle source. The major systematic variations of Sr-Nd-Pb isotopes in southern Patagonian lavas are related to geographic location. The PAVF and MCV lavas from the southernmost part of Patagonia have lower $^{87}Sr/^{86}Sr$ and higher $^{143}Nd/^{144}Nd$ and $^{206}Pb/^{204}Pb$ ratios, relative to most of the southern Patagonian lavas erupted north of 49.5°S, pointing to a HIMU-like signature. An isotopically depleted and HIMU-like asthenospheric domain may have been the main source of magmas in the southernmost part of Patagonia, suggesting the presence of a major discontinuity in the isotopic composition of the asthenosphere in southern Patagonia. On the basis of geochemical and isotope data and the available geological and geotectonic reconstructions, a link between the HIMU asthenospheric mantle domain beneath southernmost Patagonia and the HIMU mega-province of the southwestern Pacific Ocean is proposed.

Organic matter effects on xenobiotic sorption at critical zone interfaces

JON CHOROVER

School of Earth and Environmental Sciences, University of Arizona, Tucson, Arizona US. chorover@cals.arizona.edu

Processes ranging from rhizosphere exudation to anthropogenic wastewater discharge result in infusion of reduced carbon compounds into the upper critical zone. This drives incongruent (bio)weathering reactions toward products that include neo-formed secondary minerals and their nanoparticulate complexes with natural organic matter. Mobility of these colloids in soil pore water depends on system hydrochemistry and microbial response. Increasingly thrust into the mix are organic micropollutants (OMPs) from human activity. Several research groups have been documenting a widespread distribution of OMPs in watersheds worldwide. These include endocrine disrupting compounds that exhibit biological effect even at trace concentration We hypothesize that the fate of these micropollutants is coupled to their interfacial reactivity with bio-inorganic products of critical zone weathering.

Since many OMPs released to the environment are polar and/or ionic, their fate is often controlled by interfacial reactions that are highly sensitive to OMP and surface functional group composition and charge, with strong dependence on solution chemistry of contaminant sorptive partitioning. Such reactions are also affected by aqueous phase OMP complexation with solutes including dissolved organic matter (DOM). Ternary OMP-DOM-surface reactions may be particularly important in microbially-active pore waters where DOM enters and exits the aqueous phase, and where mineral surfaces are often masked by biomolecular coatings resulting from DOM sorptive fractionation.

Given the known capability of OM constituents to form aggregated “supramolecular” structures, we postulate that OMPs may enter into DOM aggregates by similar modes of association. Many OMPs possess polar, ionic and/or hydropobic functional groups like those of DOM components, and so processes such as H-bonding, cation bridging, and hydrophobic interaction that promote DOM aggregation are likely to also sequester OMPs. This should, in turn, affect OMP reactivity toward surfaces and, by extension, environmental transport. For example, we have shown via aqueous infusion experiments that effective separation and quantification of OMPs via LC-MS/MS methodologies are diminished in DOM-containing solutions (Wickramasekara et al., 2012). Additional model systems experiments under controlled laboratory conditions show that various DOM fractions differently affect the partitioning of OMPs in aqueous solutions monitoried by LC-MS/MS. To help identify the DOM components involved in OMP interaction, we measured OMP-induced quenching of bulk and DOM fraction fluorescence (Hernandez-Ruiz et al., 2012). Results of several types of experiments indicate a strong role of hydrophilic acid DOM fractions in complexing the target analytes. The effect of DOM on OMP reaction at mineral surfaces is being investigated, to assess its impact on sorptive uptake and release of OMPs in natural systems.

In situ observations on the crystallization of spodumene from aqueous solutions in a hydrothermal diamond-anvil cell

I-Ming Chou[1]*, Jiankang Li[2], Shunda Yuan[2], and Robert C. Burruss[1]

[1]US Geological Survey, Reston, Virginia, U.S.A.
imchou@usgs.gov (*I-Ming Chou); burruss@usgs.gov
[2]Chinese Academy of Geological Sciences, Beijing, China
Li9968@126.com; sdyuan011981@yahoo.com.cn

Crystallization experiments were conducted in a new type of hydrothermal diamond-anvil cell (HDAC; type V) using $LiAlSi_2O_6$ (S) gel and H_2O (W) as starting materials. The sample chamber is a hole (0.1 mm diameter) at the center of a Re gasket (0.3 mm diameter and 0.25 mm thick), sealed by compressing the gasket with two parallel diamond anvil faces. A total of 21 experiments were performed at temperatures up to 950 °C and pressures up to 788 MPa. In the samples with relatively high S/W ratios, many small crystals formed in the melt phase during cooling. Those with low S/W ratios, only few crystals with smooth surfaces crystallized from the aqueous fluid in the presence of melt droplets, which were gradually consumed during the growth of the crystals, indicating rapid transfer of material from the melt to the crystals through the aqueous fluid. The nucleation of crystals started at 710 (±70) °C and 520 (±80) MPa, and crystal growth ended at 570 (±40) °C and 320 (±90) MPa, with the cooling *P-T* path within the stability field of spodumene + quartz in the S-W system. The observed linear crystal-growth rates in the aqueous phase, calculated by dividing the maximum length of a single crystal by the duration of the entire growth step [1, 2], were 4.7×10^{-6} and 5.7×10^{-6} cm/s for the cooling rates of 0.5 and 1°C/min, respectively.

Our results show that when crystals nucleate in the aqueous instead of the melt phase, there are fewer nuclei formed, and they grow much faster due to low viscosity of the aqueous fluid, which accelerates diffusion of components for the growth of crystals. Therefore, the large crystals in pegmatite most likely crystallized from aqueous fluids instead of hydrosilicate melt. This conclusion was further supported by our homogenization experiments in HDAC for crystal-rich inclusions in spodumene from Jiajika lithium pegmatite deposit in China. During heating, decrepitation of the fluid inclusions was prevented by applying external pressures (2.7 to 5.6 MPa) to the inclusions in the sample chamber of HDAC. In these inclusions, the H_2O-CO_2-NaCl fluid phase homogenized at ~290 ℃, followed by the melting of zabuyelite and other daughter minerals (i.e., quartz, calcite, spodumene, and unidentified minerals) during heating. Finally, the melt dissolved totally into the H_2O-CO_2-NaCl fluid, which represents the "boundary-layer liquid" [3, 4] from which the host spodumene crystallized. In other words, the spodumene crystals in the Jiajika pegmatite deposit crystallized from flux-rich aqueous fluids instead of hydrosilicate melt.

On using natural chemical and isotopic tracers to monitor fracture surface area evolution in enhanced geothermal systems

John N. Christensen[1*], Giuseppe D. Saldi[1], Nicolas F. Spycher[1], Kevin G. Knauss[1], and B. Mack Kennedy[1]

[1]Lawrence Berkeley National Laboratroy, Berkeley, CA;
JNChristensen@lbl.gov; GDSaldi@lbl.gov; NSpycher@lbl.gov;
KGKnauss@lbl.gov; BMKennedy@lbl.gov (* presenting author)

It has been proposed, and various trials are taking place, to inject fluids into geothermal systems to stimulate fracturing and hence increase fluid flow and heat-exchange efficiency in such enhanced geothermal systems (EGS). We are investigating a new approach to detect increases in fracture surface area in reponse to geothermal well stimulation using natural chemical and isotopic tracers. Our working hypothesis is that freshly-created fracture surfaces are out of chemical and isotopic equilibrium with newly flowing fluids, and thus subsequent mineral dissolution and precipitation generate transient chemical and isotopic signals that can be monitored in production wells. Such signals in turn could be interpreted through reactive transport modeling to infer induced changes and the temporal evolution of reservoir fracture reactive surface and permeability.

To test this hypothesis, a series of laboratory hydrothermal experiments were conducted using altered rhyolitic tuff from core taken at the Desert Peak geothermal field in Nevada, an EGS site. Two kinds of reactivity experiments were conducted at differing water-to-solid ratios: crushed tuff of variably sized fractions (600-710, 150-180 and 63-75 μm) and a solid rock wafer. These experiments were conducted in flexible Au bag autoclaves that allow multiple acquisitions of fluid/gas samples during experiments without perturbations of temperature and pressure conditions. Experiments were run from 15 to 60 days at 220˚C and 100 bars to maintain a single fluid phase. The initial fluid was high purity water, spiked with NaCl (0.1 M). Periodically during the experiments, fluid samples were drawn off and anlyzed for chemical and isotopic (e.g. $^{87}Sr/^{86}Sr$) composition. In batch experiments with 600-710 μm sized rock fragments, $^{87}Sr/^{86}Sr$ rose over the first several days then subsequently declined, followed by several reversals in trend over the next 6 days. Overall, $^{87}Sr/^{86}Sr$ roughly follows the Rb/Sr trend. In contrast, with the rock wafer experiment, after initially falling, $^{87}Sr/^{86}Sr$ increased along with Rb/Sr for sixty days. In the case of both experiments, the Sr concentration of the fluid fell or held steady despite changing $^{87}Sr/^{86}Sr$, suggesting the precipitation of Sr bearing phases concomitant with dissolution of primamy rock minerals (e.g., plagioclase, k-spar) and/or their alteration products (e.g., carbonates) with a range of $^{87}Sr/^{86}Sr$. A flow-through experiment with 600-710 μm material exhibited similar behavior. Simulations of the experiments using geochemical and reactive transport models are being conducted to investigate the types of reactions taking place and their dependence on solid-to-water ratios. Preliminary results indicate that plagioclase dissolution is accompanied by precipitation of Al hydroxides, zeolites/clays, secondary feldspars and calcite, yielding fluid composition trends that are sensitive to initial water/rock ratios.

Review of issues associated with evaluation of Pitzer interaction parameters

CHRISTOMIR CHRISTOV[1], MIN ZHANG[2*], STEPHEN TALMAN[2], ERIC REARDON[3], TAMMY YANG[4]

Aqueous geochemical models that predict solid and gas equilibria over a broad range of water compositions and temperatures are powerful tools for studying the geochemistry of natural waters, solving environmental problems and optimizing industrial processes. The Pitzer ion interaction model has been widely accepted as the most effective approach to predict chemical behaviour in concentrated solutions; however, the description of natural waters requires a large compilation of interaction parameters. These parameters are derived from experimental data such as isopiestic, electrochemical, and solubility measurements on simpler systems.

In this study, a large number of binary systems have been evaluated to understand issues which could potentially compromise the representation of more complex solutions. The results revealed that the concentration range within which Pitzer parameters are derived, together with the aqueous species that are included in the model, and the accuracy of temperature coefficients are of most importance.

For a system that is parameterized over a limited concentration range, model predictions may deviate substantially from the experimental data outside this range, as shown in many binary salt systems of interest in environmental studies such as CaI_2, CsF, $NiCl_2$, $CuCl_2$, $ZnCl_2$, and $Th(NO_3)_2$. Further evaluations of parameters within a chemical system will be hampered if any of the data points used in evaluating new parameters fall outside this concentration range. In particular, the new introduced parameters may be biased to compensate for inaccuracies in the original model rather than real chemical effects. It is possible to reduce the potential for introducing such systematic errors into an analysis by ensuring that the parameterization is valid up to the saturation limit of binary solids, and even to supersaturated conditions, if possible.

The standard Pitzer approach treats electrolytes as being completely dissociated. In some instances ionic species can be incorporated into the model; however, the addition of ion pairs and complexes into the solution model requires the determination of interaction parameters between these new species and each of the other species in solution. In addition, inclusion of ion pairs and complexes may compromise the model when moving away from the concentration range at which the model was derived. The ideal approach is to rely on the additional parameter $\beta^{(2)}$ to account for the effect of ion pairing or complexing in solution but this may not always be possible. However, it has been successfully demonstrated for the $NdCl_3$-H_2O system, where the new model was able to eliminate $NdCl^{2+}$ and $NdCl_2^{+}$ species used in early development.

Os-Hf-Nd-Sr isotopic constraints on the origin of highly potassic basalts in northeast China

[1]State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, P. O. Box 9825, Beijing 100029, P. R. China, e-mail: zhychu@mail.iggcas.ac.cn (* presenting author)
[2]College of Earth Sciences, Jilin University, Changchun 130026, China

The very young (about 0.6Ma-1721AD) Wudalianchi (WDLC) and Erkeshan (EKS) basalts in northeast (NE) China are characterized by high K_2O contents ($K_2O/Na_2O>1$) and strong enrichment in incompatible elements, especially the large ion lithophile elements (LILEs) and light rare earth elements (LREE) and are isotopically similar to EM-I, which differ from the basalts in eastern China elsewhere. The origin of these WDLC and EKS potassic lavas is still under debate. Here, we present new Re-Os isotopic data, together with Sr-Nd-Hf isotopic and traditional elemental data to further constrain the origin of the WDLC and EKS potassic lavas. The $^{187}Os/^{188}Os$ ratios of the WDLC and EKS basalts range from 0.1187 to ~0.17. In general, samples with low Os concentrations have high $^{187}Os/^{188}Os$ ratios while samples with high Os concentrations have relatively low $^{187}Os/^{188}Os$ ratios. Since minor amounts of crustal contamination will alter significantly the Os isotopic composition of a basaltic magma with low Os concentrations, it is possible that the WDLC and EKS basalts were contaminated by minor crustal materials during magma ascent. The suprachondritic Os of some WDLC and EKS basalts may also possibly result from preferential melting of a metasomatized mantle peridotites which contain interstitial sulfides that are characterized by low Os concentrations and suprachondritic $^{187}Os/^{188}Os$. Nonetheless, since the WDLC and EKS basalts generally have relatively low $^{187}Os/^{188}Os$ ratios compared to the Cenozoic continental basalts in other localities such as Hannuoba, Columbia River, SE Australia and Central European, we think that the crustal contamination did not play an important role for formation of the WDLC and EKS basalts.

The WDLC and EKS basalts have unradiogenic Hf-Nd and radiogenic Sr isotopic compositions, with εHf range of -3.9 to -9.2, εNd values between -5.8 and -3.2 and $^{87}Sr/^{86}Sr$ ratios between 0.7051 and 0.7057, indicating the contribution of a metasomatized sub-continental lithospheric mantle (SCLM). In term of Os isotopes, the most unradiogenic sample has Os isotopic compositions as low as 0.1187, also confirming the contribution of an ancient SCLM for generation of the WDLC and EKS magmas. This sample gives a T_{RD} model age as old as 1.2Ga, indicating that the SCLM underlying the WDLC and EKS area could be at least as old as Proterozoic.

Consistent with previous reports, these lines of evidences together suggest the WDLC and EKS mainly originated from an anicent metasomatized SCLM.

CO_2 rich springs of the Far East Russia. Composition and Origin

CHUDAEV OLEG[1*] AND KHARITONOVA NATALY[1]

[1]Far East Geological Institute FEB RAS, Vladivostok, Russia
chudaev@fegi.ru*

Introduction

CO_2-rich cold springs are widespread in the Far East Russia. The measured temperatures vary from 5°C up to 10°C. In most cases dissolved oxygen (DO) is close to 0%, which means that the system is isolated from the atmosphere. pH values are in the range of 5.22-6.3. They are mainly of the Ca-Mg-HCO_3 type with high amount of CO_2. Content of elements depends on residence time, type of bedrocks and dissolved CO_2 gas. Over 90% of the cationic species occur as free ion and less than 10% as ion-pairs with HCO_3. Waters of springs are over-saturated with the clay minerals (smectite, illite, kaolinite), low temperature zeolites (heulandites, mordenite, clinoptilolite), and dolomite. Using tritium isotope study we previously showed the young age of these ground waters and the hydrogen and oxygen isotopic ratio suggested meteoric origin. Yet, the origin of CO_2 remained uncertain and is a subject of the present study.

Results and Conclusion

In studied springs dissolved CO_2 ranged from 94% to 99% and the maximum calculated CO_2 partial pressure is 1.7 bar. We hypothesized that the carbon was of magmatic origin. Geological data and young volcanic activities in some areas of location springs support this hypothesis. $\delta^{13}C$ and $^3He/^4He$ data also suggests magmatic origin (up to 70%) for the CO_2 in Primorye (Maritime region of the Russia) springs [1,2]. $\delta^{13}C$ for most studies springs ranged from -4.19‰ to -8.19‰. These values are too high for the CO_2 to have an organic source and too low to be carbon of limestone. They are, however, close to magmatic carbon, but it is difficult to assert that this, because some processes cause fractionation of these carbon isotopes. To solve the problem we sleeked an alternative method to identify carbon source. The ratio of carbon to mantle helium ($C/^3He$) had been used by others in similar situation. [3]. Using this method mantle carbon and atmosphere carbon had ratios of about $2*10^7$ - $2*10^9$ and 10^{12}, respectively. The studied springs had a value close to $2*10^9$, suggesting that most of the carbon in the studied CO_2-rich waters has magmatic origin. Similar deep origin of CO_2 in spring waters had been previously shown in other springs around the world, for example in the Malki CO_2-rich cold springs in Kamchatka [2], in Wudalianchi springs in N-E China [2] and in the springs of San-Andreas fault in California. [4].

Ferrihydrite is a poorly crystalline iron oxide nanomineral (2-7 nm) found in a variety of natural surface environments. Its occurrence is documented at near-neutral pH conditions in a variety of redox-active environments, such as soils and sediments, as well as freshwater and marine settings. As a result of its high surface area and its chemical reactivity, it is an important environmental sorbent, and plays an essential role in the geochemical cycling of pollutant (in)organic species. Under natural aqueous conditions, ferrihydrite precipitates in the presence of several inorganic species such as aluminum, silica, phosphate, etc., or in the presence of organic matter (OM). These impurities can affect the domain size, composition, and molecular-level structure of ferrihydrite, thus modifying fundamental properties that are directly correlated with solid-phase stability and surface reactivity. In this study we have characterized a series of ferrihydrite samples of variable Al, Si, and OM content by laboratory (TEM, chemical extractions, electrophoresis) and synchrotron-based techniques (high energy x-ray total scattering and pair distribution function analysis, scanning transmission x-ray microscopy) in order to place constraints on their short- and intermediate-range structure, their composition, their surface chemistry and association with organic matter. A significant decrease in crystallinity occurred with increasing impurity content. We attribute these changes primarily to the presence of strong binding ligands such as silica and organic matter, both of which are known to affect Fe polymerization and poison particle growth. It is expected that the presence of these ligands at the ferrihydrite surface will alter significantly its surface composition and reactivity in the environment.

Methane has long been a postulated component of the Archean atmosphere, but very little direct evidence exists for this contention. Ecosystem models predict that modest fluxes of methane into reducing atmospheres would result in high concentrations[1], while models of the evolution of atmospheric redox on the early Earth suggest important roles for methane associated with the rise of oxygen[2, 3]. Here, we expand previous photochemical modeling efforts[3, 4] by linking changes in methane concentration to observable geochemical signatures. In a suite of reducing model atmospheres, we increase concentrations of methane until an organic haze forms. Using particles which scatter using both classical Mie physics as well as newly postulated fractal scattering behavior [5], we find that the Archean atmosphere would exhibit bi-stability between a "clear skies" case and one with a thin organic haze. The photochemical modeling further demonstrates that the presence of the thin organic haze would significantly affect the fractionation of minor isotopes of sulfur (mass-independent fractionation of sulfur or S-MIF) by both UV opacity effects and by changing the redox chemistry of S species in the atmosphere. The prediction of an Earth system with correlated changes in methane concentration and variations in S-MIF is evident in new data from the Campbellrand-Malmani platform of South Africa [6], which indicate multiple appearances of organic haze due to a methanogen-driven high CH_4:CO_2 ratios [4] in the late Neoarchean. These combined results provide stronger evidence for a role for methane in the Neoarchean atmosphere, and support arguments that the Great Oxidation Event may have been related to the the disappearance of a large biological flux of methane [3].

Evidence for the physical conditions under which the Earth's crust can generate large volumes of magma is provided by metamorphic rocks that represent the solid residue of partial melting and chemical differentiation. Many of these rocks preserve mineral assemblages stabilised at very high-temperature and moderate pressure conditions that lie above the dry solidus for most crustal rock types. These ultra-high temperature (UHT) metamorphic rocks can only be formed after substantial degrees of partial melting and, although originally regarded as isolated thermal anomalies, there is increasing evidence that continental crust has attained UHT conditions repeatedly in time and space. Our ability to quantify this metamorphic record as absolute temperature-depth information has increased dramatically over the last 40 years with improved thermodynamic constraints on the pressure-temperature stability of mineral assemblages. At the same time, development of mathematical models for the thermal behaviour of continental crust has allowed us to compare pressure-temperature data from real metamorphic rocks with geothermal gradients predicted for simple tectonic settings, and identify possible causes of elevated metamorphic temperatures. While these thermal models can reproduce conditions recorded by the majority of metamorphic rocks, UHT metamorphism remains difficult to replicate with standard numerical models for orogenesis. In this contribution, we examine a number of heat sources that might account for these extreme temperatures and investigate the link between UHT metamorphism and magma generation.

Erosion of organic matter in a tropical mountain catchment: Implications for carbon delivery from the Andes to the Amazon River

Mountain rivers play a key role delivering carbon in particulate organic matter (POM) to large fluvial systems and the coastal ocean. In the case of the Amazon, one of Earth's most important biogeochemical systems, ~40% of the POM transported by the main river is thought to be derived from the Andes [1]. Nonetheless, we have poor constraint on POM sources delivered by tropical mountain rivers, particularly in sediment-laden flood waters. POM derived from vegetation and soil contains recently sequestered atmospheric CO_2 and exports nutrients downstream. In contrast, POM derived from bedrock may be a CO_2 source and supply nutrients downstream.

Here, we address these issues in the Peruvian Andes. We combine hydrometric measurements (water discharge) and frequent sampling of suspended sediments (every 3 hrs) during flood events in 2010, at two gauging stations (2250 masl and 1350 masl) on the Kosñipata River. We use elemental ($\%C_{org}$, %N) and stable isotope composition and radiocarbon content of the organic carbon ($\delta^{13}C_{org}$, $\delta^{15}N$, $\Delta^{14}C_{org}$) to quantify POM sources [2]. $\delta^{13}C_{org}$ vs. N/C and $\Delta^{14}C_{org}$ demonstrate binary mixing of POM derived from fossil and non-fossil (soil and vegetation) sources. Mixing analysis allows us to quantify the proportion of fossil particulate organic carbon (POC_{fossil}) and bedrock-derived nitrogen ($PN_{bedrock}$), and allows us to identify the $\delta^{13}C_{org}$ and $\delta^{15}N$ of POM derived from the terrestrial biosphere.

We find that POC_{fossil} contributes ~40% of the total river POC. We also show, for the first time, that $PN_{bedrock}$ completely dominates the riverine particulate nitrogen load, comprising over 70%. Until now, the bedrock contribution to Andean river POM has been overlooked, and our findings provide impetus for further investigation. In addition, our measurements allow the contributions of POM from vegetation and soil to be isolated. They demonstrate that during the rising limb and peak discharge of floods, POM was mobilised predominately from upper (O_H) soil horizons, with important additional input from live vegetation. The results suggest an important climatic control on the erosion and export of carbon derived recently from atmospheric CO_2.

Igneous and metamorphic garnet-clinopyroxene assemblages in eclogite and granulite, Breaksea Orthogneiss, New Zealand: major and rare earth element characteristics

CLARKE, G.L.[1],*, DACZKO, N.R.[2] AND MIESCHER, D.[2]

[1]School of Geosciences, FO9, University of Sydney, Sydney, NSW, 2006, Australia, geoffrey.clarke(at)sydney.edu.au (* presenting author)
[2] GEMOC ARC National Key Centre, Department of Earth and Planetary Sciences, Macquarie University, NSW 2109, Australia

Eclogite and omphacite granulite, interlayered on cm- to decameter-scale, form most of the Cretaceous Breaksea Orthogneiss, which experienced peak conditions of P≈1.8 GPa and T≈850°C. It is the highest grade part of the c. 125–115 Ma Western Fiordland Orthogneiss. A gneissic fabric in the host orthogneiss truncates igneous layering in coarsely layered, decametre-scale clinopyroxenite and garnetite inclusions. Field and microstructural relationships, together with rare earth element (REE) characteristics across a broad range of rock types permits the conclusion that most garnet is of igneous origin; geochemical data alone are ambiguous. Igneous diopside persists in coarse-grained, weakly deformed samples. Garnet cores in garnetite, and late-formed garnet rims in garnetite and clinopyroxenite have a range of REE contents interpreted to reflect cumulate processes involving continued grain growth isolated from the parent magma. Clear rims on inclusion- and Ca-Tschemakite-rich diopside in clinopyroxenite of composition distinct to grain cores are interpreted as recrystallization features. Garnet in granulite occurs in three textural settings, the most common Type 1 garnet having REE characteristics identical to garnet in eclogite, but depleted in heavy REE relative to garnet in garnetite. Type 2 garnet in granulite forming metamorphic coronae on omphacite has a pronounced positive Eu anomaly and is depleted in heavy REE compared with Type 1 garnet. Type 3 garnet in granulite migmatite is indistinguishable from Type 1 garnet, consistent with formation through magma injection.

Kinetics of $CO_{2(g)}$-$H_2O_{(l)}$ isotopic exchange, including $^{13}C^{18}O^{16}O$

MATTHIEU CLOG[1*], JOHN EILER[1]

[1]California Institute of Technology, Pasadena CA, USA, eiler@gps.caltech.edu (* presenting author)

The analysis of mass 47 isotopologues of CO_2 (mainly $^{13}C^{18}O^{16}O$) is established as a constraint on sources and sinks of environmental CO_2, complementary to $\delta^{13}C$ and $\delta^{18}O$ constraints, and forms the basis of the carbonate 'clumped isotope' thermometer. This measurement is commonly reported using the Δ_{47} value — a measure of the enrichment of doubly substituted CO_2 relative to a stochastic isotopic distribution. Values of Δ_{47} approach 0 (a random distribution) at high temperatures (≥ several hundred degrees C), and increase with decreasing temperature, to ~1 ‰ at 25 ˚C.

While the thermodynamic properties of doubly substituted isotopologues of CO_2 (and, similarly, carbonate species) are relatively well understood, there are few published constraints on their kinetics of isotopic exchange. This issue is relevant to understanding both natural processes (e.g., photosynthesis, respiration, air-sea or air-groundwater exchange, CO_2 degassing from aqueous solutions, and possibly gas-sorbate exchange on cold planetary surfaces like Mars), and laboratory handling of CO_2 samples for Δ_{47} analysis (e.g., re-equilibration in the presence of liquid water, water ice or water adsorbed on glass or metal surfaces).

We present the results of an experimental study of the kinetics of isotopic exchange, including changes in Δ47 value, of CO_2 exposed to liquid water between 5 and 37 ˚C. Aliquots of CO_2 gas were first heated to reach a random distribution of its isotopologues and then exposed at low pressure for controlled periods of time to large excesses of liquid water in sealed glass containers. Containers were held at 5, 25 and 37°C and durations of exchange ranging from 5 minutes to 7 days. To avoid the formation of a boundary layer that might slow exchange, the tubes were vigorously shaken during the period of exchange. At the end of each experiment, CO_2 gas was recovered from the head space of the reaction vessel, purified and analyzed for its Δ_{47}, $\delta^{13}C$ and $\delta^{18}O$ by gas source isotope ratio mass spectrometry.

Equilibrium was reached for both $\delta^{18}O$ and Δ_{47} after durations of few tens of hours. $\delta^{18}O$ values at equilibrium were consistent with known fractionation factors for the CO_2-H_2O system. The evolution of $\delta^{18}O$ and Δ_{47} with experiment duration was fitted with an exponential rate law, yielding rate constants equal to each other (within error), averaging 0.18 h^{-1} at 5°C and 0.29 h^{-1} at 25°C. We calculate an activation energy for this isotopic exchange reaction of 16kJ/mol. By comparison, Mills and Urey (1940) measured the rate of ^{18}O exchange between CO_2(aq) and water to have a rate of 11 h^{-1} at 25 ˚C and an activation energy of 71.7 kJ/mol. Our finding of a slower rate and lower activation energy is consistent with the rate limiting step of our experiment being the CO_2(g)—CO_2(aq) exchange. Our experiments also define the path through $\delta^{13}C$— $\delta^{18}O$— R^{47} composition space (where R^{47} is the ratio of mass 47 to 44 isotopologues) followed by CO_2 gas during exchange with water. The stochastic distribution is a curved surface in composition space, hence changes in composition of CO_2 during exchange with water may, in some circumstances, yield distinctive co-variations in Δ_{47} and $\delta^{18}O$. This may be relevant for the study of vital effects and other natural processes in which CO_2 and DIC species depart from local isotopic equilibrium.

Unravelling the paragenesis at one of Australia's highest-grade gold deposits

J. CLOUTIER[1*], J.L. WALSHE[1], R. HOUGH[1], A. BATH[1] AND R. HUTCHISON[2]

[1]CSIRO Earth Science and Resource Engineering Australian Resources Research Centre, 26 Dick Perry Avenue, Kensington, Western Australia 6151, Australia. (*correspondence: Jonathan.Cloutier@csiro.au)

[2]Ramelius Resource, Level 1, 130 Royal Street, East Perth WA 6004

Australia's currently producing highest-grade gold deposit, (ave. 19.7g/t Au), the Archean Wattle Dam deposit, is located in the Yilgarn Craton of Western Australia. Despite its obvious importance, very little is understood about its formation. In the current study we report on a paragenetic framework for the deposit, mineral zoning, conventional optical petrography, SEM and stable isotope data of carbon, oxygen and sulphur. These data record important characteristics of ore-forming fluids and aid with the development of accurate genetic and exploration models.

The Wattle Dam deposit is hosted within a 350m thick amphibolite grade ultramafic unit which is bounded by a 400m thick metasedimentary unit to the west [1]. The alteration envelope surrounding the main lode is gradational and extends up to 10m. The Wattle Dam deposit is atypical as it lacks quartz veining and a low gold-grade envelope surrounding the main mineralisation normally associated with other Archean gold deposits [1].

A paragenetic study of the ultramafic rocks reveals a peak metamorphism assemblage consisting of actinolite, hornblende and plagioclase followed by a patchy calcite overprint of the peak metamorphism assemblage and by retrograde metamorphism clinochlore. These assemblages were overprinted during the main alteration event which culminated with the creation of the Wattle Dam gold deposit. The main alteration event consists of the precipitation of early calcite ± pyrite veins followed by tschermakitic amphiboles, biotite, clinochlore (possibly enriched in Fe3+) and by late coarse-grained gold nuggets (quartz-free), pyrrhotite, pentlandite and breithauptite (NiSb) in veins. Dolomitisation of calcite veins and serpentinisation and talcification of the ultramafic rock were observed post-mineralisation.

Stable isotope values vary between -5.5 to -2.7‰ (VPDB) for $\delta^{13}C_{Cal2}$, +10.7 to +15.0‰ (VSMOW) for $\delta^{18}O_{Cal2}$ and +3.85 to +5.23‰ (VCTD) for $\delta^{34}S_{Py}$ distal to the deposit while elevated $\delta^{13}C_{Cal2}$ (-0.3‰) and $\delta^{18}O_{Cal2}$ (+18.1‰) were observed proximal to the deposit within the main lode. These elevated values combined with the presence of pyrrhotite, the lack of clear alteration selvages around gold nuggets and the lack of quartz within the main lode are consistent with a reduced vapour-rich, relatively water-poor environment in which $CO_{2(g)}$ is partially reduced to $CH_{4(g)}$ during the main-stage of alteration.

Tracing land use controls on silica dynamics in the soil-vegetation continuum

WIM CLYMANS[1,*], GERARD GOVERS[1], ELISABETH FROT [2], BENEDICTA RONCHI[1], BAS VAN WESEMAEL[2], ERIC STRUYF[3] AND DANIEL J. CONLEY[4*]

Bio-available silica (Si) is a key element in global biogeochemical cycling. In terrestrial ecosystems plants take-up dissolved silica (DSi), and form plant Si-bodies called phytoliths [1]. Upon die-off these return to the soil as amorphous silica (ASi), which dissolves far more easily than mineral silica. This dissolved Si is prone to recycling by vegetation, biological (e.g. bio-mineralisation) and/or pedogenic processes (e.g. precipitation or adsorption), but part of it is lost to aquatic systems [2]. Changes in the biological component of the Si cycle may lead to more rapid variations in the land-ocean Si transfer than previously thought [3].

The objective of this study is to contribute to understanding of the controls on temporal Si dynamics in terrestrial ecosystems, by studying Si budgets (fluxes and pools) from a small forested catchment and human disturbed catchments in central Belgium. Si is used as a tracer to determine pathways, and to assess land use control. Detailed concentrations and load patterns (2008-2010) of bio-available Si in pore-water, streams and soils made it possible to determine the different processes causing variation in kinetic equilibrium of DSi with land-use.

For the forested catchment, which is used as a reference, discharge-concentration relationships made it possible to distinguish the main processes responsible for Si dynamics during runoff events: (1) within-channel mobilization controls ASi-delivery, and (2) a dilution-flushing effect controls DSi-delivery. End-member mixing analysis showed that at up-stream catchments base-flow delivers 92.5±10% of the water, and a chemostatic behavior confirms the existence of an important kinetic equilibrium at the catchment scale.

In contrast, disturbed catchment tend to be less chemostatic, and had a significant lower kinetic Si equilibrium and bio-available Si pool (up to three times). This is explained by a perturbation of the interactions in the critical zone: a reduced Si restitution, increased Si leaching, reduced chemical weathering and conversion to less labile Si forms in severely disturbed catchments. Lower final bio-available Si delivery from disturbed catchments indicate a lower importance of subsurface delivery which is not compensated by increased overland sources. Land-use controls on Si pathways together with biological and pedological interactions were conceptualized. We show that deforestation of the catchment, as has historically taken place elsewhere in temperate regions, would drastically alter the the Si dynamics of the catchment.

Metal evolution during differentiation of calc-alkaline magmas (Hunter Ridge, SW Pacific)

GISELA COBENAS[1]*, LEONID DANYUSHEVSKY[1], TREVOR FALLOON[1]

[1]CODES, ARC, Centre of Excellence in Ore Deposits, University of Tasmania, Hobart, Australia,
gcobenas@utas.edu.au(* presenting author)
l.dan@utas.edu.au
trevor.falloon@utas.edu.au

Understanding the behaviour of metals during magmatic differentiation processes helps constrain the important of parental magma composition for the potential fertility of a particular magma series, i.e. whether the association of an ore deposit with a specific magma type is due to the metal-rich parental magma, or is a consequence of later processes.

Rock samples collected from the Hunter Ridge (North Fiji Basin) include a typical island-arc calc-alkaline suite that covers a very broad range of rock MgO contents (1-14 wt.%) (Fig. 1). Phenocrysts in these samples have highly variable compositions (i.e. olivine Fo 79-95, clinopyroxene Mg# from 70-92, plagioclase An 22-92). Magnesian olivine and clinopyroxene record early, pre-eruptive stages of fractionation.

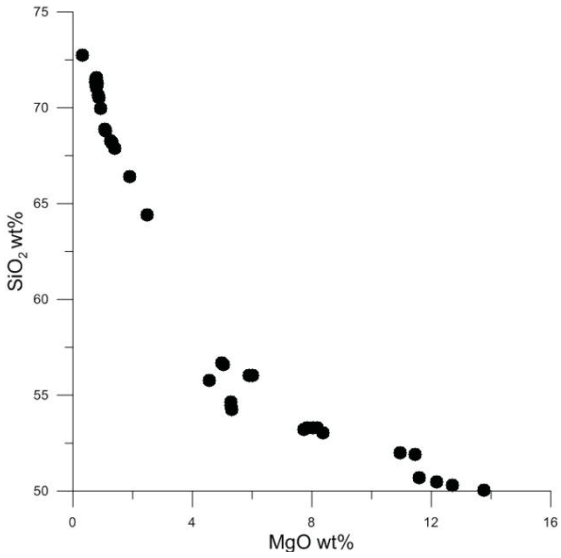

Figure1: SiO_2 wt% vs MgO wt% contents of calc-alkaline lavas from the Hunter Ridge.

In order to constrain the behaviour of metals (Cu, Zn, Pb, Co, Ni, and others) during magma fractionation, we have analysed their content in phenocrysts formed at various stages of magmatic fractionation using LA-ICPMS. A comparison of their behaviour with a wide range of lithophile elements allows for 1) a better constraint on the relative incompatibility of various metals during crystallisation processes and 2) on their distribution between immiscible phases such as fluids and sulphide melts at different stages of magma evolution.

Our results indicate that partitioning between silicate melts and water-rich fluids can affect the concentration of some metals from the earliest stages of magma evolution at crustal levels.

APATITE U-PB THERMOCHRONOLOGY: AN ID-TIMS AND LA-ICP-MS STUDY FROM SOUTHERN ECUADOR

RYAN COCHRANE[1]*, RICHARD SPIKINGS[1], DAVID CHEW[2] AND JÖRN WOTZLAW [1]

[1] Department of Mineralogy, University of Geneva, Switzerland, ryan.cochrane@unige.ch (* presenting author)

[2] Department of Geology, School of Natural Sciences, Trinity College Dublin, Ireland

Introduction

A combination of U-Pb LA-ICP-MS and ID-TIMS analyses of apatite has been used to investigate the high temperature (>450°C) thermal history of the Ecuadorian Andean margin. The rocks of the Eastern Cordillera of Ecuador evolved via Mesozoic terrane collision and accretion events, and intermittent active margin magmatism since the Early Ordovician. Our approach is novel because i) previous U-Pb thermochronological studies [1, 2] focused on the construction and stabilization of Precambrian cratons, whereas our study tests the applicability of U-Pb apatite thermochronology to relatively young rocks, and ii) we apply an inverse modeling technique to search for thermal history solutions to the data.

Apatite LA-ICP-MS and ID-TIMS U-Pb data have been acquired from a Triassic (247.2±4.3 Ma; U-Pb zircon) rift-related granite from southern Ecuador. ID-TIMS data were obtained from fifteen, euhedral apatite size-fractions, with grain radii ranging between 45-175 um, representing a theoretical Tc range of 450–510 °C at cooling rates of 10°C/my. Concordant $^{238}U/^{206}Pb$ dates range between 81.9±0.21 and 137.87±0.27 Ma, and positively correlate with grain size, supporting our hypothesis that Pb loss has occurred via volume diffusion. LA-ICP-MS ^{207}Pb corrected dates have been obtained from apatite size fractions that were fixed to a single epoxy mount. Primary and secondary standard apatites were: i) 92.5 Ma Emerald Lake with a measured weighted mean age of 91.5 ± 1.3 Ma, 2σ (N = 12), and ii) ~523 Ma McClure Mountain Syenite, with a measured weighted mean age of 519.9 ± 4.4 Ma, 2σ (N = 47). The apatite ^{207}Pb corrected dates range from 196.9 ± 11.4 to 69.1 ± 12.1, 2σ (N = 43), with a majority of ages that cluster between 90-100 Ma.

Time (t)-temperature (T) solutions for the data have been generated using a controlled random search procedure provided by the HeFTy software (version 1.7.0; Ketcham, 2011), using the diffusion parameters of Cherniak et al. (1991) [3]. The thermal history solutions simultaneously satisfy apatite ID-TIMS U-Pb ages obtained from six size aliquots. The best fit t-T solutions (Kolmogorov-Smirnoff goodness of fit >0.5) reveal periods of: i) rapid cooling (~240-220 Ma) through the Pb Partial Retention Zone (PRZ) shortly after crystallization, ii) residence at temperatures lower than the PRZ throughout the Jurassic, iii) reheating during 140-90 Ma, and iv) rapid cooling starting at 80-70 Ma. These solutions corroborate conclusions based on geochronological and sedimentological data. Additional in-situ age transects of apatite are scheduled to further determine the concentration and mechanisms for the distribution of radiogenic lead in the apatites.

A Plausible relationship between D/H in primitive Solar System organic solids, their origin, and their associated water

G. D. CODY[1*], Y. WANG[1], Y. KEBUKAWA[1], M. L. FOGEL[1], C. M. O'D. ALEXANDER[2].

Primitive extraterrestrial organic solids such as are present in type 1 and 2 chondrites (Insoluble Organic Matter, IOM, and Interplanetary Dust Particles (IDPs) are typically enriched in deuterium relative to terrestrial water, in some cases as much a 4 or more times so. The origin of such enrichment has predominantly been accepted to be a signature of a very low temperature origin of organic solids and/or their lower molecular weight precursors. Analyses of a wide range of pure IOM isolated from many different meteorites reveals no systematic relationship between IOM structure and D/H. Whether one plots D/H against H/C or the fraction of aromatic carbon, no obvious trends emerge [1]. A recent exception to this is observed with the Tagish Lake Clasts that reveal a very systematic variation in D/H with H/C [2]. We have been integrating materials characterization and laboratory based experimentation to address both the origins of primitive organic solids and gain improved understanding of the molecular nature of D/H abundances in context with gaining insight on fate of volatiles during early Solar System evolution. Towards this end we have proposed and demonstrated a likely route from interstellar formaldehyde to organic solids in comets, IDPs, and primitive chondrites [3]. We have also developed the capacity to detect deuterium speciation amongst different organic functional groups within organic solids. We find that comparison of D speciation with H speciation reveals a characteristic (apparent) intra-molecular fractionation that informs us how initial D/H enrichment reflects the environment of formation of organic solids. Finally, laboratory experiments investigating D-H exchange kinetics provide an essential understanding of why D/H in organic solids is what it is and may explain D/H variation in cometary water. It is clear that the early evolution of IOM sets the initial D/H, whereas subsequent evolution during hydrothermal processing in the parent body may affect a secondary evolution in D/H.

Revealing the signature of ancient biochemistry with Soft X-rays

G. D. CODY[1]

[1]Geophysical Laboratory, Carnegie Institution of Washington, Washington, DC

The preservation of organic fossils extends back to the dawn of the Cambrian. Notwithstanding such an extent of preservation, the preservation of intact or molecularly identifiable biological molecules extends only a much shorter interval of time, 10's of millions of years. The preservation potential of organic fossils is related to the emergence of recalcitrant biopolymers, e.g. polysaccharides and in the case of vascular plants, lignin. The disappearance of a molecular signal of discrete biopolymers results from diagenetic molecular transformation, either through thermogenic and/or microbial processes. Over the past decade we have been developing the use of Scanning Transmission X-ray microscopy (STXM) and micro-spectroscopy utilizing the fine absorption fine structure on carbon's, nitrogen, and oxygen K-edges, i.e. X-ray Absorption Near Edge Structure (XANES) spectroscopy. Exploiting the high-energy resolution of the STXM monochromator (5000 ΔE/E) and the spatially resolving power of the soft X-ray optics (25 nm) has allowed us to explore sub-micron biochemical complexity that is preserved in ancient organic fossils. Our goal has been to use the signature of sub-micron chemical differentiation to address issues related to biochemical evolution; e.g. searching for the evolutionary emergence of lignin by studying the fossil record of extinct plants near the phylogenetic root of plants [1]. Most organic fossils, either derived from arthropod cuticle or vascular plant tissue have been subjected to considerable molecular modification, yet with a judicious choice of absorption energy, remnant chemical differentiation can be still observed. Chemical differentiation is a hallmark of tissue that was originally composed of two or more biopolymeric material. For example, lignin and cellulose in the case of vascular plant tissue. Traditionally, the loss of characteristic spectroscopic and/or molecular features associated with polysaccharide was interpreted to suggest that all carbon associated with polysaccharide had been removed from the organic fossil. Thus, distorting understanding of the nature of the actual molecular transformation chemistry. Studies employing STXM and micro-XANES now reveal a more complex story in which the presence and retention of a substantial amount of polysaccharide derived carbon is an essential aspect of organic matter preservation in ancient organic fossils [2].

Objective mapping of the geographical distribution of εNd in seawater and outlook for past and present Nd budget in the oceans

ANTOINE COGEZ[1*], GAEL FORGET[2], CLAUDE ALLÈGRE[1], LAURE MEYNADIER[1] AND CARL WUNSCH[2]

[1]Equipe de Géochimie et Cosmochimie, Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Univ Paris Diderot, UMR 7154 CNRS, F-75005 Paris, France, cogez@ipgp.fr (* presenting author)

Neodymium (Nd) isotope composition (expressed in εNd notation, in per 10 000) in sediment cores are commonly used in paleoceanography and paleoclimatology to reconstruct changes in ocean circulation and/or continental weathering over the last thousands to tens of millions of years. A good understanding of the present processes affecting the transport of Nd in the oceans, the different sources and their relative influence is a prerequisite for its use in paleoceanography.

We compiled all the present data available for direct seawater measurements and authigenic fractions of core-top sediments in order to plot up-to-date interpolated maps displaying a depth averaged as well as a the deep distributions of present seawater εNd, using optimization methods. We observe clear patterns of Nd injections in the different basins, especially the clearly distinct isotopic signature of the different basins, the deep Atlantic circulation, the deep circum Antarctic water masses penetrating Pacific ocean, the Indonesian througflow into the Indian ocean, the Iceland local influence, the Himalayan rivers discharge, the East Pacific Rise local contribution… We also compared this distribution to an interpolated map of detrital εNd data, which show similar patterns. The misfits obtained help us to discuss what both types of data (sediments and seawater measurements) really tell us in such an approach.

All these observations lead us to distinguish different geographical groups consistent with εNd distribution, and to conclude on the major role of the rivers as source of Nd in seawater, the important vertical transfer in the water column from the superficial layers to the bottom and the limited exchange of Nd between the different ocean basins, due to a short residence time. These conclusions lead to conceptualize a model on Nd cycling in the oceans that will be presented in a joint paper by C.J. Allègre. Simulations on a coarse box model and on a matricial form of the MIT GCM are still in progress and will be helpful to put this model to the test.

Dating Early Archean partial melting events: whole-rock versus single grain Re-Os ages in 3.81 Ga chromitites from West Greenland

JUDITH A. COGGON[1*], AMBRE LUGUET[1], PETER W. U. APPEL[2]

[1]Steinmann Institut, Universität Bonn, Bonn, Germany, jude@uni-bonn.de (* presenting author), ambre.luguet@uni-bonn.de

[2]Geological Survey of Denmark and Greenland, Copenhagen, Denmark, pa@geus.dk

Abstract

Large melt depletion events in the mantle are recorded in refractory phases and lithologies by the ^{187}Re-^{187}Os isotope system as rhenium-depletion model ages (T_{RD}). Numerous studies have shown that the peaked distribution of these ages coincides with crustal U-Pb zircon ages providing a record of periodic episodes of significant crustal growth over the last ~3 Ga. However, the frequency of T_{RD} ages preserved decreases with time. In order to detect older events it is necessary to analyse samples that were extracted from the mantle before later events were able to dilute or overprint more ancient signals. A >3.81 Ga chromitite-ultramafic layered body from the Ujaragssuit nunât area of western Greenland provides an ideal target for this study. Peridotites (0.303 – 4.02 ppb Os) display U-shaped PGE patterns (Fig. 1) atypical of partial melt depletion, while chromitites exhibit a gentle decrease in chondrite normalised PGE concentration with increasing incompatibility. Both lithologies show anomalously high Re contents, illustrating significant re-enrichment by one or more post-magmatic events (two late Archean metamorphic events have been suggested [1]). T_{RD} ages for whole-rock peridotites and chromitites are artificially low (483 – 2926 Ma and 2666 – 3250 Ma respectively), a result of the aforementioned Re addition, hence whole-rock model ages are unreliable. We will present a comparison of data from whole-rock samples, leached chromite separates and single grains of Os-bearing minerals. This combined approach will allow us to further constrain the history of the earliest Archean genesis of continental crust, providing information that has so far been inaccessible when considering only whole-rock Re-Os analyses.

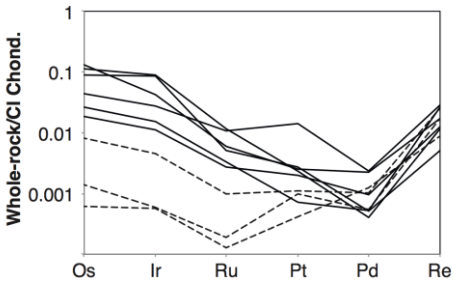

Figure 1: Chondrite [2,3] normalised PGE & Re contents of Ujaragssuit nunât peridotites (dashed) and chromitites (solid).

The CO_2-Vadose project: Numerical simulations coupled with geochemical and geophysical monitoring of CO_2 in the vadose zone

G. COHEN[1], B. GARCIA[2*], C. LOISY[1], P. DELAPLACE[2], F. LARROQUE[1], C. LAVEUF[1], C. MAGNIER[2], V. ROUCHON[2], O. LE ROUX[1], M. FRANCESCHI[1], A. CEREPI[1]

[1]EA 4592 "Géoressources et Environnement",ENSEGID, University of Bordeaux, France, adrian.cerepi@egid-u.bordeaux3.fr

[2]IFP New Energy, Rueil-Malmaison, France, bruno.garcia@ifpen.fr (* presenting author)

The CO_2-Vadose project aims at developing a facility around a cavity, in a former underground limestone quarry, to perform experimental releases of CO_2 under controlled conditions in order to study its migration along the vadose zone and to test near-surface detection techniques. Preliminary modelling carried out with the research code COORES^{TM} permitted to model the extend of the CO_2 plume, at a chosen release rate, the concentrations and flow rates expected at a specific depth, the timing of the migration and of the sampling strategy [1].

Based on the results provided by the preliminary modelling, an array of detection and monitoring tools was deployed. These tools allow the regular surveillance of water and gas compositions and fluxes as well as their samplings, all monitored. Micro-climatic parameters were also recorded by a weather station at the site surface. Geochemical signatures of carbon isotopes, and natural noble gases were also determined after samplings. A baseline, a tracers injection and also a CO_2 migration were performed in this project.

Results show that the natural CO_2 concentration at soil surface is depending of the season but rather homogenous (2.0±1.0% in october 2009 and 1.0±0.7 % in march 2010), and its carbon isotopic signature is constant ($\delta^{13}C_{CO2}$= -18.5±1.0 ‰). Natural noble gases composition at soil surface is equal to atmospheric composition. CO_2 flux is considered as a "normal" flux. Around and in the cavity, same trends were observed [2].

For the tracers injection, modelling results allow us to determine at which time the maximum concentration of Helium and Argon would arrived at soil surface. Experimental results are in good accordance with these previous modelling ones, specially around the cavity but not at soil surface by the fact of the presence of a clay zone just above the top of the cavity.

CO_2 experimental injection was realised in december 2011 with a flow of 2m^3 per hour during 9 hours (18m^3 of CO_2 injected for a cavity with a volume of 9m^3) in order to have a concentration of CO_2 at the top of the cavity equal to the injected CO_2 amount. Monitoring of CO_2 was realised with success from the cavity to the limestone around the cavity and is in good accordance with modelling results considering the clay zone.

Magnetite nanoparticles have a high surface to volume ratio and magnetic properties that can be exploited for a wide range of applications including targeted cancer therapies [1], magnetic data storage devices [2] and bioremediation [3-4]. Fe(III)-reducing bacteria produce nanoscale magnetite through the reductive transformation of low crystallinity Fe(III)-bearing oxides [5]. However, the commercial applicability of biogenic nanoparticles depends critically upon the ability to generate kg to tonne quantities of the nanoparticles. Therefore this technology relies upon the upscaling of laboratory biotransformation experiments which are commonly performed at 10 to 100 ml volumes. The goal of this study was to develop a batch fermentation of *Geobacter sulfurreducens* which could then be used to generate large quantities of biogenic magnetite that match the performance of the biomaterials made at small scale in the laboratory.

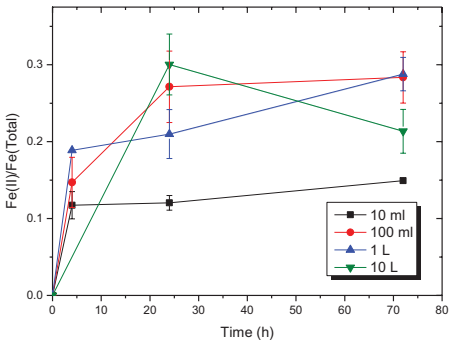

Figure 1: Fe(III) reduction (monitored by Fe(II) measurements by ferrozine) for bioreduction of Fe(III)oxyhydroxides during scale up of biomagnetite production.

Fermentation was carried out at 50 L scale and this led to production of biogenic magnetite via the reduction of Fe(III) oxyhydroxide in vessels from 10 ml to 10 L in size, containing 50 mmoles/L of Fe (Fig. 1). Spectroscopy (XAS/XMCD), microscopy (ESEM/TEM) and testing of the material against model contaminants, such as Cr(VI), was carried out to determine the quality and performance of the materials produced from the industrial scale fermentation.

Volcanic sulfur dioxide is oxidized in the atmosphere to sulfate aerosols. Volcanic aerosols present in the stratosphere, by altering the atmospheric albedo and energy balance, can impact the global climate significantly. Records of past volcanic eruptions are needed tp determine the role of volcanism in climate change.

Polar ice cores provide some of the most valuable volcanic records constructed from time series of sulfate in snow. The time coverage of such records can be as long as tens of thousdands of years. However, many of the sulfate signals in these records may be from relatively small tropospheric eruptions with no significant climatic impact and therefore should be excluded from consideration when investigating the volcano-climate connection.

We have found that the sulfate converted from volcanic sulfur dioxide in the stratosphere contains unique isotopic signatures [1,2]. Mass independent fractionation (MIF) of sulfur isotopes in sulfate indicate photolysis-based conversion reactions in the stratosphere and therefore can be used to identify climate-impacting stratospheric eruptions in the ice core records [3,4]. We present here sulfur isotope measurement of volcanic sulfate in Greenland and Antarctica ice cores. In addition to sulfur-33 data discussed in preivous work, we present data of sulfur-36 MIF excess in the sulfate of several volcanic eruptions in the last 1,000 years and discuss the possible interpretation of the new data in terms of the reaction mechanism of the oxidation of sulfur dioxide to sulfate.

Bacterial H_2S Generation in Oil Sands Process Wastes: Where Does it Begin?

TARA COLENBRANDER NELSON[1*], STEVEN P. HOLLAND[1], KATHRYN KENDRA[1], KATE STEPHENSON[1], TARA PENNER[2] AND LESLEY A. WARREN[1]

[1]School of Geography and Earth Sciences, McMaster University, Hamilton, Canada, warrenl@mcmaster.ca (* presenting author)
[2]Syncrude Environmental Research, Edmonton, Canada, penner.tara@syncrude.com

Reclamation of tailings, wastewater, and afflicted land represents one of the largest challenges facing the Alberta Oil Sands industry. Syncrude Canada Ltd., one of the largest producers in the Alberta Oil Sands, is assessing a novel reclamation strategy involving the establishment of a freshwater fen overlying a sand-cap topped, gypsum ($CaSO4{\cdot}2H_2O$)-amended, composite tailings (CT) waste material. However, a recent phenomenon resulting in the unpredicted generation of H_2S gas in CT dewatering wells has indicated the importance of constraining microbial S dynamics in the tailings system. On-going work is establishing the occurrence of microbially-linked S cycling in CT undergoing reclamation. However, this research will investigate Fe and S biogeochemistry and the hypothesized connections with porewater H_2S generation from fluid fine tailings (FFT), the gypsum-free precursor to CT, via a series of microcosm experiments. FFT is microbially rich and contains iron-rich clays; both constituents could be involved in S biogeochemical cycling within CT. Thus, in order to establish the relative roles of microbial and geochemical factors in FFT that may contribute to observed CT H_2S generation in situ, experimental microcosms were established to assess: i) microbial links to tailings porewater H_2S generation, and ii) the implications of gypsum amendment on porewater H_2S generation in variably microbially amended FFT treatments. Results of these experiments establishing the linkages between FFT and microbial S cycling prior to the amendment of gypsum and reclamation activities will be discussed.

Unraveling the Genetic Basis of an Ancient Geochemical Biomarker

R.E. COLLINS[1*], B. WING[2]

[1]Origins Institute, McMaster University, Hamilton, ON, Canada, rec3141@mcmaster.ca (* presenting author)
[2]Earth & Planetary Sciences, McGill University, Montreal, QC, Canada, boswell.wing@mcgill.ca

Abstract

Based on phylogenetic and geochemical evidence, the cycling of inorganic sulfur compounds was likely among the first metabolisms used by life. Sulfur isotope fractionation is a geochemical biomarker which has been observed in marine sediments dating back more than 2.5 billion years, but the cellular-level processes responsible for the fractionation effect are not well understood. Utilizing bioinformatic approaches in combination with measurements of sulfur isotope fractionation in pure cultures we seek to make quantitative links between SRB and their geochemical biomarkers.

The intrinsic sulfur isotope fractionation effect, ε, is essentially a measure of the preferential use of ^{32}S-substituted sulfate over ^{34}S-substituted sulfate expressed in parts per thousand, usually measured on pure cultures grown under optimal conditions. Much effort has gone into expanding the range of measured values of ε by subjecting SRB to a wide range of physiological stress, but this approach has failed to elucidate the underlying genetic basis of sulfur isotope fractionation. The mechanism is thought to involve kinetic limitation at the reaction sites of critical enzymes or the uptake of sulfur species, but there also appears to be an overarching energetic association such that SRB that completely oxidize their electron donors to CO_2 tend to have larger ε. However, this relationship is confounded by a phylogenetic split between two major Orders of SRB: within the Desulfobacterales, complete oxidation is the norm; within the Desulfovibrionales, complete oxidation is the exception. The interaction between the evolutionary history of SRB, their mode of metabolism, and their intrinsic fraction effect points towards the need for a genomic approach to unravel the basis of sulfur isotope fractionation.

Analyses of a set of genomes from 24 sulfur-metabolizing and 37 non-sulfur-metabolizing Bacteria and Archaea have identified gene families which may play a role in setting the magnitude of sulfur isotope fractionation effects. Though the members are phylogenetically divergent, genomes of SRB with moderate ε (10–20 per mille) and small ε (<10 per mille) each contain conserved gene clusters not found in the other genomes, including regulatory proteins and conserved hypothetical proteins. Unfortunately, a dearth of genome sequences from high-ε species (>20 per mille) limits our ability to further investigate the genetic basis of these large fractionation effects. The Desulfobacteraceae is a major lineage of SRB that is under-represented in genome sequences but which includes 90% of known SRB with ε >20. Presently we are expanding the representation of complete genomes by sequencing *Desulfobacula phenolica*, *Desulfospira joergensenii*, and *Desulfotignum balticum*, which have large ε values of 37, 26, and 21, respectively. Our ongoing biogeochemical measurements continue to expand the range of known fractionation effects, and sequencing of these SRB will increase the phylogenetic coverage of fractionation effects observed in vitro.

How to measure the pure dissolution kinetics of a soft mineral?

JEAN COLOMBANI[1*], AGNES PIEDNOIR[1], EDGAR A. PACHON-RODRIGUEZ[1]

[1]Laboratoire de Physique de la Matière Condensée et Nanostructures, Université de Lyon, Université Claude Bernard Lyon 1, CNRS, Villeurbanne, France, Jean.Colombani@univ-lyon1.fr (* presenting author)

Among interfacial processes, dissolution of minerals is present in countless problems: durability of mineral materials, management of nuclear wastes, sequestration of atmospheric CO2, pollution of drinking water … The modelling of all these situations requires the knowledge of the mineral dissolution kinetics, which in turn necessitates, to be reliable, a precise understanding of all the basic mechanisms intervening in the reaction.

The understanding of these fundamental mechanisms has progressed during the last decade. For instance, the use of molecular simulations and atomic-scale microscopy has enabled to understand the weak role of etch pit density on the dissolution kinetics, or the role of the surface history on this kinetics. But beside these successes, the measurement of the pure dissolution kinetics, and accordingly the identification of the basic processes driving the kinetics, is often a delicate experimental task.

We present here two situations of apparently inconsistent dissolution kinetics results of a soft mineral in the literature. In the two cases, a detailed data analysis and the identification of external phenomena blurring the results have permitted to gain the pure dissolution kinetics and then determine the basic processes:

- The dissolution rate constants of gypsum in water measured by various bulk methods are inconsistent. We have shown that the removal of the contribution of mass transport to these dissolution rates enables to obtain the pure chemical reaction rate constant of gypsum in water, coherent with all the measurements.

- The dissolution of gypsum proceeds via the migration of atomic steps. The step velocities, measured by Atomic Force Microscopy, show a large dispersion. We have shown that this dispersion stems from the influence of the AFM tip. The force applied by the lever increases locally the solid elastic energy, which promotes dissolution, and hence the step velocity.

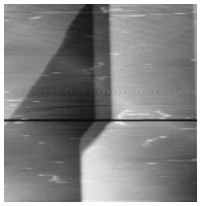

Figure 1: AFM picture of the cleavage plane of gypsum during dissolution. The black line shows the AFM tip path during a step velocity measurement performed just before the picture.

Microbial production of methylmercury from Hg(0)

MATTHEW COLOMBO*, JUYOUNG HA, JOHN R. REINFELDER, TAMAR BARKAY AND NATHAN YEE

School of Environmental and Biological Sciences, Rutgers University, New Brunswick, NJ, USA, mcolombo@eden.rutgers.edu (* presenting author)

Introduction

Mercury [Hg] is a global pollutant and its accumulation in food as methylmercury [MeHg] has caused serious public health crises this past century. In order to predict the fate and deleterious effects of Hg in the environment, a mechanistic understanding of MeHg production in aquatic ecosystems is required. Previous studies have elucidated the mercuric [Hg(II)] species that are bioavailable to methylating microbes [1,2]. Although it is generally assumed that elemental Hg [Hg(0)] is unavailable for biologic methylation [3], the uptake and transformation of Hg(0) by anaerobic Hg-methylating bacteria have never been tested. Here we demonstrate that Desulfovibrio desulfuricans ND132 produces MeHg when provided with dissolved Hg(0) as its sole mercury source.

Materials and Methods

D. desulfuricans ND132 was grown to exponential phase and subsequently exposed to a constant source of dissolved Hg(0) under anaerobic conditions in the dark. At periodic intervals, samples were collected for total non-purgeable Hg analysis. These samples were purged with N_2 gas, digested with BrCl, and analyzed for Hg by cold vapor atomic absorption spectroscopy. Cell suspensions containing non-purgeable Hg were filtered (0.2 µm filter) to determine the amounts of dissolved and cell-associated Hg. To examine the chemical speciation of cell-associated Hg, cells were collected and examined using X-ray absorption near edge structure (XANES) spectroscopy. Finally, ND132 cultures were analyzed for MeHg production by distillation, ethylation-gas chromatography, and cold vapor atomic fluorescence spectroscopy.

Results and Discussion

We observed a rapid transformation of Hg(0), with bacterial cultures producing ~40 µg/L of non-purgeable Hg within 30 min. Examination of the Hg L_{III}-edge position in the XANES spectra revealed that Hg oxidation to Hg(II) had occurred. After 24 h of incubation, D. desulfuricans ND132 produced up to 700 µg/L of non-purgeable Hg and 50 µg/L of MeHg. Similarity between the XANES spectra of bacterial samples at 30 min. and 24 h and a Hg-$(cysteine)_3$ reference compound suggested that most of the Hg(II) was associated with cells via coordination with thiol functional groups. The formation of Hg-thiol structures is consistent with Hg(II) uptake into the cell, since Hg(II) transfter into and within bacterial cells is governed by thiol-containing protiens [3]. The results of this study demonstrate a previously unrecognized source of MeHg in the environment.

The HP stability of Bloedite ($Na_2Mg(SO_4)_2\ 4H_2O$: a contribution to the knowledge of asteroids and icy satellites

PAOLA COMODI[1]*, SABRINA NAZZARENI[1], TONCI BALIC-ZUNIC[2], AZZURRA ZUCCHINI [1], MICHAEL HANFLAND[3]

[1] Dipartimento Scienze della Terra, Università di Perugia, Italy; comodip@unipg.it (* presenting author)

[2]Natural History Museum of Denmark, University of Copenahgen, Denmark, TonciB@snm.ku.dk

[3] ESRF, Grenoble, France, hanfland@esrf.fr

Bloedite, $Na_2Mg(SO_4)_2H_2O$ is a common mineral in evaporitic marine sediments. Being one of the phases in the system H_2O-$MgSO_4$-$NaSO_4$ it has a large planetological interest. In fact volatiles of icy satellites are considered to contain brines with sulphates, as well as carbonates and chlorides. To understand their internal structure and to evaluate the presence of a deep internal ocean, it is important to know the phase relation between water and brine mixtures [1]. Bloedite crystal structure consists of parallel layers of $MgO_2(H_2O)_4$ and $NaO_4(H_2O)_2$ octahedra, interconnected through SO_4 tetrahedra and hydrogen bonds [2]. This paper intends to investigate the high-pressure behavior of bloedite to determine the equation of state, the density evolution, as well as the dehydration conditions. Data were collected at ID-09 beamline, at ESRF (Grenoble, France). We used a diamond anvil cell with 300 micron diamond culet, Neon gas as pressure transmitting medium and ruby chip as pressure calibrant. The very large image-plate detector, Mar555, allowed to collect data of high quality from single crystals. Lattice parameters and reflections intensities were obtained by Crysalis software. SHELXL software was used to refine the structure at different pressures up to 12 GPa. Equation of state (EoS) of bloedite was determined with data collected up to 12 GPa and EOS-Fit program [2]. A second order Birch-Murnaghan EoS fit yields V_0 = 495.6(9) Å^3 and K_0 = 40.5(7) GPa, whereas a third order Birch-Murnaghan EoS fit yields V_0 = 497.6(4) Å^3 , K_0 = 34(1) GPa and K' = 5.8 (4) GPa^{-1}. The lattice parameters compressibilities are β_a = -0.0074 (4) GPa^{-1}; β_b= -0.0069 (4)GPa^{-1}; β_c = -0.0054 (2) GPa^{-1} with an anisotropic ratio of 1: 1.07: 1.37. The structure is more incompressible along the direction perpendicular to open sheet, than the other directions. The SO_4 tetrahedra are incompressible, K_{MgO6} octahedra is 90 GPa and K_{NaO6} octahedra is 42 GPa. No phase transitions were observed in the bloedite structure up to 12 GPa, who remained stable at very HP. Hydrogen bonds evolution were followed through the O_{donor}-$O_{acceptor}$ distance, whose configuration explained the large compressibility of *a* and *b* parameters with respect to *c* lattice parameter. The lack of strong structural rearrangement, essential to compensate the dehydration process, suggested that water remaineds in the structure of bloedite in the investigated P range.

Syenitic Provinces in the São Francisco Craton, Brazil

HERBET CONCEIÇÃO[1*], MARIA LOURDES SILVA ROSA[1], DÉBORA CORREIA RIOS[2]

[1]Sergipe Federal University, Núcleo de Geologia, Aracaju, Brazil, herbet@ufs.br

[2]Bahia Federal University, Instituto de Geociências, Salvador, Brazil, dcrios@ufba.br

The Paleoproterozoic in the Bahia State, Brazil, is characterized by the generation and emplacement of varius syenite bodies. The mainly occour in two mobile belts that represent parte of the basemente of the São Francisco Craton. These mobile belts are: (i) the Salvador-Curaçá mobile belt (SCMB), located in te eastern parte of the state, and (ii) the Urantdi-Paratinga mobile belt (UPMB), in the western part. Both are characterized by the emplacement of alcali-syenitic, potassic to ultrapotassic rocks, during the late stages of the stabilitaztion of these mobile belts, which occurred between 2.1 and 2.0 Ga. However, in the east parte the syenite is placed as tabular bodies and shows gneissic texture, while in the west parte they are related to pull-part system and developt only magmatic textures. The UMPB syeinte occur as wide single batholith (6,000 km^2), the Guanambi Batholith (GB), dated 2.05±0.02 Ga (U-Pb age). In the GB two main domins were recognized; (i) multipe intrusions (about 92% of the batholith), and (ii) late intrusions. Both have composiiton from syenite to mafic syenite towards monzonite. The U-Pb data show that the difference between the empacement of late intrusions was less them 5 Ma. The Eastern Bahia State, the SCMB syenite consist mainly of four massifs, discontinuously disposed. From north to south occur the following bodies: Itiúba (1800 km^2, 2.00±0.03 Ga, Pb/Pb age), Santanápolis (180 km^2, 2.10±0.04 Ga, U-Pb age), São Felix (32 km^2, 2.09±0.01 Ga, Pb-Pb age) and Anuri (70 km^2, 2.10±0.020 Ga U-Pb age). All intrude both gneiss-migmatitic and granulitic terrains. These syenite, despite the mobile belt in which they occur, show the same petrographic characteristics. They are leucocratic, porphyritic, mainly composed of perthitic alkali-feldspar, diopside, hornblend, phlogopite and biotite, ilmenite anda magnetite. In the syenites was found lamprophiric dykes (minette). Geochemical data indicate theat all these syenites are SiO_2-sturated to oversatured, alkalic to sub-alkalic and metaluminous. The K_2O/Na_2O ratios is always greater tham the unity, being higher in mafic terms. In some cases, these mafic terms can be classified as ultrapotassic. Ba (up to 8,0000 ppm), Sr (up to 6,000 ppm) and Rb (up to 940 ppm) are strongly enriched in these rocks. Cr (from 50 to 700 ppm), Ni (from 80 to 270) and Mg# (form 0.20 to 0.77) are reltively high form common syentic rocks. Chrondite-normalised REE patterns show strongely fractionated LREE with a small negative Eu anomaly, $\varepsilon_{Nd(t)}$ range from -10 to 0 (SCMB), and -11 to -7 (UPMB) and Sr_i values are around 0.705. From those data, we can concluded that the Paleoproterozoic was a propicius time form the generation of syenitic rocks in these two mobile belts of the Bahia State, independely from the tectonic regime. The syenitic result probably from fractionated crystallizaton of a lamprophiric magma, the later gernerated buy melting of Paleoproterozoic enriche mantle.

Zircon age gaps in the Great Proterozoic Accretionary Orogen: a possible connection between the 1.5-1.3 Ga granite-rhyolite province and subduction erosion

KENT C. CONDIE[1*], DAVID W. SCHOLL[2]

[1]Department of Earth & Environmental Science, New Mexico Tech, Socorro, NM, USA, kcondie@nmt.edu (* presenting author)
[2]Department of Geology & Geophysics, University of Alaska, Fairbanks, AK, USA, dscholl@usgs.gov

Collisional zircon ages record the assembly of Nuna between 2100-1900 Ma (early phase) and 1900-1800 Ma (main phase). During this time collisional convergent margins shifted to the perimeter of Nuna forming the possibly contiguous Great Proterozoic Accretionary Orogen (GPAO) in Laurentia-Baltica-Amazonia (1900-1300 Ma). Accompanying this shift is an increase in the proportion of juvenile crust as reflected by eHf values in detrital zircons. Major gaps in both *in situ* and detrital zircon age spectra occur at 1750-1700 (Baltica, Amazonia), 1600-1500 (Laurentia), and 1300-1200 (all three cratons). The two oldest age gaps in the GPAO may be due to subduction erosion related to initial rifting of Siberia from Baltica and of Amazonia from West Africa (1750-1700 Ma) and Laurentia from Siberia (1600-1500 Ma). The 1300-1200-Ma gap may record major breakup and limited dispersal of the supercontinent. Depending on how much Paleoproterozoic crust is buried beneath the margin of the Grenville orogen, as much as 30% of the original crustal volume of the GPAO may have been lost by subduction erosion. Subduction of 1600-1500-Ma continental crust along the coast of Laurentia may have resulted in enrichment of the mantle wedge above a low-dip subduction zone between 1500 and 1300 Ma as the convergent margin migrated inwards towards the center of the supercontinent. This may have given rise through multi-stage melting of the mantle wedge and its mafic melting products to the extensive 1500-1300 Ma granite-rhyolite province in south-central and southwestern Laurentia.

Integrated Sr-Pb-S-O-Cu Isotopes of Sulfide and Mn-oxide Mineralization of the Boléo Cu-Co-Zn-Mn District, Baja California Sur, Mexico

ANDREW G. CONLY[1*] AND RYAN MATHUR[2]

[1]Department of Geology, Lakehead University, Thunder Bay, Canada, andrew.conly@lakeheadu.ca
[2]Department of Geology, Juniata College, Huntingdon, USA, MATHUR@juniata.edu

Introduction

Stable and radiogenic isotope composition of stratiform Cu-Co-Zn-Mn mineralization from the Boléo district of the Miocene Santa Rosalía basin, Baja California Sur, are used to constrain the source and evolution of fluids and the mechanisms responsible for sulphide and oxide deposition. Mineralization consists of finely disseminated sulfides and Mn-Fe-Cu-oxides within claystones and tectonically triggered debris flows that occur near the base of five cyclical fan-delta sequences of the Boléo Formation, which developed in response to development of the Proto-Gulf of California.

Results

Newly acquired isotope data and data compliled from [1,2] are provide in Table 1. Results from this study are compariable to those recently reported by [3].

Table 1: Range in radiogenic isotope compositions of Boléo manto Mn oxides and sulphides.

Phase	$^{87}Sr/^{86}Sr$	$^{208}Pb/^{204}Pb$	$^{207}Pb/^{204}Pb$	$^{206}Pb/^{204}Pb$
Mn-ox	0.70750 to 0.70584	38.70 to 38.40	15.67 to 15.57	18.80 to 18.70
Sulfide	n/a	38.49 to 38.41	15.60 to 15.57	18.80 to 18.72
	$\delta^{18}O$ (‰)	$\delta^{34}S$ (‰)	$\delta^{65}Cu$ (‰)	
Mn-ox	12.5 to -2.9	n/a	1.86 to 0.50	
Sulfide	n/a	1.8 to -13.7	-0.39 to -2.72	

Discussion and Conclusions

Strontium and Pb isotopes indicate that the ore-forming brines originated as basin seawater that interacted with basement volcanic and plutonic rocks and the evaporite sequence that underlies the Boléo Formation. $\delta^{34}S$ values of pyrite-Cu-sulfide-bearing mineralization show that sulfur originated from bacterial sulfate reduction, with more enriched $\delta^{34}S$ values indicating sulfate reduction at higher temperatures during the infiltration of the metal-bearing brines. The $\delta^{65}Cu$ composition of sulfides is consistent with reaction of Cu-rich fluids ($\delta^{65}Cu \approx 0‰$) with a framboidal pyrite reductant [e.g., 4]. Higher $\delta^{65}Cu$ values for Mn oxides are the product of abiotic oxidative leaching of chalcocite-covellite mineralization [e.g. 5], during the wanning stages of discrete hydrotheral episodes.

Evaluating the robustness of Pb-Pb ages of meteorites

JAMES N. CONNELLY* AND MARTIN BIZZARRO

Centre for Star and Planet Formation, Copenhagen University, Øster Voldgade 5-7, 1350 Copenhagen K, Denmark. connelly@snm.ku.dk (* presenting author)

A variety of methods for acquiring Pb-Pb data to constrain the ages of meteorites and their components exist today, all capable of yielding ages with varying levels of complexity. Regardless of the method employed, basic measures exist to evaluate the degree of confidence in a calculated age, including:

1. The analyses should yield sufficient spread in Pb-Pb space (courtesy of either stepwise dissolution methods and/or analyzing separate mineral concentrates from a single sample) to yield an internal isochron free of any model or presumed initial Pb isotopic composition that cannot be independently verified,
2. The array defining an isochron must represent mixtures of in situ radiogenic Pb and only one other source of common Pb, most typically initial Pb or, less typically, secondary contaminant Pb. At least one analysis that is more radiogenic than modern terrestrial contaminant Pb assures that the resulting array does not reflect a binary mix of initial Pb and terrestrial contaminant Pb,
3. Back projection of the isochron should yield a permissible isotopic composition for an initial Pb component given the context of the object being dated (except atypical cases where it is presumed that only contaminant common Pb exists as the non-radiogenic component),
4. The U isotopic composition of the object being dated must be known by direct measurement,
5. All U and Pb isotopic analyses must be corrected using an internal measure of instrumental isotopic mass fractionation,
6. All errors on final ages should reflect errors for the Pb and U isotopic measurements and assumptions therein,
7. Analyses of accepted, appropriate standards run concurrently with the samples and using the same protocols should be reported with the geochronological results,
8. When stepwise dissolution is employed, at least the acid type and concentration, exposure time and temperature should be reported in the data table,
9. When feasible, critical ages should be verified by an independent research group in a second laboratory.

While these criteria may be obvious, there is presently no standardization of data presentation or consistent culture of critical evaluation of the confidence level of ages for meteorites that would include exploring alternative interpretations where appropriate. Where the listed criteria are not fulfilled, practitioners of Pb-Pb geochronology of meteorites have the obligation to make clear the assumptions and/or shortcomings of each data set. Only through such an open dialogue regarding the true robustness of each age will we publish results that can be used confidently by the meteoritics community at large. Towards this end, we are working to erect an absolute Pb-Pb chronological framework for the early solar system based on FUN and normal CAIs, chondrules and differentiated bodies that will be evaluated by these criteria.

The role of ArxA in photosynthesis-linked arsenite oxidation by bacteria from extreme environments

ALISON CONRAD[1*], SHELLEY HOEFT[2], LAURENCE MILLER[2], RONALD OREMLAND[2], MICHAEL ROSEN[3], AND CHAD SALTIKOV[1]

[1]University of California, Santa Cruz, CA, USA, atconrad@ucsc.edu[+]
[2]United States Geological Survey, Menlo Park, CA, USA
[3]United States Geological Survey, Carson City, NV, USA

Background

The metabolic process of photosynthesis-linked arsenite oxidation (arsenophototrophy) has likely existed on earth since 2.7 - 3.5 billion years ago [1]. However, it is poorly understood and has only been identified in thermal springs on Paoha Island of Mono Lake, CA [2]. As this metabolism utilizes solar energy to convert the more toxic arsenite to the less toxic arsenate, it has implications for bioremediation. The arsenite oxidase ArxA is thought to be responsible for the oxidation of arsenite in arsenophototrophy. However, the first and only isolated arsenophototroph, *Ectothiorhodospira sp.* str. PHS-1, has not proven amenable to genetic manipulations. This makes genetic confirmation through gene disruption or deletion of the *arxA*-like gene in the organism impossible, leaving the hypothesis unconfirmed. The first aim of this work is to study the microbial ecology of anoxygenic arsenophototrophs in arsenic-rich environments other than Mono Lake and secondly, to isolate and develop an arsenophototroph which can serve as a genetic model for arsenophototrophy.

Materials

Water, sediment, microbial mat and tufa collected from Big Soda Lake (Churchill County, NV), Mono Lake and various hot springs in the Mammoth Lakes (CA) area were used for enrichment culturing and functional gene analyses.

Results

Currently *arxA*-specific primers have successfully amplified products from 15 out of 18 environmental samples, and all products so far cloned and sequenced show high homology to existing *arxA*-like sequences. Additionally, strains containing *arxA*-like sequences and capable of arsenite oxidation belonging to the genera *Ectothiorhodospira* and *Halomonas* have been isolated. One strain in particular, *Ectothiorhodospira* sp. str. BSL-9 is aerotolerant, grows well on plates, and is susceptible to common antibiotics, making it a potential model for arsenophototrophy.

Conclusions

This work demonstrates that ArxA is unlikely limited to the Mono Lake area and may be widespread in arsenic-rich environments. It is also a necessary stepping-stone in actualizing a genetic model for photosynthesis-linked arsenite oxidation.

Highly depleted Colorado Plateau gypsum deposits attributed to multiple episodes of redox cycling

MARK E. CONRAD[1*], KENNETH H. WILLIAMS[1], JENNIFER L. DRUHAN[1,2] AND WAYNE W. LUKENS[1]

[1]Lawrence Berkeley National Laboratory, Berkeley, CA, USA, msconrad@lbl.gov (* presenting author)

Introduction

The Department of Energy's Old Rifle site is a former uranium mill site situated along a floodplain of the Colorado River in western Colorado. The aquifer underlying the site consists of 6-7 m of Quaternary alluvium overlying the Tertiary Wasatch Formation. Sulfate concentrations in Old Rifle groundwater are elevated (8-10 mM), with unusually low sulfur isotope ratios ($\delta^{34}S$ values from -6 to -10‰). The source of the low $\delta^{34}S$ sulfate in groundwater appears to be gypsum veins within the Wasatch Formation, which outcrops above the site and through which regional groundwater recharges the Old Rifle aquifer. Veins of gypsum sampled from the upper Wasatch have $\delta^{34}S$ values lower than any previously reported in the literature (as low as -56‰). The veins are associated with Fe-oxide minerals and visible iron staining and are in close proximity to fossilized plant material within the Wasatch sediments (Figure 1). The low $\delta^{34}S$ gypsum is inferred to result from oxidation of ^{34}S-depleted sulfide minerals that formed in reducing zones associated with organic matter. Subsequent oxidation of the isotopically light sulfides mobilized low $\delta^{34}S$ sulfate that precipitated as gypsum infillings within high permeability fractures. Modern analogs of such naturally reduced zones occur within the alluvial sediments at Old Rifle, which are characterized by lignitic organic carbon and framboidal pyrites having low $\delta^{34}S$ values (as low as -70‰). Associated with these pyrites are greatly elevated concentrations of uranium [1]. Oxidation of such reduced zones within the alluvium and Wasatch Formation could lead to mobilization of reduced metals, such as uranium, that may explain the high background concentrations of metals in the Rifle groundwater outside of the tailings-impacted area.

Figure 1: Petrified branch or root in upper Wasatch Formation replaced with quartz, Fe-oxides and gypsum ($\delta^{34}S$ = -55.4‰).

Nearly 50 mafic and ultramafic rocks were sampled for a Sm-Nd isotopes study in 6 plutons coeval to the La Bostonnais complex, each <1 to 3 km^2 of surface and spread over 100 km within a north-south belt called the Portneuf-Mauricie Domain (PMD). Results show Nd T_{DM} ages that range from 1400 to 1970 Ma and $\varepsilon_{Nd}(t)$ mostly between +2.5 and +4.3. Trace element patterns of these 6 plutons normalized to the primitive mantle show strong negative Ta anomaly and moderate to strong negative Zr, Hf, and Ti anomalies. Two mafic lithologies within two plutons from the PMD (Lac Nadeau, Rochette West) with TIMS U-Pb zircon ages respectively of 1.396 and 1.386 Ga that are interpreted to represent crystallization ages [1]. A regression of 18 samples from the Nadeau and Lac-à-la-Vase plutons provide a Sm-Nd isochron age of 1423 ±28 Ma (MSWD=4), similar within error to the U-Pb ages. The Lac-à-la-Vase pluton is compatible with derivation from a near-depleted mantle reservoir whereas the other plutons suggest a mantle separation time of 100 to 400 millions years earlier than 1.39 Ga. Pyroxenites hosting the Lac Edouard Ni-Cu deposit show the lowest ε_{Nd} of the 6 PMD plutons with values between +0.85 and +2.6.

A second region of interest is the Renzy Terrane (RT), identified over an area covering at least 50 km^2, where sub-kilometric pyroxenites lenses have REE and HFSE ~1x to 10x primitive mantle contents with strong negative Ta anomaly and moderate to strong negative Zr, Hf (±Ti) anomalies. Coeval mafic gneisses have REE and HFSE ~5x to 50x primitive mantle contents and were divided in 3 distinct groups, although a majority have trace element signatures akin to subduction zone processes [2]. Both RT and PMD ultramafic rocks have 15-30 ppm Zr rendering them difficult to date by U-Pb zircon methods. A regression of 14 pyroxenites and 4 mafic gneisses samples from the RT provided a Sm-Nd isochron age of 1504 ±67 Ma (MSWD = 2.5) in agreement with U-Pb zircon ages of 1457 ±15 Ma obtained by ion microprobe on 3 different mafic to intermediate rocks. A Sm-Nd isochron including pyroxenites, mafic gneisses and felsic gneisses yields an age of 1508 ±47 Ma, and these rocks have a range of $\varepsilon_{Nd}(t)$ between +1.7 and +3.9, an average Nd T_{DM} age of 1.77 ±0.14 Ga (n=32) and therefore ~300 millions years older that their crystallization age.

Most of the trace element chemistry of the DMP and RT mafic and ultramafic rocks indicate that they probably originated from arc and back-arc magmatic activity. The RT was probably accreted to Laurentia as a thrust sheet over the Paleoproterozoic belt of the Grenville Province.

A composite speleothem paleoclimate record for the last 400 ka from Romania

SILVIU CONSTANTIN[1*]

[1]"Emil Racovita" Institute of Speleology, Bucharest, Romania, silviu.constantin@iser.ro

Paleoclimate studies based on speleothem records from Romania have seen a constant increase in the last 15 years. Hence, an increasing number of speleothem isotope records have become available form the karst regions of both SW and NW Romania. Here we review the available data and present a composite speleothem $\delta^{18}O$ record that spans roughly over the last 400,000 years. The record is based on several high resolution dated speleothems from the SW Carpathians and is correlated with coeval samples from the NW Carpathians. The record (Figure 1) shows a higher variability for the SW Carpathians when compared with the NW Carpathians. This is considered as a direct effect of the Mediterranean climate influence as opposed to the distal-NAO influence on the climate from the inner part of the Carpathian arch, i.e. the NW Romania. Probability density function graphs based on dated speleothems were constructed for both regions and they too show a much higher response during warming periods for regions located in the southern part of the Carpathians. The record is compared with known composite records from the Eastern Europe and Eastern Mediterranean and potential biasing factors when comparing other $\delta^{18}O$ records are discussed.

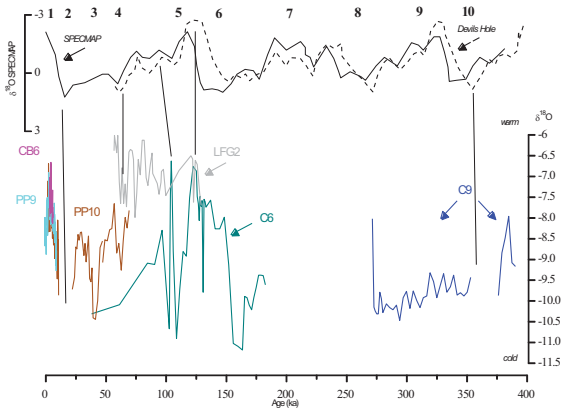

Figure 1: A cumulative speleothem record from Romania showing higher variance of the $\delta^{18}O$ values for the Mediterranean-influenced SW Romania when compared with the NW Romania.

Petrogenesis of recent trachytic eruptions from Sete Cidades volcano, São Miguel, Azores (Portugal)

E. CONTE[1]*, E. WIDOM[1] AND Z. FRANCA[2]

[1]Dept. of Geology & Environmental Earth Science, Miami University, Oxford, Ohio, USA, conteer@muohio.edu (*presenting author)

[2]Departamento de Geociências, Universidade dos Açores, Ponta Delgada, São Miguel, Açores, Portugal, zfranca@uac.pt

Sete Cidades has produced 12 intracaldera, trachytic eruptions (Sete A-L) within the last ~4-5 ka [1,2]. We have completed detailed petrographic, major and trace element, Sr, Nd and Pb isotope and U-series disequilibria studies of whole rock samples from the Sete A-L deposits to constrain petrogenetic processes, eruptive ages and repose intervals associated with the Sete Cidades magmatic system [3]. Major and trace element analyses were performed on a suite of 16 samples representing all of the deposits from Sete A-L. The data show limited major element variation (~63% SiO_2) but highly variable trace element abundances (e.g. >1.6-fold variations in Zr and ~4-fold variations in Sr). Trace element abundances show a complex relationship with stratigraphy that we interpret to reflect a 3-stage evolutionary process. Stage 1 (Sete A-B), characterized by an increase in Zr concentration with stratigraphic height, reflects evolution of a trachytic magma via 35% fractionation of the observed mineral assemblage including sanidine>biotite>clinopyroxene>Fe-Ti oxides>apatite. Stage 2 (Sete B-F) is characterized by decreasing Zr concentrations with stratigraphic height, suggesting injection of a less evolved trachytic magma into the Sete Cidades magma chamber. Stage 3 (Sete F-L) is recorded by an increase in Zr with stratigraphic height, and is consistent with 54% crystallization of the observed mineral assemblage. Sr isotopic variation in leached whole rock samples ($^{87}Sr/^{86}Sr$=0.70375-0.70439) further requires assimilation of hydrothermally altered syenite wall-rock [4,5]. Nd and Pb isotopic compositions are essentially invariant ($^{143}Nd/^{144}Nd$=0.51287; $^{206}Pb/^{204}Pb$=19.52-19.56) and within the range of local basalts, consistent with trachytic magma evolution from parental basalts derived from a single mantle source over the past ~4-5 ka. Six samples have also been analyzed for U-series disequilibria, and all are Th-enriched and Ra-depleted. With one exception, $^{238}U/^{232}Th$ and $^{230}Th/^{232}Th$ activity ratios are constant with ($^{238}U/^{232}Th$)≈0.88 and ($^{230}Th/^{232}Th$)≈0.96, similar to basalts from the Sete Cidades region, and consistent with the trachytes deriving from parental basalts that evolved rapidly (within ~10 ka) to produce the Sete A-L trachytic magmas. Present-day $^{226}Ra/^{230}Th$ activity ratios range from 0.32-0.75, consistent with recent and extensive sanidine fractionation during trachyte magma evolution, and further allowing constraints on the maximum eruptive ages. Preliminary data indicate a maximum eruptive age of 912 years B.P. for Sete B, which suggests that the recent recurrence interval of Sete Cidades may be only ~42 years, much shorter than the recurrence intervals of 200 and 1200 years at neighboring Furnas and Fogo volcanoes [6].

Iron isotopes in the eastern North Atlantic

TIM M. CONWAY[1*], SETH G. JOHN[1] AND ANGELA D. ROSENBERG[1]

[1]Dept. Earth and Ocean Sciences, University of South Carolina, USA
[*]Presenting author (correspondence tconway@geol.sc.edu)

Iron (Fe) is a crucial nutrient for phytoplankton and the marine food chain, and low dissolved Fe concentrations limit growth in many regions of the oceans. Knowledge of the sources, sinks and cycling of Fe in the ocean is vital to our understanding of marine biogeochemical cycles; however, concentration measurements alone are often unable to discriminate between different fluxes and processes. Fe isotope ratios address this limitation, and provide us with the unique opportunity to discriminate between biological utilization of Fe, Fe from continental shelf sediments or aerosols, and Fe from hydrothermal activity. Fe isotope values also allow investigation of internal cycling of Fe, and provide an insight into the relative importance of kinetic and equilibrium controls on dissolved Fe concentrations in the oceans.

This study presents new methodology for the simultaneous extraction of dissolved Fe, Cd and Zn from seawater using a chelating resin, followed by ion-exchange column purification and isotopic analysis by Neptune multi-collector ICP-MS. This method has been developed in order to make determinations of multiple isotope systems in the same sample as part of the GEOTRACES program, and generates a lower blank than previous methods [1].

We present the first Fe isotope (δ^{56}Fe) depth profiles from the GEOTRACES A10 (North Atlantic) Transect. This work focuses on A10 stations along 17.4° N (North Africa to Cape Verde), where multiple sources of dissolved Fe, a pronounced oxygen minimum zone at depth, and internal cycling of Fe complicate the dissolved Fe picture. δ^{56}Fe values indicate surface input of isotopically heavy Fe, biological utilisation at the surface and input of isotopically light Fe from the sediments. Relatively little variation in δ^{56}Fe through the intermediate ocean adds support to the hypothesis that rapid exchange between the dissolved and particulate Fe pools may be important in controlling dissolved Fe concentrations and δ^{56}Fe in the North Atlantic.

Mantle thermal anomalies associated with large igneous provinces

LAURENCE A. COOGAN,[1*], ANDREW D. SAUNDERS[2] & ROBERT N. WILSON[2]

[1]School of Earth and Ocean Science, University of Victoria, Victoria, Canada, lacoogan@uvic.ca
[2]Department of Geology, University of Leicester, Leicester, LE1 7RH, UK, ads@le.ac.uk, rnw@le.ac.uk

The classical mantle plume model involves heat transport across the core-mantle boundary, heating the lowermost mantle, leading to a thermally buoyant mantle upwelling; melting of the upwelling material in the upper-mantle can generate large volumes of mantle-derived melt in geological short time periods such as large igneous provinces (LIPs). If correct, this is of fundamental importance for the thermal evolution of our planet. A key prediction of the thermal plume model is that some melts generated by the plume should show evidence of having been generated from mantle with a higher potential temperature than the ambient upper mantle.

Testing the 'hot mantle' prediction has proved controversial. Olivine-melt thermometry has been the most popular approach but has been used to argue for both large and negligible temperature anomalies in the mantle in regions of intraplate volcanism [e.g. 1,2]. This approach invariably involves the back-calculation of an observed lava composition, via olivine addition, to a melt composition thought to be in equilibrium with an observed primitive olivine composition. Since the primitive olivine and its host basalt are not in equilibrium, it is unclear if *any* form of recalculation will produce a melt composition that ever existed. In particular, because Mg-Fe diffusion in olivine is rapid at high-temperatures [3], primitive olivine are unlikely to simply be 'early crystallization products' from the parent to the host melt. Differentiation to produce an evolved residual magma occurs much more slowly than diffusive Mg-Fe exchange will change the olivine composition.

In an attempt to overcome these problems we have applied the Al-in-olivine thermometer [4] to primitive olivine-spinel pairs from several LIPs as well as primitive MORB. This thermometer is based on the exchange of Al between olivine and spinel and requires no back-calculation of initial compositions. Also, as Al diffusion in olivine is much slower than Mg-Fe diffusion this thermometer has a better chance of preserving the temperature of initial crystal growth. However, the thermometer can only record the temperature at co-saturation of these two phases and will not (directly) recover mantle temperatures. Application to primitive MORB from several locations, containing primitive olivine (Fo up to 91.3), gives maximum olivine-spinel co-precipitation temperatures of 1300°C. Applying the same approach to LIPs (N. Atlantic igneous province, Gorgona, Madagascar) gives higher temperatures in all locations of up to 1450°C. Relative temperature differences between MORBs and LIPs suggest that LIPs are generated by melting hotter than average mantle. The absolute temperatures for MORB are consistent with the thickness of oceanic crust.

PLIOCENE EAST ANTARCTIC ICE SHEET INSTABILITY

C. COOK[1]*, T. VAN DE FLIERDT[1], T. WILLIAMS[2], S. HEMMING[2], E. L. PIERCE[2] AND IODP EXPEDITION 318 SCEINCE PARTY

[1]Imperial College London, London, UK, SW7 2AZ (*correspondance: c.cook09@imperial.ac.uk)

[2]Lamont-Doherty Earth Observatory, Palisades, NY 10964-1000 USA

Warm climatic intervals during the Pliocene Epoch (5.33-2.58 Ma) are apt analogues with which to compare future climate scenarios, but there are currently no direct constraints on the dynamics of the East Antarctic Ice Sheet (EAIS) in potentially vulnerable low-lying regions during these times. Analyses of the isotopic provenance of multiple detrital marine sediment components can offer novel insights into the spatial and temporal response of the EAIS to climatic change, on both glacial-interglacial and longer-term timescales.

Here we present results of neodymium and strontium isotopic analyses of clay and silt sediment fractions (<63um), and argon isotope ages of individual hornblende grains from ice-rafted detritus (IRD) (>150um), from ODP Site 1165 (64˚22-77S, 67˚13-14E), Prydz Bay, and IODP Site U1361 (64˚24-57S, 143˚53-19E), Adelie Land. Both sites are ideally located to receive terrigenous sediments sourced from the Wilkes and Aurora Subglacial Basins, where large areas of the EAIS lie below sea level in direct contact with the Southern Ocean.

Pliocene clay and silt sediments from IODP U1361 reveal two distinct ε_{Nd} and $^{87}Sr/^{86}Sr$ endmembers – the first matches Early Paleozoic terranes found to the east (ε_{Nd}:- -11 to -16 and $^{87}Sr/^{86}Sr$ values of 0.721 to 0.730), and the second displays a mixed signature between these same terranes and the Jurassic-Triassic Ferrar Large Igneous Province (FLIP) (ε_{Nd}: -4 to -7; $^{87}Sr/^{86}Sr$: 0.712 to 0.719). Sediments characterised as the latter endmember are consistently found during high productivity (warm) intervals as revealed by physical property and bulk geochemistry measurements in U1361, at 4.8-4.6, 4.3-4.2 and 4.05-3.9 Ma. These time intervals additionally appear to correspond to maxima in modelled solar insolation. In fact, FLIP strata have been inferred within the Wilkes Subglacial Basin by aero-geophysical surveys as far as 74.3°S, suggesting this area may be the most likely source for the endmember approaching FLIP composition identified in U1361, and implies that the Wilkes Subglacial Basin may be a source of EAIS destabilisation during warm intervals in the Pliocene.

Late Pliocene sediments (3.3-2.8 Ma) from ODP Site 1165 display an increase in IRD hornblende $^{40}Ar/^{39}Ar$ ages of 1100-1300 Ma during interglacial intervals. This signature has not been identified on-land proximal to the study site, but matches very well hornblende argon isotope ages in modern marine sediments offshore of the Aurora Subglacial Basin, some 2000 km away from Site 1165. A Wilkes Land IRD provenance signal is positively correlated to detrital $^{87}Sr/^{86}Sr$ and εNd signatures in the <63um fractions, implying that ice sheet destabilisation of the Aurora Subglacial Basin played an important control on bulk sediment composition in the Prydz Bay area in the Late Pliocene.

Overall, the radiogenic isotope compositions of multiple detrital marine sediment components at two locations in the Southern Ocean suggest significant destabilisation events of the EAIS in the vicinity of the Wilkes and Aurora Subglacial Basins in response to Pliocene climatic warmth, with significant implications for future sea level estimates.

W isotopic composition of IVB iron meteorites

DAVID L. COOK[1*], THOMAS S. KRUIJER[1,2], THORSTEN KLEINE[1]

[1] Institut f r Planetologie, Westf lische Wilhelms-Universit t, M nster, Germany, d.cook@uni-muenster.de (* presenting author)

[2] Institut of Geochemistry and Petrology, ETH, Z rich, Switzerland

Introduction

The investigation of W isotope anomalies in meteorites is of interest because of the former presence of the short-lived isotope ^{182}Hf, which decays to ^{182}W. Thus, variations in ^{182}W can be used to infer timescales of early solar system processes [e.g., 1] However, the application of Hf-W chronometry relies on the assumption that W isotopes were homogeneously distributed in the solar nebula. This assumption appears to be valid for most meteoritic samples, but small deficits in s-process W isotopes have been observed in group IVB irons [2] and CAIs [3]. More recently, excesses in ^{180}W have been measured in several magmatic iron groups [4]. These data seem to imply heterogeneity of W isotopes in the early nebula, but these results have been questioned [5]. We report new isotopic measurements for several IVB irons to examine the extent of nucleosynthetic W isotope anomalies in this group.

Samples and Analytical Methods

We analyzed three IVB irons, and we processed two aliquots of the NIST W solution standard (SRM 3163) and one aliquot of a NIST Fe-Ni steel (SRM 361) using our chemical separation protocol for W. Isotopic measurements were made with a ThermoScientific Neptune Plus MC-ICPMS in low resolution mode. Signal intensities for both ^{180}W and ^{178}Hf were measured using 10^{12} Ohm resistors. The interference correction on ^{180}W from ^{180}Hf was tested by analyzing several aliquots of SRM 3163 doped with Hf.

Results and Discussion

All three of the NIST samples of terrestrial W have $\varepsilon^{180}W$ values within uncertainty of zero. These results demonstrate the accuracy of the method and do not suggest the presence of analytical artefacts on the W masses in low-resolution mode, which was recently suggested [5] to explain a previous report [4] of ^{180}W excesses in magmatic iron meteorites. Furhermore, the results for SRM 3163 doped with Hf show that the interference correction on ^{180}W is accurate for the range of Hf/W ratios of the samples. The $\varepsilon^{180}W$ values for all three IVB irons agree within uncertainty; the data hint at a slight $\varepsilon^{180}W$ excess, but this excess is not unambiguously resolvable at the current level of precision. All three IVBs exhibit small $\varepsilon^{184}W$ deficits, consistent with previous results [2]. The $\varepsilon^{182}W$ values of all three IVBs are below the CAI initial [3], indicating neutron-capture induced shifts in the W isotope abundances caused by cosmic rays. This process may also lower $\varepsilon^{180}W$ values, but the magnitude of the effect is currently unknown. Efforts are underway to improve the precision of the measurements as well to perform analysis of additional samples.

Hg deposition in the tropics during the Younger Dryas

COLIN A. COOKE[1*] AND NATHAN D. STANSELL[2]

[1]Yale University, Department of Geology & Geophysics, New Haven, CT, 06511, USA, colin.cooke@yale.edu (* presenting author)

[2]The Ohio State University, Byrd Polar Research Center, Columbus, OH, 43210, USA

Mercury (Hg) loadings to even the most remote aquatic ecosystems have increased by 3-fold or greater since the 20th century, greatly accelerating human exposure to this toxic trace metal. The rise in environmental Hg has been documented from a range of natural archives, including ice cores, snow deposits, peat cores, and (most frequently) lake sediment cores. A majority of these study sites are from to high- and mid-latitude locations; considerably less is known about trends in Hg deposition from low latitudes. In addition, few studies have investigated long-term variability in natural (i.e., pre-industrial) Hg deposition rates, despite evidence for changes in Hg cycling associated with environmental change. Long-term sedimentary archives of past climatic and environmental variability therefore offer a unique opportunity to asses how natural processes serve to influence natural Hg cycling in the environment. Here, we present new Hg geochemical data from a low-latitude lacustrine sediment core collected from Laguna de los Anteojos, a high-altitude (3920 m a.s.l.) cirque lake located in the Mérida Andes of Venezuela. This ^{14}C-dated sediment core spans 14,680 to 9,350 years before present (BP), and includes multi-proxy evidence for large paleoclimatic and paleoecological shifts associated with the Bølling-Allerød, Older Dryas, and Younger Dryas climatic intervals [1].

There are two clear end-member sediment facies within the Anteojos core: clastic-rich sediments high in titanium (Ti) and low in organic matter (OM), and the opposite. Sediment [Hg] spans an order of magnitude (12-124 ng g^{-1}), and is, to some degree, associated with OM (r^2=0.38). [Hg] and Hg flux are lowest during the Younger Dryas, which was not only cold but also arid. Southerly migration of the intertropical convergence zone (ITCZ) during the initial stages of the Younger Dryas chronozone [2] likely decreased regional precipitation and thus Hg deposition to the lake. The return of the ITCZ and a warmer and wetter climate ~12,200 BP appears to have initiated a rapid increase in [Hg] within Anteojos sediment, as both [Hg] and Hg flux rise by >4-fold in less than a century. Alternatively, the demise of regional snowfields and glaciers, which expanded during the Younger Dryas, may have released legacy Hg into the lake. The Anteojos sediment record presented here offers a well-dated and multi-proxy archive of past environmental change through a period of rapid climatic transitions.

Isotopic evidence for preindustrial mercury emissions to the atmosphere

COLIN A. COOKE[1*], HOLGER HINTELMANN[2], HARALD BIESTER[3], AND JAY J. AGUE[1]

[1]Yale University, Department of Geology & Geophysics, New Haven, CT, USA, colin.cooke@yale.edu (* presenting author)

[2]Trent University, Department of Chemistry, Peterborough, ON, Canada

[2]Technische Universität Braunschweig, Institut für Umweltgeologie, Pockelsstraße 3, 38106 Braunschweig, Germany

Lake sediment cores from the South American Andes record anthropogenic Hg emissions to the atmosphere extending as far back as 1400 BC [1]. Early Hg pollution resulted from a range of activities including cinnabar (HgS) mining [1], Hg amalgamation [2], and the smelting of non-ferrous ores [3]. While Hg may spend centuries or even millennia circulating in the environment, it remains unclear just how far early these Hg emissions were transported and to what degree they influenced the global biogeochemical cycle of Hg. Here, we present new Hg stable isotopic data from two lake sediment cores that offer insight into the magnitude and geographic extent of early anthropogenic Hg emissions. One of the cores is from the Peruvian Andes, and records clear increases in Hg associated with Andean cinnabar mining and Hg amalgamation [1]. The other sediment core is from a crater lake on San Cristobal Island (Galápagos archipelago), and thus is far removed Hg emission sources, both past and present.

Concentrations of Hg in both sediment cores increase above stable background values after ~1500 AD, signaling the onset of intensive Hg emissions and subsequent deposition resulting from Colonial cinnabar mining and Hg amalgamation. In addition, both mass dependent (MDF; δ^{202}Hg) and mass-independent fractionation (MIF; Δ^{201}Hg) of sedimentary Hg is evident in both sediment cores (Fig. 1). Pre-pollution sediments (uncontaminated by even the earliest metallurgical activities) consistently record negative MDF (-2‰) and MIF (-0.2‰). However, early increases in Hg concentration are matched by a positive shift in sediment δ^{202}Hg of nearly 2‰; Δ^{201}Hg values, in contrast, remain stable across this transition. The same trends are present in both sediment cores, suggesting they record hemispheric scale processes. Moreover, the Hg stable isotopic signature of preindustrial Hg pollution overlaps with new determinations of MDF and MIF in Peruvian cinnabar, which strongly suggests that early Hg emissions can be isotopically linked to their primary mineralogical sources.

The rise of global Hg pollution during the 20th century is also recorded in both sediment cores. However, while MDF values remain constant across the preindustrial-industrial transition, MIF values shift from negative to positive. This suggests either a difference in the MIF signature of preindustrial and industrial Hg sources, or a change in the direction of photochemically-induced MIF since ~1900 AD. Collectively, these results suggest Hg stable isotopic ratios can offer insight into Hg emissions associated with both preindustrial and industrial anthropogenic activities.

Insights into magmatic processes from combined crystal age and compositional data

KARI M. COOPER[1]*, GARY R. EPPICH[2], ERIK W. KLEMETTI[3], PHILIPP RUPRECHT[4], MARK E. STELTEN[1]

[1]Department of Geology, University of California Davis, Davis, CA, USA, kmcooper@ucdavis.edu (*presenting author)
[2]Lawrence Livermore National Laboratory, Livermore, CA, USA, eppich1@llnl.gov
[3]Department of Geosciences, Denison University, Granville, OH, USA, klemettie@denison.edu
[4]Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, USA, ruprecht@ldeo.columbia.edu

Many, if not most, crystals in volcanic rocks preserve chemical records of subvolcanic processes (such as growth in multiple magmas and storage in a mush or plutonic body) that extend well beyond the life time of the liquids that brought them to the surface. Uranium-series disequilibria represent one of few methods of measuring absolute crystal ages in young volcanic systems, thereby placing chemical, textural, and/or isotopic data in a temporal framework. We present here a synthesis of our recent work [1-5] combining U-series crystal ages with other types of information, which provides new insights into magmatic processes.

Intermediate magmas erupted at Volcán Quizapu, Chile, and Mt. Hood, USA, are the result of mixing of silicic and mafic magmas. We used U-series ages of plagioclase in combination with crystal size distributions, trace-element zoning, and diffusion modeling to constrain both the pre-mixing and post-mixing storage times of crystals [3-5]. Plagioclase in both systems have U-series ages of ka to tens of ka, representing the total average storage time of the crystals. In contrast, diffusion modeling permits a maximum of days to weeks of crystal storage in the host magmas post-mixing. These data suggest that crystals remain in the 'active' (i.e., eruptible) part of the reservoir for thousands of years yet eruption follows quickly on mixing.

Studies of crystals in rhyolitic systems of different volumes may provide insights into processes that are common in silicic melt generation yet may be obscured in larger systems. We have analyzed zircon and plagioclase in three rhyolitic systems ranging from small (South Sister, USA [2]) to intermediate (Okataina Caldera Complex, New Zealand [1]) to large (Yellowstone, USA). Combinations of age data with trace-element and Hf isotopic compositions show the coeval presence of chemically-distinct magma or mush bodies in all three systems; only Yellowstone shows evidence for effective homogenization of the liquid fraction of the magma prior to eruption. If these results generally hold for other systems, it would imply that (only) the largest silicic eruptions are preceded by accumulation of a significant body of liquid that remains in the subsurface long enough to homogenize. Such bodies would likely be detectable by seismic imaging prior to eruption.

Discrimation between biotic and abiotic rates of stabilization of Se(VI) in soil

F.COPPIN[1*], N. LOFFREDO[1], S. MOUNIER[2],Y. THIRY[3] AND L. GARCIA-SANCHEZ[1]

[1] IRSN, PRP-ENV/SERIS/L2BT, Saint paul lez Durance, France, frederic.coppin@irsn.fr (* presenting author)

Selenium (Se) is an essential micronutrient for organisms, with a narrow range of concentrations lying between deficiency and toxicity. ^{79}Se is a long-lived fission product generated by the nuclear industry and in the context of risks assessment studies from nuclear waste repository, it is one of the main potential contributor to the dose to population [1]. Selenium is present in the soil under different oxidation states (+VI; +IV; 0 and–II), that controlled its behaviour. Selenate (Se(VI)) which may preferentially form highly mobile complexes on the surface of numerous solids, is considered to be potentially the most mobile form in the environment[2]. However, biotic or abiotic reduction processes could transform selenate into lower Se oxidation state promoting its stabilization in soil [3], [4].

To discriminate between the impacts of biotic and abiotic processes on Se(VI) stabilization in soils, stirred flow through reactor (SFTR) experiments were realised. A regenerated cellulose dialysis tubing containing a sterilised (abiotic modality) or a raw (biotic modality) silty clay loam soil suspension was placed in SFTR containing a $3x10^{-3}$ mol.L^{-1} NaCl solution. A 10^{-8} mol.L^{-1} radiolabelled ^{75}Se(VI) solution was injected in SFTR during 3 to 20 days (flow rate between 2 to 30 ml.h^{-1}) and then flushed by a NaCl solution (6 days). Se interactions with soil were followed by analyses on the outlet solution.

The results obtained showed that a simple equilibrium model based on reversible exchange reactions can not be applied to fit the experimental data as, for both biotic and abiotic conditions a fraction of Se(VI) was stabilised in soil. The use of a simple kinetic model that involves a fraction of selenate sorbed on the solid surface sites accessible for water lixiviation, and another fraction stabilized resulting in biotic or abiotic reduction was shown to better describe experimental results. (Figure 1).

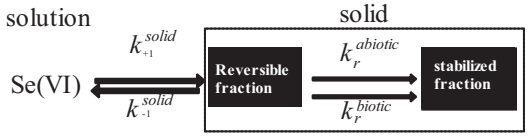

Figure 1 : Kinetic model describing Se(VI) stabilisation in soil under biotic or abiotic conditions

The kinetic parameters of the model were adjusted in two steps : (1) on abiotic experiments for k_{+1}^{solid}, k_{-1}^{solid}, $k_r^{abiotic}$ (with $k_r^{biotic} = 0$) and (2) on the biotic conditions, for k_r^{biotic},by considering that abiotic parameters remain constant.

Reducing the uncertainty of spent nuclear fuel dissoluon: an investigation of UO_2 analogue CeO_2

CLAIRE L. CORKHILL[1*], DANIEL J. BAILEY [1], MARTIN C. STENNETT[1], AND NEIL C. HYATT[1]

[1]The Immobilisation Science Laboratory, Department of Materials Science and Engineering, The University of Sheffield, UK (* c.corkhill@sheffield.ac.uk)

In the safety case for the geological disposal of nuclear waste, the release of radioactivity from the repository is controlled by the dissolution of the spent fuel in groundwater. Therefore, to assess the performance of the repository after infiltration of groundwater and contact with spent fuel, the dissolution characteristics must be determined. In spent nuclear fuel, high energy sites occur at grain boundaries and within the material as naturally occurring surface defects. Current studies of spent nuclear fuel dissolution have not considered the effect of high energy surface sites within the material structure.

In this investigation, CeO_2 analogues, which approximate as closely as possible the characteristics of fuel-grade UO_2, were characterised after dissolution under a wide range of conditions. Samples were powdered to three different size fractions to investigate high energy surface site density on dissolution rates, while monolith samples were monitored for development of surface defects as pores, steps and dissolution pits. These samples were subject to a range of aggressive and environmentally relevant alteration media with different solubility controls, including 2M HCl, a simplified groundwater of dilute NaCl (10mM) buffered to pH 7.5 by $NaHCO_3$ (2mM) and 0.01M NaOH, and reacted at a range of temperatures from 90°C to 150°C. Dissolution was monitored through analysis of the coexisting aqueous solution, and morphological changes at the surface using atomic force microscopy, confocal profilometry and scanning electron microscopy. Dissolution rates were found to be greater in high pH solutions, and at higher temperatures, and greatest for samples with the highest reactive surface area. Chemical analysis of additional monolith samples reacted in ^{18}O-enriched aqueous solutions was conducted using TOF-SIMS. The data demonstrate re-precipitation of Ce-hydroxide species on the sample surface, which may form a passivating barrier to dissolution.

Nanometer scale characterization of fossil bacteria in an Eocene phoshorite sample

JULIE COSMIDIS[1*], KARIM BENZERARA[2], IMÈNE ESTÈVE[3] AND EMMANUEL GHEERBRANT[4]

[1]IMPMC & IPGP, Paris, France, Julie.Cosmidis@impmc.upmc.fr (* presenting author)

[3]IMPMC, Paris, France, Imene.Esteve@impmc.upmc.fr
[4]CR2P, CNRS & MNHN, Paris, France, Gheerbra@mnhn.fr

A great number of microstructures described as fossilized microbial bodies have been described in phosphorites of all ages in the past years (e.g., [1]). Most of these putative fossils have been identified based on their morphology (sizes and shapes) using SEM observations only. However, this approach might be misleading since micrometer-sized calcium phosphate globules ressembling bacteria can also be produced by abiotic processes, as we will show here.

Here, we will present the study of an Eocene phosphatic coprolite from Morocco containing numerous purported bacterial fossils. We characterized the mineralogical structure and chemical composition of these objects down to the nano-meter scale using a combination of FIB-SEM, TEM dans STXM .

The fossils are composed exclusively of francolite ($Ca_{10}(PO_4,CO_3)_6(F,OH)_2$). However, some variations in electron density outlining these fossils could be evidenced. Based on TEM and STXM analyses, we interpret them as variations of mineralogical texture and chemical composition, resulting from the precipitation of francolite in the cell wall of the bacteria during their fossilization.

We compare these fossils with modern bacteria calcified in the laboratory on the one hand, and with bacteria-free and enzymatically-produced hydroxyapatite globules on the other hand. We will show that although they present great morphological similaritires at the SEM scale (Figure 1), theses different objects can be discriminated unambigously at greater spatial resolution.

This study provides new signatures for identifying microbial activity in past and present phosphorites and illustrates the importance of using high resolution analytical tools for the search of biosignatures in terrestrial and extraterrestrial rocks.

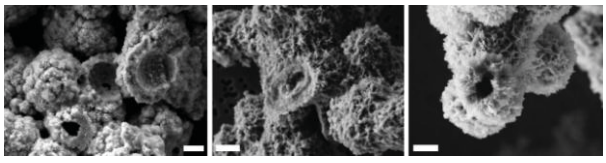

Figure 1: SEM images of the fossils in the Eocene phosphorite (left), bacteria calcified in the laboratory (middle) and bacteria-free, enzymatically-precipitated hydroxyapatite globules (rigth). Scale bars: 1 µm.

Methylation of Hg in sediments is a crucial process that controls Hg accumulation in biota. Several studies have reported a significant positive correlation between methylmercury (MeHg) and total Hg in aquatic sediments. However, these relationships differ among studied systems due to geochemical and biological controls. We show here, by compilling published and unpublished HgT-MeHg couples from riverine, estuarine and marine sediments covering various environmental conditions, from deep pristine abyssal to heavily contaminated river sediments, that a general relationship relies the two parameters. The net methylation, i.e. methylation/demethylation equilibrium, governs the position of the points within the drawing. This global equation suggests that most of the variability in the MeHg concentration is explained by the inorganic Hg availability, a proxy of which is HgT in the sediment. The position of the points on both sides of the equation line are discussed in terms of redox and sedimentation conditions, with surface sediment points above the line.

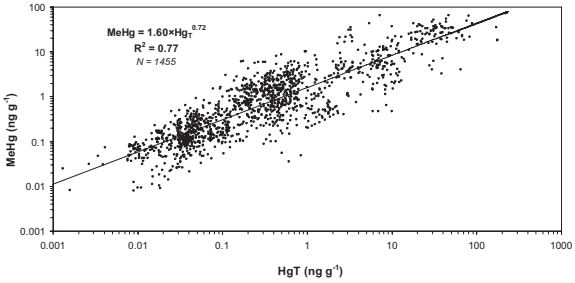

Figure 1: The unpublished results are from abyssal plains of the Arctic Ocean and the Mediterranean Sea, and continental shelf and bays of the Mediterranean Sea. Published results are from references 1 to 15.

Time scales of magmatic processes and volcanic unrest at caldera systems

FIDEL COSTA[1*], TIM DRUITT[2], ETIENNE DELOULE[3], MICHAEL DUNGAN[4], AND BRUNO SCAILLET[5]

[1]Earth Observatory of Singapore, Nanyang Technological University, Singapore, fcosta@ntu.edu.sg

[5]ISTO-CNRS, Universite d'Orleans, Orleans, France, bscaille@cnrs-orleans.fr

Calderas are capable of producing the largest and most explosive eruptions on Earth. The type of unrest in many caldera systems consists of long periods (years or decades) of deformation and earthquake activity (e.g. Campi Flegrei - Italy, Yellowstone or Long Valley – USA); however not all periods of unrest culminate in a volcanic eruption and not all eruptions are related to a caldera collapse. Despite the importance of properly interpreting the caldera unrest signals as magmatic proceses, there are few historical caldera eruptions that have been well monitored. We have taken a complementary approach to understanding the dynamics of magmatic processes at calderas by studying crystal zoning styles from the Minoan eruption of Santorini. Modeling the zoning patterns of the crystals can provide the times involved in destabilization of the magmatic system, and allows first order comparisons with the time scales of unrest signals. We investigated more than 300 plagioclase crystals with the electron microscope. A subset of these were investigated with the electron microprobe, and from these the trace element zoning of six crystals were measured by SIMS.

We distinguished two main types of plagioclase; a dominant one with cores at about An $_{43\text{-}58}$ and another, very rare, type with cores at An$_{30\text{-}36}$. Both types have similar rims at about An $_{36\text{-}43}$, and also rare high An cores (58-88). We think that these crystals record at least two mixing events. A first involved a basaltic-andesitic magma with an dacitic one at relatively deep levels, and later on these two magmas mixed with a rhyolitic magma located much closer to the surface. We have modeled the Mg and Sr zoning profiles across the different zones of the crystals using a diffusion model. We find two time scales associated with the different mixing events. A few decades occurred since the first and deeper mixing event and eruption, whereas the last transfer of the mixed dacite into the shallow rhyolite only occurred a few months prior to eruption. Mass balance constraints indicate that the dacitic magma that intruded in the upper reservoir accounted for at least 15 % of the total hybrid magma erupted, or about 5-9 km^3 of replenishment. The two time scales we have found are analogous with the three decades of deformation and seismic unrest that occurred at Rabaul caldera during 1973-1994, and which culminated in eruption in 1994 after an increased seismicity and deformation only about 5 months before eruption.

Monazite petrochronology by laser ablation split stream inductively coupled plasma mass spectrometry (LASS-ICPMS)

JOHN M. COTTLE[1*], ANDREW KYLANDER-CLARK[1] AND BRADLEY R. HACKER[1]

[1] Department of Earth Science, University of California Santa Barbara, CA 93106-9630, USA, cottle@geol.ucsb.edu (* presenting author)

Because monazite readily incorporates actinide and lanthanide elements and is reactive across a broad range of pressure, temperature, and fluid conditions, it is an ideal recorder of the nature and rates of a wide variety of diagenetic, metamorphic, magmatic and fluid-flow processes. It is common for monazite to preserve multiple episodes of growth, dissolution and re-precipitation within distinct intra-crystal compositional domains that are typically at, or below, the tens of micron scale. Development of measurement protocols to obtain age and petrologic information at high spatial resolution is therefore crucial to advancing monazite petrochronology.

This contribution details a new analytical configuration that enables simultaneous collection of both isotope and trace-element data. The laser ablation split stream inductively coupled plasma mass spectrometry (LASS-ICPMS) system at the University of California, Santa Barbara, uses two mass spectrometers (a Nu Plasma HR and an AttoM) coupled to a 193 nm ArF excimer laser ablation system to rapidly determine simultaneous *in-situ* U/Th-Pb dates, Sm-Nd isotopic compositions and trace-element concentrations. Hardware innovations include i) a modified collector configuration that enables simultaneous determination of Th-Pb and U-Pb dates by LA-MC-ICPMS using either Faraday cups or ion counters for Pb isotopes, and ii) increased instrument sensitivity and signal transmission resulting in a spatial resolution of 5 μm for U-Th-Pb dates and 9 μm for U-Th-Pb + Sm-Nd + trace-element determinations on Tertiary monazite; these allow the ability to directly tie measured dates to specific petrologic processes via Sm-Nd ratios, and/or trace-element abundances and ratios. Long-term accuracy and precision for Th-Pb and U-Pb dates is ~2% (2σ). Individual Nd ratio measurements have precisions of 20–30‰ and are accurate to within 5‰. Trace-element concentrations are accurate to within 3–5%.

The utility of the LASS approach—combining U-Th-Pb dates, isotopic compositions and trace-element abundances and ratios—will be illustrated with a broad range of geologic examples ranging from new insight into detrital monazite provenance, resolving fine-scale timing and duration of ultrahigh-pressure tectonics and unraveling the pressure–temperature history of Himalayan metamorphic rocks.

δ^{66}Zn profiles in five highly Zn-contaminated soils

E. COUDER[1,2*], E. SMOLDERS[3], B. DELVAUX[1], C. CAMBIER[1] & N. MATTIELLI[2]

[1] Earth and Life Institute, Université catholique de Louvain, 1348 Louvain-la-Neuve, Belgium - Eleonore.Couder@uclouvain.be (*presenting author)

[2] Laboratoire G-TIME, Université Libre de Bruxelles, 1050 Brussels, Belgium - nmattiel@ulb.ac.be

[3] Division of Soil and Water Management, Katholieke Universiteit Leuven, 3001 Heverlee, Belgium

Metalurgical industry, through emission and slag dumping, has strongly modified metal biogeochemical cycling. The soil-plant system is crucial for the understanding of metal transfer between terrestrial pools. In Belgian soils, zinc (Zn) is a main inorganic pollutant.

Variations in δ^{66}Zn between compartments of the plant-soil system are indicative of abiotic and biotic processes. Our previous data indicate that Zn isotopic compositions (δ^{66}Zn) of topsoils reflect the Zn isotopic signature of the main Zn-emitter. The main goal of the present study consists to examine the δ^{66}Zn profiles in five contrasted soils covered by various plant species.

Two natural soils, a calcareous soil (CS) and a shale-derived soil (SS), both contaminated by Zn aerial fallouts, and three soils developed on a slag heap were chosen. Throughout the soil profiles, the soils have been characterized: (i) the total Zn concentrations in bulk soil (Zn_{tot}), which vary from 0.2 up to 74.8 g kg^{-1}, and (ii) the oxidizable Zn fractions (Zn_{ox}, i.e. proportion of Zn-bearing organic matter *vs* Zn_{tot}) ranging between 3.5 and 34.7 % of Zn_{tot}. High precision δ^{66}Zn data measured by MC-ICP-MS are reported (relative to the JMC Zn standard solution) for bulk soils, gravity soil solutions, surrogate soil solutions obtained by 0.01M $CaCl_2$-extraction and shoots from plants growing on-site.

Relative to the bulk soils (δ^{66}Zn from -0.7±0.03‰ to +0.56±0.03‰), enrichment in light Zn isotopes is observed both in the gravity and surrogate solutions (δ^{66}Zn varies from -0.25±0.01‰ to +0.25±0.01‰ (±2SD)) as well as in shoots (δ^{66}Zn from -0.05±0.02 to +0.14±0.02‰). As a result of Zn uptake by plants or Zn leaching, the residual topsoils will be comparatively enriched in heavy isotopes.

Throughout the soil profiles (CS and SS), an increase in δ^{66}Zn values with depth is observed and is negatively correlated with Zn_{ox}. This trend reflects transport of Zn-bearing organic matter, coming from the dead plant material and enriched in light Zn isotopes, from the topsoil to the depth via bioturbation and/or mass movement processes.

In summary, the δ^{66}Zn profiles in the five contaminated soils reflect the combined processes: (i) soil leaching, (ii) dead plant return to soil, and (iii) organic matter transfer to depth.

Abstract

The evolution of Earth environments has been deeply linked with that of Cyanobacteria for billions of years. Cyanobacteria have impacted major geochemical cycles (C, N & O) through Earth history. They have played a major role in the carbon cycle by converting CO_2 into organic carbon and carbonates and by enriching the atmosphere in oxygen. They have been looked for in the geological record in the form of fossil encrusted cells based on the assumption that cyanobacterial calcification is always an extracellular process. Here, we report the discovery of a cyanobacterium found in microbialites from Lake Alchichica (Mexico) [1,2] that forms intracellular carbonate phase inclusions, revealing an unexplored pathway for calcification. Electron diffraction shows that these phases are amorphous although XANES nanospectroscopy reveals local ordering consistent with the structure of benstonite, a Mg-Ca-Sr-Ba carbonate. Phylogenetic analyses place this cyanobacterium within the deeply divergent order Gloeobacterales. Accordingly, we tentatively name it *Candidatus* Gloeomargarita lithophora. This discovery opens the possibility that ancestral calcifying cyanobacteria may have biomineralized carbonates intracellularly, and thus are not prone to encrustation in extracellular precipitates. This lack of encrustation provides an alternative explanation for the absence of cyanobacterial microfossils in the oldest fossil stromatolites and opens questions about the evolution of calcification in cyanobacteria.

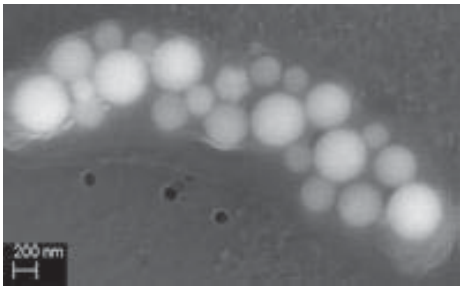

Figure: SEM picture (secondary electron mode) of a cell of *Ca.* G.lithophora. Intracellular carbonate inclusions filling the cell are visible.

Diminished S isotope fractionation accompanies internal sulfate accumulation by sulfate-reducing bacteria

M.L. COUSINEAU[1]*, D. FORTIN[1], AND B.A. WING[2]

[1]Earth Sciences, University of Ottawa, Ottawa, Ontario, Canada, mlcousineau@gmail.com (*presenting author)
[2]Earth and Planetary Sciences, McGill University, Montréal, Québec, Canada, boswell.wing@mcgill.ca

Microbial sulfate reduction (MSR), one of the earliest metabolisms to appear on Earth, is a process by which some prokaryotes use sulfate as an electron donor to obtain energy for metabolic processes. BSR results in the fractionation of sulfur isotopes, with the reactant sulfate enriched in ^{34}S, and the product sulfide depleted in ^{34}S. As studies have shown that MSR in low sulfate conditions results in small S isotope fractionations, limited variability in S isotope fractionation in ancient biogenic sulfides has been interpreted to indicate sulfate-poor conditions in early oceans.

We conducted closed-system experiments using two pure strains of acid-tolerant sulfate-reducing bacteria (M1, optimum pH 4; and GBSRB4.2, pH 4.2) in non-sulfate-limiting conditions. We identified two distinct fractionation regimes during the growth cycle: 1) low (<5‰) fractionation in the beginning lag phase, when sulfate reduction and growth are negligible, and 2) higher fractionation (≈11-24‰) during the exponential phase, when cell growth and sulfate reduction are occurring rapidly. The low fractionation during the lag phase apparently results from initial sulfate uptake by the cells, which leads to internal sulfate accumulation prior to the initiation of sulfate reduction.

The small S isotope fractionations that we have identified are consistent with rare experiments that have been designed to specifically investigate sulfate uptake during MSR. Isotopic calibration of the first link in the MSR processing chain contributes to our understanding of the multi-step process of MSR and may help in developing a mechanistic interpretation of S isotope compositions in modern and ancient biogenic sulfides.

Physico-chemical and structural controls on copper isotope fractionation during its sorption by benthic algae and a phototrophic biofilm

AUDE COUTAUD[1,2*], OLEG S. POKROVSKY[1], PIETER GLATZEL[3], GLEB S. POKROVSKI[1], JÉRÔME VIERS[1] AND JEAN-LUC ROLS[2]

[1]GET, Toulouse, France , aude.coutaud@get.obs-mip.fr (* presenting author)
[2]EcoLab, Toulouse, France
[3] ESRF, Grenoble, France, pieter.glatzel@esrf.fr

The interaction of one of the most phyto-toxic but also essential metals, copper, with different phototrophic microorganisms as a function of exposure time was studied via physico-chemical characterization of metal adsorption on and incorporation into cells under controlled laboratory conditions. The novelty of the present study is to combine two different approaches, the "macroscopic" stable-isotope techniques with the "microscopic" molecular-level observations using X-ray absorption spectroscopy (XAS) of the complexes formed on the surface and inside the cells. The isotopic study included batch and flow-through experiments which allowed to distinguish among assimilation, excretion and adsorption processes within the mature biofilm dominated by cyanobacteria. Moreover, relationships between the fractionation of Cu stable isotopes and the biofilm growth cycle in a Taylor Couette flow-through reactor was quantified. To investigate the local atomic environment of Cu in peryphytic biofilms and benthic algae, freeze-dried samples with 1 to 5000 ppm Cu were examined by XAS at beamline ID26 (ESRF). The high-resolution mode, for the first time used for Cu in biological matrices, allowed establishing specific features of the Cu pre-edge and quantifying the oxidation state, the nature and the number of neighbours around Cu. Results show that the degree of isotope fractionnation depends on the metal concentration in the biomass, the degree of Cu reduction and the structural environment of Cu. For instance, heavy Cu isotopes are preferentially adsorbed on the surface whereas the intracellular incorporation favours light Cu isotopes. Theses trends may be linked to the drastic changes in the local chemical environment of copper occured upon its adsorption onto or incorporation in the cells, similarly to Zn and Cd [1-3]. However, in contrast to other heavy metals, Cu undergoes Cu(II) to Cu(I) reduction during its uptake by our biomodels. Thus, low-concentrated samples (1-20 ppm), demonstrate the presence of sulfur in the nearest atomic shell of Cu(I), whereas in concentrated samples, the carboxylic complexes of Cu(II) predominate. These findings help to establish the interaction mechanism of autotrophic photosynthetic microorganims with copper both at trace and toxic level of metal concentration. The results of this integrated study can be useful for tracing the environmental effects of copper - biofilm interactions, and allow to identify the factors exerting the direct control on the mechanisms of Cu stable isotope fractionation in biological systems.

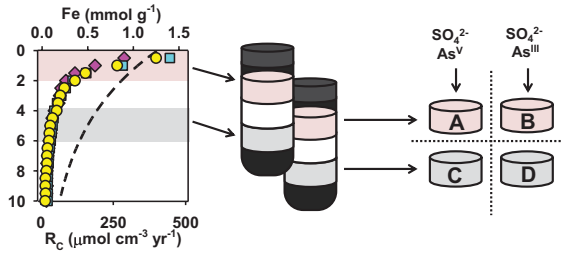
Arsenic sequestration during early diagenetic sulfur redistribution

RAOUL-MARIE COUTURE[1,*], JÉROME ROSE[2], DIRK WALLSCHLÄGER[3] AND PHILIPPE VAN CAPPELLEN[4]

[1]University of Waterloo, Waterloo, Canada, raoul.couture@uwaterloo.ca (*presenting author)
[2]CEREGE, Aix-en-Provence, France, rose@cerege.fr
[3]Trent University, Peterborough, Canada, dwallsch@trentu.ca
[4]University of Waterloo, Waterloo, Canada, pvc@uwaterloo.ca

Despite accumulating evidence that thiolated arsenic (As) species play a major role As cycling, the pathways leading to the formation of these elusive species in freshwater environments, as well as their sorption affinity in redox-active sediments, remain poorly studied. We used flow-through reactors (FTRs) to look at the fate of As species during the degradation of sedimentary organic carbon (C_{org}) and iron (Fe) oxyhydroxides under sulfate (SO_4^{2-}) reducing conditions. Sediment samples from Lake Tantaré, a well studied oligotrophic lake whose surface sediments are supplied with both labile C_{org} (C_{org} oxidation rates, R_C, up to 400 µmol cm^{-3} yr^{-1}) and reactive ferric Fe (Fe ≥ 1 mmol g^{-1}), were incubated for 8 weeks in reactors supplied with SO_4^{2-} and soluble As (Fig. 1). Lactate was added to the inflowing solutions after depletion of the labile sedimentary C_{org} pool, witch occured after 21 days. As and sulfur (S) solid phase speciation was investigated using X-ray absorption spectroscopy (XAS), and aqueous speciation using a combination of ion chromatography, voltammetry, spectro-photometry.

Figure 1. Sample selection based on the Fe (symbols, triplicate) and R_C values (line) measured in the sediments of Lake Tantaré [1].



Aqueous S speciation throughout the experiment was dominated by (poly)sulfides, while As speciation was dominated first by arsenite and then, in FTR A (Figure 1), by mono-thioarsenate. The availability of labile C_{org} exerted the following dual control on the fate of S during the incubations: i) higher SO_4^{2-} reduction rates were observed in FTRs A-B than in FTRs C-D, and ii) evolving sulfides were sequestered as organic-S^{-II} in FTRs A-B and as FeS_2 and $\alpha S_{8(s)}$ in FTRs C-D. Similarly, As removal proceeded through either realgar (FTR A-B) or orpiment (FTR C-D) formation, confirming the key influence of free S^{-II} on the mechanisms of As sequestration [2]. XAS data also show that solid-phase tetra-thioarsenate was present, probably as a sorbed complex, representing up to 35% of total As in FTR C. While current geochemical models are able to reasonably predict As speciation in the aqueous phase, they fail to predict the prevalent form of As in the solid phase.

The critical role of hydrothermal activity in forming hyperenriched deposits of metals in black shales

RAYMOND M. COVENEY, JR.*; JAMES B. MUROWCHICK

* presenting author

Introduction

Certain black shale-hosted deposits contain exceptional metal values that are several orders of magnitude greater than average black shale (which typically contains, for example, 300 ppm Zn; 10 ppm Mo)[1,2]. In Illinois and Indiana, for example, bed B of the Carboniferous Mecca Quarry Shale Member[3,4] contains an average of 1100 ppm Mo as well as erratic values for Zn that average 3000 ppm but in some cases even exceed 10,000 ppm. Elsewhere, the Ni-Mo sulphide beds in Cambrian shales of southern China contain more than four weight per cent Mo and nearly as much Ni[5,6]. We suggest that mineralized beds containing such highly concentrated deposits of metals be called "hyperenriched". Known examples of such deposits are all located in exceptionally metal-rich geological environments (i.e. in the Mississippi Valley of North America, the rich ancient mining areas of southern China in Guizhou and Hunan or are adjacent to *bona fide* sedex deposits[7]).

Origins of Hyperenriched Deposits

Although hyperenriched deposits of metals in black shales have been studied since the days of Goldschmidt's early 20th Century work on the Kupferschiefer, a consensus on the mode (or modes) of origin has yet to emerge. Workers have variously attributed black shale-hosted deposits to a wide range of agents including syngenetic or epigenetic hydrothermal activity, bolide impact, or accumulation from sea water.We note, however, that the hyperenriched deposits in black shales that we cite are associated regionally with coeval hydrothermal ore systems that have left evidence in the form of hot saline fluid inclusions found in association with the shales. For these reasons, we infer that the metalliferous black shale deposits, such the Late Paleozoic American black shales, and the unusual Ni-Mo deposits of China, primarily owe their origins to hydrothermal processes.

Conclusions

Besides the evidence cited above, we and others[8] note the absence of a clear modern analog for deposition of hyperenriched enriched deposits directly from sea water as has been proposed by some other workers. We conclude, therefore, that hyperenriched deposits result from hydrothermal sources.

Influence of salinity on methanogenesis in the Alberta oil sands region

BENJAMIN R. COWIE[1], LISA M. GIEG[1], AND BERNHARD MAYER[1].

[1]University of Calgary, Calgary, Alberta, Canada.
brcowie@ucalgary.ca

This study examined the relationship between water chemistry and methanogenic microbial activity in the Alberta oil sands using a bench-scale experiment. The terminal redox process, methanogenesis, is common in many shallow hydrocarbon reservoir systems and is thought to be a central process in the geological history of Alberta's oil sands. The biodegradation of light oil over geological time via methanogenesis has been proposed to be a primary formation process of the oil sands reserves in western Canada [1]. Shallow hydrocarbon reservoir environments are favourable to methanogenic communities that require moderate temperature, pH and reducing geochemical conditions to conduct their metabolic processes. In the McMurray formation, the predominant Athabasca oil sands reservoir, formation water geochemistry is variable and salinities vary from fresh to brine. Furthermore, quaternary-aged glacial channels have brought fresh groundwater into contact with oil sands deposits since the last glaciation [2], possibly stimulating increased methanogenic activity in the sedimentary basin [3]. Therefore the relationship between microbial processes and aqueous geochemistry requires investigation to gain insight into potential biodegradation mechanisms and rates of oil sands.

Laboratory cultures of methanogenic communities grown on an oil sands substrate were prepared using waters with three different geochemical compositions and salinities ranging from fresh to saline. Methane generation rates, microbial community composition and stable isotope geochemistry of carbon and sulphur systems were determined over eight months to assess the influence of variable salinity on biodegradation of oil sands via methanogenesis.

Microbial methane generation was variable among replicates with similar chemical water compositions. However, mean methane generation rates were higher in brackish and freshwater cultures than in saline cultures. Carbon isotope measurements indicated that neither CO_2 reducing, nor acetoclastic methanogens were dominant, and that a mixed methanogenic community was most likely active in all three geochemical variants. Sulphur isotope data suggested that bacterial sulphate reduction (BSR) is a likely process in the saline cultures where sulphate concentrations were elevated. However, in the cultures with active BSR, methanogenesis was not inhibited. Increasing concentrations of acetate in all cultures suggest syntrophic fermenting bacteria play a dominant role in the microbial ecosystem under all geochemical conditions tested.

These preliminary results indicate that both CO_2 reduction and acetoclastic methanogenesis are potential processes for oil sands biodegradation under laboratory conditions, and may also be active in modern oil sands reservoirs.

The reappearance in the geological record of sedimentary iron formations after a ~1 Ga hiatus [1,2] is a geologically unique feature of the Cryogenian (~850 Ma to 625 Ma). Whereas their close association with globally distributed glacial deposits invites interpretation that they are the product of snowball glaciation, they have also been interpreted to be a local product of rifting, similar to modern Red Sea metalliferous sediments. Based on major element, REE, and $^{143}Nd/^{144}Nd$ data from stratigraphically-constrained samples from South Australia (Holowilena), NW Canada (Tindir and Rapitan) and southern Namibia (Numees), Cryogenian iron formations can be characterized as a mixture between a hydrothermal source and mid ocean ridge basalt (N-MORB), with very little contribution from the continental crust. Similar positive-upward iron isotope profiles in each of these basins suggest a common depositional process for the iron formation. These data indicate that both snowball glaciation and local rifting are prerequisites to Cryogenian iron formation. Notably, the Cryogenian IF patterns are distinct from both Archean-Paleoproterozoic banded iron formation and Phanerozoic ironstones.

Stable Isotopes of Platinum: A New Geochemical and Cosmochemical Tracer?

JOHN CREECH[1*], MONICA HANDLER[1], JOEL BAKER[1], LORETTA CORCORAN[1], VICTORIA BENNETT[2]

[1] School of Geography, Environment and Earth Sciences, Victoria University of Wellington, P.O. Box 600, Wellington, New Zealand, john.creech@vuw.ac.nz (* presenting author)
[2] Research School of Earth Sciences, Australian National University, Canberra, ACT 0200, Australia

Platinum is a highly siderophile transition metal with 6 naturally occuring isotopes (^{190}Pt, ^{192}Pt, ^{194}Pt, ^{195}Pt, ^{196}Pt, ^{198}Pt). The platinum stable isotope system is of cosmochemical and geochemical interest due to its strong sequestration into planetary cores during planetary differentiation and its range of oxidation states which are found in planetary environments from core to crust (Pt^0, Pt^{2+}, Pt^{4+}). As with other non-traditional stable isotope systems, the ability to make precise and accurate measurements of Pt isotope compositions in natural samples may provide possibilites to trace a range of natural processes. Potential examples include planetary core formation under different redox conditions, Pt mineralisation in ore deposits, and redox controlled behaviour of Pt in the oceans and marine sediments where it potentially exists in the 2+ and 4+ state.

We have developed, for the first time, mass spectrometric methods for the precise determination of platinum stable isotopes. Pt stable isotopes have been measured with a Nu Plasma multiple collector ICPMS using a ^{192}Pt-^{198}Pt double-spike to correct for instrumental mass bias. Samples are introduced to the MC-ICPMS with a DSN-100 desolvating nebuliser. Repeated measurements of standards consuming ca. 50 ng of Pt show that an external reproducibility of < 25 ppm/amu (2σ) can be obtained on double-spike corrected ratios using this technique. Three commercially available Pt standards have been measured to high precision, and show resolvable differences in isotopic composition.

A method for the chemical separation of Pt from geological materials (silicates, metals, Fe-Mn oxyhydroxides) has also been developed using anion exchange techniques. This method yields ≥ 85% of Pt, with > 90% purity. Analytical tests of Pt doped with a range of elements show that this degree of separation does not compromise the accuracy of the double-spike corrected Pt isotope ratios. We will also present Pt stable isotope data for a range of international reference materials, where samples have been double-spiked prior to chemistry.

Alkali and alkaline earth metal adsorption to goethite

LOUISE J CRISCENTI[1]*, DAVID HART[2], AND KIDEOK KWON[3]

[1]Sandia National Laboratories, Geochemistry, ljcrisc@sandia.gov (*presenting author)
[2]Sandia National Laboratories, National Security Applications, dbhart@sandia.gov
[3]Sandia National Laboratories, Geochemistry, kkwon@sandia.gov

The adsorption of metals to Fe-hydroxides such as goethite influences contaminant migration in the subsurface environment. Many surface complexes have been proposed for cation adsorption to goethite. In this study, we use classical molecular dynamics (MD) simulations to investigate the specific location of surface species with respect to both the mineral surface and to the structured water at the interface. Simulations are conducted for a range of NaCl, $MgCl_2$ and $BaCl_2$ concentrations to evaluate the impact of ion adsorption on the interfacial water structure, and to evaluate how surface speciation might change with increased surface loading.

Figure 1 illustrates preliminary results for the (100) and (101) surfaces of goethite in a 5 M NaCl solution. Interfacial water at the (100) surface exhibits more ordered arrangements of interfacial water and more hydrogen bonding with surface hydroxyl groups than at the (101) surface. The overall water structure is not affected by Na^+ and Cl^- adsorption. Sodium binds as an inner-sphere complex in 1 M NaCl solutions, but in a 5 M NaCl solution, it adsorbs both as inner and outer-sphere complexes. In 1M – 5 M NaCl solutions, the Cl^- ion adsorbs strictly as an outer-sphere complex.

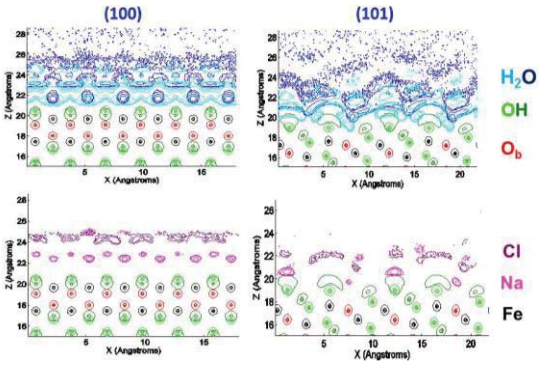

Figure 1: Water, Na^+, and Cl^- adsorption on goethite surfaces.

Comparisons will be made between the adsorption of Na^+, Mg^{2+}, Ba^{2+} from NaCl, $MgCl_2$ and $BaCl_2$ solutions of different concentrations. Atomic density profiles, partition coefficients, statistics on the types of species formed on the surfaces (i.e., inner- vs. outer-sphere, ion-pairs), and water dipole orientation data will be presented. Differences in the electric double layer formed at the (100) and (101) surfaces will be discussed.

Negative C-isotope excursion in carbonates during 2.0 Ga Shunga Event

ALENKA E. ČRNE[1*], VICTOR A. MELEZHIK[1], AIVO LEPLAND[1], ANTHONY E. FALLICK[2], ANTHONY R. PRAVE[3], AND ALEXANDER T. BRASIER[2]

[1]Geological Survey of Norway, Trondheim, Norway, alenka.crne@ngu.no (* presenting author), victor.melezhik@ngu.no, aivo.lepland@ngu.no
[2]Scottish Universities Environmental Research Centre, East Kilbride, UK, t.fallick@suerc.gla.ac.uk, alex.brasier@glasgow.ac.uk
[3]University of St. Andrews, St. Andrews, UK, ap13@st-andrews.ac.uk

The ~2.0 Ga Shunga Event (SE), characterized by worldwide accumulation of extraordinary amounts of organic material, was among several global Paleoproterozoic events associated with the rise of atmospheric oxygen that were targeted by ICDP Fennoscandia Arctic Russia – Drilling Early Earth Project (FAR-DEEP). The SE appears to be linked to major disturbances in the C-cycle during the Paleoproterozoic, and follows or transitionally overlaps with the Lomagundi-Jatuli positive isotopic excursion of carbonate carbon at ~2.3-2.1 Ga. Four FAR-DEEP drillholes intersecting 670 m of sedimentary and volcanic rocks of the Zaonega Formation (ZF) offer a unique opportunity to study the C-cycle during the SE. Compositionally heterogeneous carbonate phases with $\delta^{13}C$ values ranging from -22 to +8 ‰ indicate a complex, multistage formation and alteration of sedimentary carbonates. In order to make a distinction between primary and secondary phases and their compositional signatures, a suite of samples was characterized by SEM-BSE imaging and geochemical investigations (major and trace elements, C- and O-isotopes).

The lowermost part of the drilled succession, where sedimentary rocks are sandwiched between mafic lavas and sills, contains one carbonate phase. This is patchy calcite, with relatively constant, low $\delta^{13}C$ values around -10 ‰. As the calcite is overgrowing previous mineral phases (e.g. pyrite), it is interpreted as a seconday carbonate phase unrelated to depositional or early diagenetic environmental conditions. The middle part of the drilled succession contains carbonate beds consisting of dolomite in the middle and calcite associated with talc in the outer parts of the beds. The talc-calcite association, which overgrows dolomite, indicates a metamorphic origin of the calcite through dolomite-silica reaction in marginal parts of the carbonate beds. Samples containing nearly pure dolomite, which is the earliest preserved carbonate phase, have highest $\delta^{13}C$ values, between +3 and +8 ‰. Samples with a mixture of calcite and dolomite have $\delta^{13}C$ values as low as -10 ‰ depending on the relative amount of the two mineral phases. Dolomite-dominated samples in the upper part of the succession are isotopically lighter with values from -2 to -5 ‰.

Even though the C-isotope composition of the carbonates of the ZF has been affected by post-depositional alteration, a negative C-isotope shift of 10 ‰ is recognized in best preserved dolomite samples with $\delta^{13}C$ values from +8 to -2 ‰ over a 260-m thick stratigraphic interval. This shift may reflect a global change in isotopic composition of atmospheric/oceanic CO_2 [1], but local factors related to petroleum generation and spilling together with volcanic activity might have also influenced $\delta^{13}C$ of the ambient sea-water.

Changes in the deglacial NW Atlantic from deep sea coral ε_{Nd}

KIRSTY C. CROCKET[1*], TINA VAN DE FLIERDT[1], LAURA F. ROBINSON[2], AND JESS F. ADKINS[3]

[1]Earth Science and Engineering, Imperial College London, UK (*k.crocket@imperial.ac.uk; tina.vandeflierdt@imperial.ac.uk).

[2]Department of Earth Sciences, University of Bristol, UK (Laura.Robinson@bristol.ac.uk).

[3]Californian Institute of Technology, Pasadena, USA (jess@gps.caltech.edu)

Carbon storage in the deep ocean during glacials and its subsequent release during deglaciation undoubtedly played a role in glacial/interglacial variation of atmospheric CO_2, with the Southern Ocean a strong candidate for both glacial storage and deglacial venting to the atmosphere. While radiocarbon records support this hypothesis [1], they cannot unambiguously identify the water masses involved. To do so requires pairing the radiocarbon data to a conservative water mass tracer, such as the Nd isotope composition (ε_{Nd}).

We describe the use of deep sea corals as an archive material providing same-sample U/Th ages, radiocarbon, and Nd isotope compositions. The majority of corals in this study are deglacial in age and span intermediate water depths of 1000 to 2600 m on the New England Seamounts (NW Atlantic), where pronounced changes in water column radiocarbon across the last glacial/interglacial cycle have already been identified [2, 3].

In the modern ocean, North Atlantic Deep Water has an offset to atmospheric radiocarbon of ~-65‰ ($\Delta^{14}C$), whereas Antarctic Bottom Water has a larger offset of ~-165‰ due to longer storage time in the deep ocean. During the last glacial maximum, this storage time probably increased, leading to offsets of perhaps as much as -300‰ or greater for Southern source water [1, 4]. Circulation of these waters in the Atlantic should be identifiable from Nd isotope compositions due to their distinct compositional source regions, resulting in unradiogenic North Atlantic Deep Water (~-13.5 ε_{Nd}; [5]) and more radiogenic Antarctic Bottom Water (~-9 ε_{Nd}; [6]). These are not thought to have changed significantly over the last glacial/interglacial cycle [7].

Shifts in coral radiocarbon are most pronounced between 15 and 17 ka, demonstrating incursion of radiocarbon-depleted water masses (i.e. -150 to -200‰ $\Delta^{14}C$) up to depths of ~1700 m in the NW Atlantic [3]. The corresponding Nd isotope compositions are -13 to -14.5 ε_{Nd}, typical of Northern source waters. Overlying this are comparatively well ventilated waters (-100 to -150 ‰ $\Delta^{14}C$) with ε_{Nd} compositions in the range of -11 to -12 ε_{Nd}, suggestive of mixing between Northern and Southern source waters. It is emphasised that these Nd isotope data are contrary to expectations, where shifts to more radiogenic compositions were forecast to reflect incursion of Southern source water against the less radiogenic background of the North Atlantic. These data raise several questions concerning our current understanding of ocean circulation changes during the deglaciation as well as the Nd isotope proxy as a tracer of ocean circulation, which will be discussed in this presentation.

Chloride: the Unexpected Poison in the Growth of Crystalline Iron Oxides

NYSSA CROMPTON[1*], SATISH MYNENI[2]

[1]Princeton University, Chemistry Dept., Princeton, USA, crompton@princeton.edu (* presenting author)

[2] Princeton University, Geoscience Dept., Princeton, USA, smyneni@princeton.edu

Introduction

Iron is one of the essential elements to life on Earth, existing primarily in various insoluble ferric (Fe^{III}) iron oxide and oxyhydroxide phases. These phases exhibit varying degrees of solubility and bioavailbility: the amorphous Fe-oxide and ferrihydrite being the most soluble, and hematite and goethite being the least soluble and most stable phases. Different cations and anions substitute into or interact with these phases, modifying their growth and solubility. If ligands bind strongly to the freshly precipitated iron oxide phase or ferrihydrite, they block polymerization reactions and slow the transformation to more stable Fe-oxide phases. This is expected for strongly complexing ligands, such as sulfate, phosphate, and carbonate. Ligands such as chloride are not expected to play a large role; however, this study found that chloride deters iron oxyhydroxide growth.

Freshly precipitated iron hydroxides and their transformation to crystalline phases were monitored by IR and X-ray absorption spectroscopy (XAS) methods. The structural information about Cl, S, and Fe was found using XAS techniques at the National Synchrotron Light Source (Brookhaven National Laboratory, NY, USA). Studies were conducted at room temperature and at pH values of 5.5 and 8.1.

Results & Discussion

At pH 5.5, IR spectroscopy shows that transformation from freshly prepared ferric hydroxide to goethite was found to be hindered to the greatest extent by the presence of chloride. Spectral features corresponding to goethite (bending vibrations of OH) arose out of a broad band corresponding to the amorphous iron hydroxide. Even after 250 days, chloride containing samples showed no evidence of goethite. In contrast, the sulfate containing samples showed evidence of transformation into goethite before 120 days. The XANES spectra at the chlorine K-edge exhibit a clear pre-edge feature, which is indicative of a chlorine-iron bond. Additionally, Cl-EXAFS data on these samples indicate a Cl-Fe bond, supporting the XANES observations. At pH 8.1, the spectral features of goethite start appearing after just 70 days, and the Cl-Fe pre-edge feature is missing from the Cl-XANES spectra, indicating that the Cl-Fe bonds are not forming at the higher pH and the transformation is proceeding unhindered.

These results indicate that amorphous iron hydroxides and ferrihydrite can be stable for a long time, and could be the most prevalent phase when chloride is present in reacting solutions at slightly acid pHs. Additionally, chloride's direct role in the growth of iron oxides indicates that it is not simply an inert electrolyte in these systems, and its role cannot be ignored.

O_2 controls the Biogeochemical cycling of Cd, Fe and Mn along 85˚50´ W in the Oxygen Minimum Zone of the Eastern Tropical South Pacific

P. CROOT[1], F MALIEN[2], L STRAMMA[3] P STREU[4] AND K. WUTTIG[5]

[1] National University of Ireland Galway, Galway, Ireland (croot.peter@gmail.com)
[2] Geomar, Kiel, Germany (fmalien@geomar.de)
[3] Geomar, Kiel, Germany (lstramma@geomar.de)
[4] Geomar, Kiel, Germany (pstreu@geomar.de)
[5] Geomar, Kiel, Germany (kwuttig@geomar.de)

Oxygen Minimum Zones (OMZs) in the Eastern Tropical South Pacific (ETSP) is formed via a complex interplay of weak ocean ventilation (oxygen supply) and biological resipration (oxygen consumption). Dissolved oxygen (O_2) concentrations are a critical controlling parameter for the partitioning between redox states for a number of bio-essential metals such as Fe and Mn. Under low O_2 conditions (< 10 μM) the more soluble lower oxidation states are stabilized leading to longer residence times for these elements in the water column with implications for the distribution of these elements in these waters. Potential feedbacks may also occur whereby enhanced Fe concentrations, fuel surface water productivity resulting in higher fluxes of sinking organic matter which when respired further decreases O_2 in the OMZ.

In early 2009 we undertook a meridional transect across the ETSP OMZ from 14° S to the equator along 85˚ 50´ W using the German research vessel Meteor (Expedition M77-4). During this expedition we focused on the relationships between the location of the OMZ, the absolute O_2 concentrations and the concentrations and distributions of the redox sensitive metals Fe and Mn in order to assess the current state of this OMZ with regard to redox sensitive metals. We also estimate here fluxes for Fe and Mn to the 85˚ 50´W transect supplied by upwelling, aeolian deposition or via the transport of Fe and Mn rich waters from the Peruvian shelf to the study area.

In this work we also observed that OMZs can influence the biogeochemistry of non-redox sensitive elements. Most notably for Cd, as our data suggested changes in the remineralization length for Cd was most likely linked to changes in Zooplankton diel migration due to the depth of the OMZ.

Organic Geochemistry and Toxicology of Fluids from Shale Gas Wells

LYNN CROSBY[1*], MATTHEW VARONKA[1] and WILLIAM OREM[1]

[1*]U.S. Geological Survey, Reston, VA, USA, lcrosby@usgs.gov

Background

Hydraulic fracturing frees energy resources previously thought uneconomical to produce, allowing contemporary industrial and societal needs to be met. Fluids resulting from this process (frac fluid and produced water) are complex chemical mixtures that contain various additives used for hydrofracing and naturally-occurring substances extracted from the shale. A list of hydrofracing additives used can be found in publically available registries such as FracFocus, www.fracfocus.org and additives are disclosed in a growing number of states. However, scientific research on this issue is still lacking and few studies have been published regarding the geochemistry of these fluids or their possible effects on human cell lines.

Results and Conclusion

In the present work we quantified and identified the dichloromethane-extractable organic constituents in the fluids (frac and produced waters) using gas chromatography/mass spectrometry. We also used short term *in vitro* bioassays with human lung (A549) and liver (HepG2) cells to assess the toxicity of fluids (frac and produced waters) from several hydraulic fracturing wells (HFX) at dilutions ranging from full strength to 1:1000 and exposure times from 36 hr - 2 weeks. Major organic constituents included: C10-C17 branched alkanes, ethylene glycol monododecyl ethers, di-n-octyl-phthalate, and 2,2,4-trimethyl-1,3-pentanediol. Using the fluids at full strength 50-75% of cells were killed after 36-60 hr. After 72 hr 4 of 8 HFX samples killed ≥92% of HepG2 cells ($p<0.05$) and the other 4 killed 50-80% of the cells. After two weeks, 100% of A549 cells initially plated in HFX at full strength were dead. We also examined HFX waters collected from 1 - 10 days following hydraulic fracturing in order to assess whether toxicity would abate. Toxicity in HFX waters remained significantly higher than in laboratory pure water ($p<0.05$) without a clear trend. Future studies will determine whether the observed toxicity was due to these organic compounds, inorganic constituents, hypersalinity or a combined effect.

A stable isotope methodology to trace nanoparticles fates in biota

MARIE-NOËLE CROTEAU[1]*, AGNIESZKA DYBOWSKA[2], SUPERB MISRA[3], SAMUEL LUOMA[4] AND EUGENIA VALSAMI-JONES[5]

[1]USGS, Menlo Park, USA, mcroteau@usgs.gov (* presenting author)
[2]Natural History Museum, London, UK, a.dybowska@nhm.ac.uk
[3]Natural History Museum, London, UK, s.misra@nhm.ac.uk
[4]Univeristy of California, Davis, USA, snluoma@ucdavis.edu
[5]University of Birmingham, Birmingham, UK, e.valsamijones@bham.ac.uk

Introduction

One challenge in understanding the environmental implications of nanotechnology lies in tracing nanoparticles in organisms during controlled experimental studies as well as in the environment. Stable isotope methodologies offer great potential to address this challenge. Metallo-nanoparticles can be synthesized from a metal enriched with a rare stable isotope [1,2]. Here we quantify the bioavailability of metal nanoparticles (NPs) from food and water under conditions that might be typical of nature, and develop links to toxicity. Metal oxides NPs (CuO, ZnO) as well as Ag NPs were synthesized with an enriched stable isotope. We use a tracing technique that allows us to determine uptake and loss rates in freshwater snails exposed to NPs dispersed in water or mixed with food. The rate constants developed in these experiments were used to model bioaccumulation from both routes under environmentally realistic conditions. The isotope tracer was also used to quantitatively evaluate physiological processes like feeding rates and assimilation efficiency that might be adversely affected by exposure to metal NPs in diet.

Results and Conclusion

We demonstrate that isotopically modified ^{67}ZnO and ^{65}CuO NPs are required in uptake experiments because the high natural background metal concentrations limit the ability to detect bioaccumulation at environmentally relevant exposures. A tracer is also required when studying uptake of Ag NPs at environmentally relevant concentrations. For example, we demonstrate that Ag concentrations as low as 0.005 nmol g^{-1} can be detected in freshwater snails exposed to 0.1 nM of dissolved Ag enriched with ^{109}Ag (Fig.1). Exposures more than 20-times higher would be required to detect Ag uptake if no tracer were used. Without a tracer, uptake rates can only be determined at concentrations typical of extreme contamination.

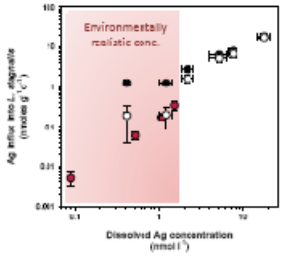

Figure 1. Silver uptake rates in snails after exposure to $AgNO_3$ (solid circles) or enriched ^{109}Ag (red circles). Open circles show uptake rates when Ag background is removed with a mathematical correction.

Cr isotope signatures have recently been introduced as a robust paleo-redox proxy and Cr isotopes in banded iron formations (BIFs) broadly track Earth's oxygenation history as revealed by other proxies [1]. Cr isotopes, however, appear to reveal additional structure in the evolution of atmospheric oxygen not exposed by other proxies. Notably, Cr isotopes indicate an oxygen pulse nearly 400 Ma prior to the widespread oxygenation of the atmosphere at the 2.3 Ga Great Oxidation Event (GOE). To better constrain the behaviour of Cr isotopes and their record of paleo-redox conditions, we examined the Cr cycle and its accompanying isotope fractionation in Lake Matano—a modern analogue for the iron-rich oceans from which BIFs were deposited [2]. Cr speciation in Lake Matano's oxic surface waters and inflowing streams is dominated by Cr(VI). This Cr(VI) is quantitatively reduced in the lake's ~100m deep chemocline. With δ^{53}Cr values between +2.2 and +3.3 ‰ (δ^{53}Cr ‰ = $[(^{53}Cr/^{52}Cr)_{sample} - (^{53}Cr/^{52}Cr)_{NIST\ SRM\ 979}] / (^{53}Cr/^{52}Cr)_{NIST\ SRM\ 979} \bullet 1000$), this Cr(VI) is isotopically heavy relative to mantle inventories, and the catchment bedrock and soils. Cr(III) in the lake's anoxic bottom waters is also isotopically heavy (δ^{53}Cr = +2.22 to +2.61 ‰), suggesting that Cr(III) records the heavy composition of Cr(VI) from the lake's surface waters and inflowing streams. Our observations are thus consistent with the mechanisms proposed to explain the δ^{53}Cr record in BIFs.

Pearls as Biomineralization Models for Layered Growth and Crystallization

JEAN-PIERRE CUIF[1*], YANNICKE DAUPHIN[2], JULIUS NOUET[3]

[1] University Paris-Sud Orsay, Geology, jean-pierre.cuif@u-psud.fr (* presenting author)
[2] University P. and M. Curie, Paris yannicke.dauphin @upmc.fr
[3] University Paris-Sud Orsay, Geology , julius.nouet@u-psud.fr

Cultivated pearls are produced by introducing a *graft* (a fragment of the mantle cut from the nacre producing area of the *Pinctada*) in the body of a "receiver" pearl oyster. The mineralizing side of the graft (the outer cell layer) is placed against the surface of a *nucleus* (a sphere of Ca-carbonate acting as substrate). After a recovery period during which the nucleus is completely wrapped by the graft spreading on the nucleus surface, resulting in formation of the *pearl-sac*, the mineralizing epithelium regains activity. But in contrast to what can be expected, minerals deposited by the newly formed tissue exhibit a great diversity in structures, correlated to an equivalent diversity in the associated biochemical compounds.

Taking advantage of an on-going research program (ADEQUA) granted by the Polynesian Office for Marine Resources, several tens of pearls grafted and grown in controlled similar conditions have been submitted to different physical methods allowing correlated mineralogical and biochemical data to be collected.

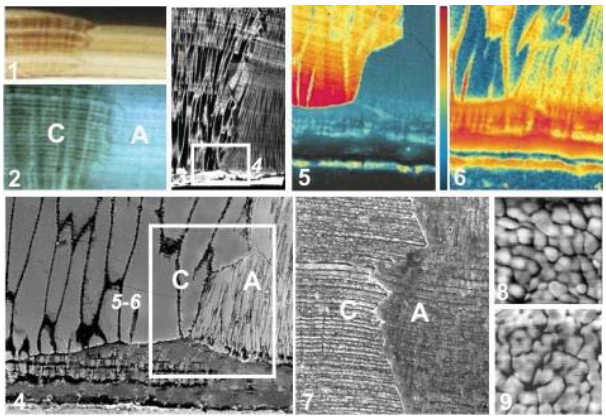

Figure 1: Example of a composite (calcite aragonite) pearl layer early developmental stage. 1: optical; 2: UV-fluo; 3: Laser conf.; 4: BSE; 5: XANES S-polysaccharides; 6: XANES S-protein; 7: SEM; 8-9: AFM.

Physical *in-situ* characterizations (Fig. 1) illustrate the strict correlation between organic secretions and mineralogical properties of distinct areas of the pearl bed [1]. AFM data show that whatever the biochemical composition of the organic phase, mineralized material exhibit a reticulate pattern without any crystalline growth faces. Extensive investigation [2] suggests that this layered mode of growth and crystallization is a widely shared process.

Durability of the Uranium resources

MICHEL CUNEY

UMR7566-CNRS CREGU-Université de Lorraine, FRANCE
michel.cuney@g2r.hup-nancy.fr

Introduction

Uranium is a major mineral resource for the production of energy. Primary resources (conventional and unconventional) derived from mining, can be supplemented by secondary resources [1]. However, only a small fraction of the U from the primary resources is presently used in nuclear reactors and a small part of the various materials issued from nuclear fuel cycle (secondary resources) are reprocessed to be re-used as a nuclear fuel.

Conventional uranium Resources

U deposit types are extremely diverse and form at all steps of the geological cycle [2], but three types: Olympic Dam, diagenetic-hydrothermal and deposits related to meteoric water infiltration represent over 75% of identified world U resources [3]. Identified resources recoverable at less than $260US /kg U ($118US/pd) reach 6.306 Mt U [1], and can last for 100 years at the present rate of consumption by the nuclear reactors.

Unconventional uranium Resources

The durability of the U resources can be greatly increased by the recovery of U as minor by-product of the mining of phosphorites, carbonatites, black shales, lignite, seawater. A variety of other non-conventional U resources are being or may be developed in a near future: production from the cleaning of waters deriving from former U mines and tailings, reprocessing of tailings produced by previous U or other metal extraction, recovery from Ni-Zn black shale ores by bio-heapleaching (Talvivaara, Finland), recovery from lignite-coal ash, from porphyry copper operations, from monazite of sand placers if REE recovery from this resource restart.

Secondary uranium Resources

The durability of the U resources can be further increased by developing the use of secondary resources. Only ^{235}U (1/140 of the natural U) is burned in most nuclear reactors. In fact, 0.25 to 0.30% ^{235}U remains in depleted U after enrichment, and 0.8 to1% remains in the spent nuclear fuel. The production of 1 t U enriched at 3.5% ^{235}U leaves 6.7 t of depleted U. Burning of ^{235}U produces a series of nuclides, among which about 1% of ^{238}U is transformed to ^{239}Pu, with a world production of 70t Pu /year (www.worldnuclear.org). Several processes have been or are being developed for a sustainable use of these secondary resources: dilution of military highly enriched U (HEU), re-enrichment of depleted U or spent fuel after preprocessing, use of Pu for MOX production, the burning of ^{238}U with Pu or HEU in the 4th generation reactors increasing about 60 times the durability of the U resources.

Conclusion

Beside conventional U resources large amounts of nuclear fuel can be recovered from unconventional and secondary resources. A sustainable development of nuclear energy requires a wider development of existing technologies and the development of new ones to use more thoroughly these differents types of U resources.

Brachiopods recording seawater temperature – grow up and be a good proxy

M. CUSACK[1]* AND A. PÉREZ-HUERTA[2]

[1] School of Geographical & Earth Sciences, University of Glasgow, UK. Maggie.Cusack@glasgow.ac.uk

[2] Dept. of Geological Sciences, The University of Alabama, Tuscaloosa AL 35487, USA. aphuerta@as.ua.edu

Brachiopods are attractive proxies

The stable, low- magnesium shells of brachiopods and their long geological record means that they are an attractive source of past seawater temperature data. Although brachiopod shells appear simple, analysis of their crystallography e.g. [1-2] or shell punctae (perforations) [3], reveals the extent of the biological control that is exerted as these shells form. This biological control makes it all the more impressive that the calcite fibres of the secondary (inner) layer of low magnesium-calcite brachiopod shells are in oxygen isotope equilibrium with ambient seawater [4-5].

Maturation or class?

In *Terebratalia transversa*, micromilling and conventional mass spectrometry revealed that oxygen isotope equilibrium is not achieved instantly with the abrupt switch from primary (outer) to secondary (inner) layer secretion but rather that oxygen isotope equilibrium is attained towards the innermost shell [6]. Thus, the first formed calcite fibres of the secondary layer of *T. transversa* are not in isotopic equilibrium while the later fibres of mature valves are in oxygen isotope equilibrium with seawater.

This study exploits the high spatial resolution of secondary ion mass spectrometry (SIMS) to investigate this oxygen isotope trend in *Terebratalia transversa* as investigated by Auclair [6] as well as *Terebratulina retusa* and *Notosaria nigricans*. Thus, three species of brachiopod from two Orders and two sub-orders are investigated by high resolution SIMS. This will help us understand whether only mature valves can be relied upon in proxy measurements or whether this caveat is restricited to *T. transversa*.

Introduction

It is well known that As(V), arsenate, is toxic to marine phytoplankton when phosphate concentrations drop to the 10-15 nM levels of arsenate found in oligotrophic surface waters. This toxicity is due to the chemical and biochemical similarities of the two. Interestingly, many phytoplankton have evolved arsenic detoxification mechanisms that include reducing arsenate to arsenite (AsIII) and/or methylating it to monomethyl (MMAs) and dimethyl arsenic (DMAs); these species are not taken up by phytoplankton. Thus, phytoplankton in oligotrophic, low P waters have a two-fold problem: first phosphate stress and then arsenate toxicity. Existing methods to assay phosphate stress via measurements of the enzyme alkaline phosphatase's activity (APA) have no associated time clock to establish how long the stress has occurred. Depending on their residence times, the As detoxification products could provide this missing temporal information.

The coupled biogeochemistries of As and P were examined on the US GEOTRACES cruises from Lisbon, Portugal to Cape Verde and then Charleston, South Carolina USA in 2010, and Woods Hole, Massachusetts USA to Cape Verde in 2011. Surface samples were acquired with a trace metal-clean towed "fish" at two hour intervals, 0.2 μm filtered, immediately refrigerated, and analyzed within 24 hours. Additional samples for APA were unfiltered and passed through an 80 μm mesh to remove zooplankton; assays were begun within 4 hours. Nanomolar reactive phosphate was determined using a modified molybdenum blue method and liquid core waveguides. Arsenic speciation was determined using selective hydride generation coupled to gas chromatography with photoionization detection.

Results and Discussion

On the two transects, phosphate varied from 3-20 nM (except near the coasts). AP activities were highest in the oligotrophic central gyre with the lowest phosphate concentrations. Arsenite varied between 0.2-5 nM, the highest values in the gyre. Arsenite has an surface residence time of ca. 3d and showed a significant correlation with APA (r=0.6), suggesting it may be a good short term indicator of P-stress. MMAs was relatively uniform in its distribution, while DMAs varied more, 0-4 nM. Neither methyl species correlated with APA, but if their residence times (to be determined) are longer, then no direct relationship would be expected. Overall, it does appear that As speciation may be a useful integrator of P-stress.

Early Archean Fe oxidation revealed by meso- and micron-scale Fe isotope analyses of the 3.7–3.8 Ga Isua BIFs

ANDREW D. CZAJA[1,2*], CLARK M. JOHNSON[1,2], BRIAN L. BEARD[1,2], STEPHEN MOORBATH[3]

[3]Department of Earth Sciences, University of Oxford, Oxford, GBR

Iron isotopes are increasingly used to constrain the conditions of Earth's paleoenvironments and even suggest the influence of biological activity. Interpretations of Fe isotope fractionations in Archean and Paleoproterozoic banded iron formations (BIFs), shales, and carbonates suggest a role for biological processes (bacterial dissimilatory iron reduction (DIR) and anoxygenic photosynthetic iron oxidation (APIO)] and abiological processes (oxidation by free O_2). Measurements of rock powders micromilled from individual magnetite layers and of individual magnetite grains analyzed by femtosecond laser ablation ICP-MS (fs-LA-ICP-MS) from BIFs of the 3.7–3.8 Ga Isua Greenstone Belt reveal a consistently narrow range of non-zero δ^{56}Fe values. Analyses by fs-LA-ICP-MS allow for precise and accurate micron-scale analyses without the orientation effects associated with secondary ion mass spectrometry analyses of magnetite [1]. Magnetite δ^{56}Fe values range from +0.4‰ to +1.1‰ among different bands, but within individual layers magnetites are homogenous. In buld samples, δ^{56}Fe and SiO_2 concentration are negatively correlated, whereas δ^{56}Fe and total Fe concentrations are positively correlated, reflecting mixtures between magnetite and Fe silicate. A simple mixing model between a low-δ^{56}Fe component (Fe silicate) and a high-δ^{56}Fe component (magnetite) can explain the range in Fe isotope compositions of the micromilled rock powders. Although these BIFs have been metamorphosed to greenschist- to amphibolite-facies, the isotopic heterogeneity observed on both scales suggests that the Fe isotope compositions reflect primary, low-temperature sedimentary values.

The positive δ^{56}Fe values measured from the Isua magnetites are best explained by deposition of Fe-oxides produced by partial oxidation of Fe(II)-rich ocean water either by free O_2 or APIO. Comparison of the Fe isotope data from the Isua BIFs with those from the 2.5 Ga BIFs from the Hamersley and Transvaal basins suggests a striking difference in Fe sources and pathways. The Neoarchean magnetite facies BIFs of Australia and South Africa have δ^{56}Fe values that range from -1.2 to +1.2 ‰ [2] and are on average significantly lower than those reported here from the Isua BIFs. Such a range suggests a role for DIR, the most likely means by which to produce large masses of negatively fractionated Fe. The absence of low δ^{56}Fe values in the Isua BIFs may indicate formation prior to the evolution of DIR or in an environment that excluded this metabolism.

One of the main aspects for evaluating the safety case of a potential radioactive waste repository in a deep geological formation is to understand and quantify the geochemical and physical processes that influence the mobility of the radionuclides in the geochemical environment imposed by the host rock. This information is needed to make reliable predictions of the long-term retardation behaviour of radionuclides. The present study focuses on the interaction of a key radionuclide with the Boda Claystone Formation (BCF) of the planned high level radioactive waste repository in Hungary. BCF is rich in illite and hematite. The aim is to identify the mineral phases responsible for the uptake of Ni by BCF, and to investigate the uptake mechanisms of radionuclides on clays and other minerals present in the host rock.

Small pieces of selected BCF core hole samples from a depth of 540 m were prepared as thins sections and equilibrated with $NiCl_2$ solutions at pH = 7.05 in a 0.1 M NaCl background electrolyte. Combined µ-XRF/XAS/XRD measurements were performed at HASYLAB Beamline L (Hamburg, Germany) and µ-XRF/XRD at the ANKA FLUO Beamline (Karlsruhe, Germany). µ-XRF maps were recorded from pre-selected areas of the samples, using a step size comparable to the beam size (20 µm at HASYLAB and 5 µm at ANKA) and 1 s counting time per pixel. The elemental maps served as a basis for selection of small areas of interest where µ-XRD images were collected by a CCD detector. The µ-EXAFS measurements were measured in fluorescence mode at HASYLAB Beamline L, at 20 µm lateral resolution for certain points of interest.

The distribution maps indicate that Ni is mainly associated to K- and Fe-rich phases. µ-XRD analyses with a 5 µm beam diameter indicate that the composition of the argillaceous rock matrix on the micro-scale agree well with the mineral composition of the clay rich areas obtained by bulk-XRD measurements. The good correlation of Fe with K is mainly caused by the high K content in illite (a K-rich 2:1 clay mineral). Micro-EXAFS investigations demonstrated that inner-sphere complexation of Ni occurred to clay minerals. At higher Ni concentrations (10^{-3} M Ni) surface precipitation processes prevailed. The formation of Ni precipitated phases such as Ni-phyllosilicates has important geochemical implications because layered silicates are stable minerals in mildly acidic to basic pH conditions and can irreversibly bind metals in waste and soil matrices. The uptake of contaminants on mineral surfaces forming inner-sphere complexes strongly reduces the mobility of metals in the geosphere. The results of the analyses demonstrated that for Ni(II) the clay mineral illite is an effective sinks in the BCF sample.

Tracing Euxinia in Ancient Oceans with molybdenum

TAIS W. DAHL[1,*] AND DONALD E. CANFIELD[1]

[1] Nordic Center for Earth Evolution and University of Southern Denmark, Odense, Denmark, tdahl@biology.sdu.dk

Elevated molybdenum (Mo) concentrations in organic-rich sediments are a characteristic feature of deposition in sulfidic waters. A comparative study of modern sediment cores from more than 200 marine sites worldwide show that all euxinic basins display >25 ppm Mo [1]. Conversely, all organic-rich sediments with >25 ppm Mo are deposited from a permanently or intermittently sulfidic water column. We show that this last observation can now be determined in <30 seconds using handheld X-Ray absorption Fluorescence spectroscopy (HH-XRF). The new tool enables euxinic classification in the field.

The Mo enrichment process in euxinic settings is expected based on the critical role that aqueous H_2S plays in breaking Mo=O double bonds when soluble MoO_4^{2-} forms reactive Mo sulfides [2]. However, we have identified Neoproterozoic euxinic settings based on Fe-speciation indicators [3] with only small sedimentary Mo enrichments [4]. The Fe speciation technique is unlikely to give false-positive identifications of euxinia, and the question remains what controlling factors could have obstructed the Mo enrichment process at that time.

First, we speculate that the Mo supply to the basins was particularly slow. However, the Mo enrichment process takes place today even in settings with low Mo supply, whether limited by basinal restriction and a slow deepwater renewal rate (e.g. Black Sea) or low Mo load in the source waters of only (e.g. 10 nM in Lake Cadagno).

We have established a one-box model for the oceanic Mo cycle, where Mo burial rates are linked 1st order with respect to ambient Mo reservoir. It shows that seawater Mo concentrations, today 105 nM, never decreased below modern riverine values (~6 nM). Hence, a low seawater inventory is insufficient to obstruct the Mo enrichment process in settings with supply comparable to Lake Cadagno, but a combination of both widespread euxinia (lowering seawater Mo inventory) and basinal restriction (lowering basinal Mo relative to open ocean) could potentially compromise Mo enrichment in the Neoproterozoic sediments.

This illustrates how expansion of oceanic euxinia derived from our models rests on a rigorous understanding of the key factors involved in the removal pathway of Mo from oxic surface waters to euxinic sediments. We discuss how laboratory and field-based studies elucidate which factors, other than H_2S, could influence the Mo burial pathway in the past. Overall, we illustrate the linkage between studies of modern euxinic systems and reconstructions of global-scale ocean conditions of the past.

The nature of orogenic lithospheric mantle: constraints from geochemistry of postcollisional mafic-ultramafic rocks in the Dabie orogen

LI-QUN DAI*, ZI-FU ZHAO, YONG-FEI ZHENG

CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China, lqdai@mail.ustc.edu.cn

Oceanic and continental arc volcanic rocks are a window into crust-mantle interaction in oceanic subduction zones, with involvement of the asthenospheric mantle. They are assumed to originate from partial melting of altered peridotite in the overlying mantle wedge, with trace element geochemical signature inherited from aqueous fluids released from subducting oceanic crust. While this process-product link has been a common percept in geochemistry, it is intriguing whether there is the similar relationship in continental subduction zones. Ultrahigh-pressure (UHP) metamorphic rocks are a typical product of continental deep subduction to mantle depths, but arc magmatism is absent above continental subduction zones. While the subducted continental crust can be reworked as postcollisional granitoids, it is unclear whether the overlying subcontinental lithospheric mantle (SCLM) was involved in postcollisional mafic magmatism.

Postcollisional mafic-ultramafic rocks from the Dabie orogen were studied for their zircon U-Pb ages and Lu-Hf isotopes, whole-rock major-trace elements and Sr-Nd-Pb isotopes as well as whole-rock and mineral O isotopes. The results provide insights into the nature of orogenic lithospheric mantle in the continental collisional orogen. The zircon U-Pb dating gave consistent ages of 125 ± 3 to 129 ± 1 Ma for magma crystallization. Few residual zircon cores have U-Pb ages of 234 ± 5 Ma and 739 ± 9 Ma, respectively, in agreement with tectonothermal events for UHP metamorphism and protolith formation in the Dabie orogen. The mafic-ultramafic rocks have high contents of MgO (up to 18.0 wt.%), Cr (up to 1546 ppm) and Ni (up to 349 ppm), but low contents of SiO_2 (41.0-51.9 wt.%), and show the arc-like patterns of trace elements distribution and the enriched signature of Sr-Nd-Pb-Hf isotopes. These geochemical features indicate their derivation from partial melting of the orogenic lithospheric mantle that is fertile in lithochemistry and enriched not only in LILE and LREE but also in radiogenic isotopes. The orogenic lithospheric mantle is suggested to be generated by metasomatic reaction of the overlying SCLM-wedge peridotite with hydrous felsic melts derived from the subducted continental crust during the Triassic continental collision, with the enriched signatures imparted by the felsic melts. In this regard, the crust-mantle interaction is implicated during the continental deep subduction, with the postcollisional mafic-ultramafic rocks as its derivatives. On the other hand, significant differences in elemental and isotopic compositions between different mafic-ultramafic intrusions suggest that the orogenic lithospheric mantle is geochemically heterogeneous, with the possible presence of hornblende-rich and pyroxene-rich lithologies in mantle sources. This difference is attributed to differences in the compositions of subducted crustal-derived melts with a tectonic affinity to the South China Block, but the same SCLM wedge of the North China Block was involved in the crustal metasomatism. Therefore, the compositional variations in the orogenic lithospheric mantle are recorded by the geochemical compositions of postcollisional mafic-ultramafic intrusions.

A spatially-structured model for Proterozoic ocean biogeochemistry

STUART DAINES[1*], ANDY RIDGWELL[2] AND TIM LENTON[1]

[1]University of Exeter, UK, s.daines@exeter.ac.uk (* presenting author). [2]University of Bristol, UK.

The picture for Proterozoic ocean biogeochemistry from marine proxy data and simple box models has been of an anoxic and ferruginous ocean prior to 1.85 Ga, with a switch to either oxic or euxinic conditions then responsible for removing iron from the deep ocean and halting Banded Iron Formations ~1.85 Ga [1]. However, recently-gathered geochemical data from what remains of the Proterozoic ocean margins reveal a more complex picture with some euxinic intervals prior to 1.85 Ga, and a largely ferruginous ocean with only some sulphidic intervals and/or sulphidic waters at intermediate depths post-1.85 Ga [2],[3].

Here we use a spatially-structured biogeochemical model GENIE to propose a scenario consistent with proxy data, and also consistent with constraints from both oxygen demand and ventilation, and ocean mixing and Fe, S residence timescales. A robust feature of scenarios that avoid global euxinia is a vertical redox gradient from an oxygenic mixed layer, through euxinic mid-depths in shelf or upwelling regions, to a suboxic deep ocean. A suboxic (rather than fully anoxic and ferruginous) deep ocean is consistent with evidence from hematitic cherts [4]. This model makes two testable predictions: (i) that the "ferruginous" water column state inferred from iron-speciation proxy data arises from iron transport in a marginally suboxic or anoxic region underlying euxinic region, and (ii) that feedback processes must exist to balance the deep ocean on the edge of anoxia.

Nitrogen cycling in the mixed aerobic/anaerobic surface/mid-depth regions results in relatively high levels of denitrification and nitrification with small marine nitrogen reservoirs and short residence times.

Selection for Gaia at multiple scales

STUART DAINES, RICHARD BOYLE, JAMES CLARK, HYWEL WILLIAMS AND TIM LENTON*

University of Exeter, UK, s.daines@exeter.ac.uk (*presenting author)

Biological regulation of the environment is present at scales from individuals, to ecosystems, to the global biosphere. However, the emergence of regulation at scales which cannot have been units of natural selection is a very different problem from the Darwinian evolution of organism-level homeostasis. Nevertheless, at local ecosystem level, regulation is beginning to be understood as a consequence of "niche construction" [1]. Recent work [2] has also demonstrated the evolutionary emergence of global regulation from local selection in spatially structured environments that tend to distribute the benefits from regulation preferentially to regulators (and not free-riders or organisms with a destabilising effect). At global scales, biosphere regulation must in addition be reconciled with geochemical feedbacks, often involving well-mixed global reservoirs such as the atmosphere, or geological time delays. This temporal and/or spatial decoupling of effects from actors make evolutionary explanations problematic.

Here we investigate mechanisms by which global regulation might emerge by a non-evolutionary process of self-organisation. We argue that the global biota is assembled over time by a process analogous to ecological community assembly [3], but operating at global scale over geological and macroevolutionary timescales and perturbed by macroevolutionary innovations [4] and geological events. By a process of "sequential selection" [5], fragile systems, or those that destabilise their environment, are then short-lived, and result in extinctions and reorganisations until a relatively stable (but possibly lifeless) state is temporarily reached. We employ simple conceptual models for community assembly, evolutionary innovation, life-environment interaction, and anthropic bias to test three hypotheses for the implications of this mechanism for the stability and regulation of an observed biosphere. The limited information input and the "satisficing" (rather than optimising) nature of the sequential selection mechanism make it probable that: (i) regulation at the global level involves only simple configurations of multiple (individually local and Darwinian) physiologically limited "biotic plunder" mechanisms [7],[8] combined with abiotic feedbacks, and (ii) regulation of the environment is strongest at limits, rather than at optimal conditions for life. Anthropic bias [6] applies a further filter to the distribution of biosphere properties such that (iii) our observed biosphere need be only sufficiently stable for the evolution of complex life.

This study presents a combination of field measurements and state-of-the-art modeling to investigate N and P cycling in sediments of two contrasting oxygen stressed systems. Boknis Eck is a 28 m deep channel in the southwest Baltic Sea which experiences severe hypoxia (< 2 μM O_2) in boreal summer lasting until October [1]. A time series analysis of benthic nutrient analyses based on monthly samplings from February to December 2010 revealed that N and P fluxes were elevated in winter due to porewater pumping by bioirrigating organisms which efficiently flushed the upper 10 cm of sediment. During hypoxia, no bioirrigation was measurable, macrofauna were absent and phosphate accumulated to concentrations exceeding 400 μM, resulting in a large diffusive flux to the water column. At the same time, denitrification rates were elevated yet dissimilatory nitrate reduction to ammonium (DNRA) by sulfide oxidizing bacteria (*Beggiatoa* spp) played a much larger role in recycling N between the water column and sediments, thus conserving reactive N in the system. By January 2011, typical winter conditions were once again established.

In the Peruvian OMZ, anoxia is more permanent and ventilation events are less predictable. Benthic N and P cycling investigated at six stations along 11 °S using landers revealed very high rates of ammonium and phosphate fluxes on the shelf and upper slope (80 – 250 m water depth) where extensive areas of mats of *Beggiatoa* were present [2]. DNRA dominated total N turnover (≤ 2.9 mmol N m^{-2} d^{-1}) and accounted for ≥ 65 % of nitrate uptake by the sediments from the bottom water. Only at greater water depths within the OMZ (300 – 1000 m) were the sediments a net sink for reactive N due to denitrification. Overall, our findings in Peru and the Baltic Sea show that high measured benthic uptake rates of oxidized N within OMZs do not necessarily indicate a loss of fixed N from the marine environment, but are instead recycling sites converting nitrate into ammonium. Phosphate release is elevated in both environments, which altogether indicate that similar processes occur in sediments underlying seasonal and more permanent OMZs. Due to the high rates of benthic N and P turnover in OMZs, pelagic models ought to incorporate benthic dynamics in their calculations.

Osmium and oxygen isotopes in Etendeka picrites and their olivines: mantle melts and crustal interaction

CHRISTOPHER W. DALE [1*], R. N. THOMPSON [1], D. G. PEARSON[2], A. J. V. RICHES[2], D. P. MATTEY[3]

[1]Dept. of Earth Sciences, Durham University, UK christopher.dale@durham.ac.uk (*presenting author)
[2]Dept. Earth & Atm. Sciences, University of Alberta, Edmonton, Canada
[3]Dept. Earth Sciences, Royal Holloway, University of London, UK

The existence of basal picrites and picritic dykes in the Etendeka large igneous province (LIP) provides the opportunity to study high-degree, relatively unfractionated melt products from a hot plume head and hence gain the best insight into the source composition. Moreover, highly magnesian olivine phenocrysts (occasionally up to Fo 93.3), which reflect crystallisation from melts with up to 24 wt% MgO [1], provide particularly primitive isotopic information. Such high MgO melts require mantle potential temperatures up to 1700°C [1], amongst the highest known for the Phanerozoic. At the same time, the eruption of the picrites through continental crust allows the role of assimilation, in imparting an isotopic signature, to be investigated.

Here we present major and trace elements and Sr, Nd, Pb and Os isotopes for whole rocks, and combine these with major elements and osmium and oxygen isotopes for olivine phenocrysts. Highly siderophile element abundances are also presented.

The Pb isotopic compositions of whole rocks covary with Pb content and are clearly controlled by a local crustal sedimentary input, and give little information on the source. Strontium and Nd isotopes in the Horingbaai dykes covary negatively, indicating variable contributions from depleted and slightly enriched endmembers, the latter likely local crust.

The $^{187}Os/^{188}Os$ compositions of the primitive Horingbaai and more evolved Spitzkoppe picrites (0.128-0.131) are in the same range as some other high-T plume melts (e.g. North Atlantic Igneous Province picrites: 0.127-0.134 [2]). The least radiogenic values support a predominantly mildly-depleted peridotite source for the highest temperature volcanism in the region, which is also consistent with MORB-like REE patterns. The Os data exclude the possibility of a long-term strongly Re-depleted source input, such as old lithosphere. The more radiogenic values could reflect a contribution from an isotopically enriched mantle component. Olivines from the Horingbaai and Spitzkoppe picrites, however, have similar or slightly lower isotopic compositions than their respective whole rocks, suggesting that, at least in part, the more radiogenic Os isotope values are a result of crustal assimilation after olivine crystallisation, even in these Os-rich picritic melts.

Oxygen isotope compositions in olivines ($\delta^{18}O$ up to 6.5‰) extend higher than typical mantle, and are associated with more radiogenic $^{187}Os/^{188}Os$. Although it is difficult to rule out a mantle eclogite component as a source of coupled O-Os enrichment, a crustal input is the likely cause of this effect, and is supported by the combined isotopic and elemental data.

Fe(III) reduction by the Gram-positive bacterium *Desulfotomaculum reducens*

ELENA DALLA VECCHIA[1], PAUL SHAO[1], ELENA SUVOROVA BUFFAT[1], JULIEN MAILLARD[2], RIZLAN BERNIER-LATMANI[1,*]

[1] Environmental Microbiology Laboratory, Ecole Polytechnique Federale de Lausanne, EPFL, Lausanne, Switzerland, rizlan.bernier-latmani@epfl.ch (* presenting author)
[2] Environmental Biotechnology Laboratory, EPFL, Lausanne, Switzerland, julien.maillard@epfl.ch

Microbial Fe(III) reduction, specifically that of solid phase Fe(III), presents a challenge to bacteria as electrons must be transported to an extracellular electron acceptor. This process has been studied extensively for Gram-negative bacteria such as *Shewanella oneidensis* and *Geobacter sulfurreducens*. Several strategies have been documented in these microbes: (a) the secretion of endogenous redox mediators that are reduced by cells following oxidation by Fe(III); (b) direct contact of outer-membrane multi-heme cytochromes with the solid-phase substrate or (c) the extension of micron-long electroconductive pili that can transport electrons away from the cell. The transfer of electrons in the latter two cases was dependent on several multi-heme cytochromes located in the cytoplasmic and outer membranes as well as in the periplasmic space.

In the case of Gram-positive bacteria, there is evidence either for the involvement of redox mediators [1] or the requirement for direct contact with the electron-receiving surface [2]. In both cases, the mechanism remains unknown. In this study, we probe the reduction of soluble Fe(III) [as Fe(III)-citrate] and of solid-phase Fe(III) [as hydrous ferric oxide, HFO] by the Gram-positive bacterium *Desulfotomaculum reducens*. The best growth was obtained with pyruvate due to fermentation but some growth was detected with lactate as an electron donor. In the presence of HFO, pyruvate was rapidly (~3 days) converted to acetate and Fe(III) slowly reduced over 25 days. Tests with spent medium from pyruvate- and HFO-grown cells indicate the presence of an endogenous redox mediator able to reduce anthraquinone disulfonate (AQDS). In contrast, HFO reduction occurred concomitantly with lactate oxidation to acetate and there was no evidence for a redox mediator. Experiments with HFO enclosed in glass beads (and thus only accessible to diffusable redox mediators) confirmed those findings as reduction of Fe(III) was observed in the pyruvate case but not detectable in the lactate case.

The *D. reducens* genome harbors a sole multi-heme *c*-type cytochrome complex (NrfHA) with homology to the nitrite reductase in *Desulfovibrio vulgaris*. Quantitative reverse transcription PCR (qRT-PCR) showed that while *nrf*HA was expressed during fermentation, there is no evidence for expression during Fe(III) reduction. Hence, we conclude that (a) HFO reduction occurs via a redox mediator with pyruvate while it is mediator-independent in the presence of lactate; (b) the sole *c*-type cytochrome complex present in the genome of *D. reducens is* not involved in Fe(III) reduction. Ongoing work focuses on the characterization of the mechanism of lactate-dependent HFO reduction and aims at providing a mechanistic understanding of electron transfer across the Gram-positive cell wall.

Continental surface temperatures inferred from the investigation of fossil hydrothermal systems

LUIGI DALLAI [1*] AND RAY BURGESS[2]

[1]Institute of Geosciences and Earth Resources - CNR, Pisa, Italy dallai@igg.cnr.it (* presenting author)

[2] SEAES, University of Manchester, UK ray.burgess@manchester.ac.uk

Plutonic and sub-volcanic igneous rocks have been shown to be a promising source of data relevant to paleo-temperature reconstruction. A first Antarctic terrestrial record of climate variations through the Cenozoic has been recently published, based on the hydrogen isotope composition of hydrothermally altered minerals of intrusive rocks from the coastal areas of the Wilson Terrane, Northern Victoria Land, Antarctica (Dallai & Burgess, 2011). Cenozoic land surface temperature data for this remote area located at 73-74°S latitude are poorly known but may be crucial to understand how and possibly why, the climate changed in continental Antarctica before and during the Eocene-Oligocene transition. In this investigation, the variations of hydrogen isotope composition of hydrothermal waters have been studied in detail. By dating the minerals formed upon hydrothermal alteration, a record of meteoric-hydrothermal water compositions has been reconstructed, enabling the atmospheric conditions during the Cenozoic era to be inferred. This continental record of polar climates in Antarctica is in reasonable agreement with the global climatic records derived from oceanic deep cores and with the model curve for atmospheric pCO_2. These observations give insights into the climatic evolution of continental areas in an important region over a critical time interval suggesting that temperature fluctuations as large as 20°C occurred repeatedly during the Eocene. The aim is to determine continental paleo-temperatures for different periods of the Cenozoic and to merge data from hydrothermal systems from high latitude regions of both hemispheres to define bi-polar climatic conditions through geological time. Preliminary data of hydrothermal systems from high latitude regions of the Northern Hemisphere fit the hydrogen based paleo-temperature curve, thereby implying that extending this study to other Cenozoic (and older) intrusive bodies may better constrain continental paleo-temperature records both in space and in deeper times.

Evolution of silicic magmas and the origin of the Daly Gap at Santa Barbara volcano, Terceira, Azores

G. E. DALY[1*], E. WIDOM[1] AND Z. FRANÇA[2]

[1]Department of Geology, Miami University, Oxford, Ohio, USA, dalyge@muohio.edu (*presenting author)

[2]Departamento de Geociências, Universidade dos Açores, Ponta Delgada, São Miguel, Açores, Portugal, zfranca@uac.pt

The origin of compositional gaps (e.g. the Daly Gap) and high volumes of silicic rocks among volcanic deposits in ocean islands have remained controversial subjects. Although silicic magmas can be produced by fractional crystallization of parental basalts, the paucity of intermediate compositions and the relatively large volumes of silicic compositions amongst erupted materials are difficult to explain by this mechanism. Several hypotheses have been proposed for the scarcity of erupted intermediate rocks, including development of physical/chemical properties (density, viscosity and/or volatile content) that may inhibit them from erupting [1]. Alternatively, melting of altered mafic crust may produce bimodal volcanism without formation of intermediate magma compositions, and can potentially explain large volumes of silicic deposits [2].

Santa Barbara volcano (Terceira, Azores) is an ideal locality for investigating these problems. Terceira has an uncommonly high percentage (~50%) of silicic volcanic rocks relative to mafic compositions [1], and Santa Barbara exhibits a well defined Daly Gap from 54 to 64 wt.% SiO_2 amongst eruptive products, including flank basalts and trachytes erupted from the central vent [3]. However, we show that the compositional gap closes if plutonic nodules contained in air fall deposits from Santa Barbara are considered.

We have performed petrographic, major and trace element, and Sr–Nd-Pb isotopic analyses on eruptive products from the relatively recent (<2ka) Santa Barbara-G trachyte deposit [4], as well as flank basalts [5] and plutonic nodules collected from older trachytic air fall deposits from Santa Barbara. These data demonstrate an essentially continuous compositional variation from 45 to 69% SiO_2, with the plutonic nodules ranging from 45 to 65 wt% SiO_2, and thus effectively filling in the compositional gap defined by the bimodal basaltic-tracyhtic volcanic products. Trace element systematics indicate that the plutonic nodules are genetically related to the basalts and trachytes, following a common fractional crystallization path. The plutonic nodules exhibit large (~4- to 10-fold) variations in concentrations of trace elements including highly incompatible elements (Hf, Nb, and Zr) and compatible elements (Ba and Sr). Most significantly, some of the plutonic nodules have incompatible element concentrations equal to those in the Santa Barbara G trachytes. Together, these data suggest that the plutonic nodules represent liquid rather than cumulate compositions, as inferred for syenites from Fogo volcano (Sao Miguel, Azores; [6]).

These results indicate that intermediate magma compositions are produced during fractional crystallization from parental basalts to trachytes, and that these intermediate magma compositions generally fail to erupt as volcanic products. Ongoing Sr-Nd-Pb and planned U-series isotopic analyses of the plutonic nodules will further constrain their genetic relationship to the Santa Barbara basalts and trachytes, and potentially allow evaluation of their crystallization ages.

Analysis and modelling of arsenic dynamics in coastal sediments

DUC HUY DANG[1*], ERWAN TESSIER[1], VÉRONIQUE LENOBLE[1], GAËL DURRIEU[1], CHRISTOPHE LE POUPON[1], JEAN-ULRICH MULLOT[2], STÉPHANE MOUNIER[1] AND CÉDRIC GARNIER[1]

[1]Laboratoire PROTEE, Université du Sud Toulon Var, BP20132, 83957 La Garde, France, duc-huy.dang@univ-tln.fr

[2]LASEM-Toulon, Base Navale de Toulon, BP 61, 83800 Toulon, France

Sediments of the Toulon bay (SE, France) are significantly polluted by trace metals, metalloids and organic contaminants, due to historical events (2nd World War...). Contaminants behavior in sediments and transfer to the water column should be investigated to evaluate the risks linked to such pollution. This work focused on As dynamics in the Toulon Bay by studying two major processes: effect of early diagenesis and subsequent diffusive flux.

Interface sediment cores were sampled at contrasted locations and seasons, followed by porewater analysis of physico-chemical parameters (pH, Eh, DOC), diagenesis tracers (Fe, Mn, S, Ca, DIC, …) and As species. The obtained sediment depth profiles showed a significant variation of Eh, SO_4^{2-}, DOC and arsenic in porewaters between the campaigns. Such observation could result from different diagenesis activities, linked to inputs of labile organic matter (e.g. plankton bloom). Additionally, in the deepest layer (> 15 cm), As appeared to be significantly correlated (R^2 0.89) to the DOC content, indicating a possible association between As and organic matter.

Based on the measured phyco-chemical parameters and the dissolved species concentration (majors, diagenesis tracers, arsenic,...), PHREEQC was used to calculate As chemical speciation [1]. Then, PROFILE fitting of diagenesis tracers and As depth profiles allowed the evaluation of their diffusive fluxes at the sediment/water column interface [2]. Finally, As depth profiles were successively simulated by PHREEQC, taking account of solid As concentration, dissolved organic matter, carrier solid phases (clays, calcite, iron oxy(hydroxide), iron (mono)sulfide), and the affinity of these components for each As species.

The As dynamics in Toulon coastal sediment appears to be mainly controled by its chemical speciation in porewater, immobilization on carrier phase, and interaction with dissolved organic matter (as AsV but also as AsIII). Association of analysis and modelling tools (thermodynamic calculation, reactive transport fitting and sorption simulation) is suitable to better understand trace elements behavior at the sediment/water interface.

Colloidal stability of TiO_2 nanoparticles in the presence of phenolic carboxylic compounds

KARIN DANIELSSON*, JENNY PEREZ HOLMBERG, JULIÁN GALLEGO-URREA, ELISABET AHLBERG, ZAREEN ABBAS, MARTIN HASSELLÖV, AND CAROLINE M. JONSSON

University of Gothenburg, Department of Chemistry and Molecular Biology, Gothenburg, Sweden
karin.danielsson@chem.gu.se (* presenting author), perezj@chem.gu.se, julian.gallego@chem.gu.se, ela@chem.gu.se, zareen@chem.gu.se, martin.hassellov@chem.gu.se, caroline.jonsson@chem.gu.se

Nanotechnology is a rapidly growing industry, which leads to an increased amount of synthetic nanoparticles released into the environment. Nanoparticles generally have higher reactivity than larger particles of the same material. As the particle size is decreased to the nanometer size range (1-100nm), the surface chemistry changes and this might influence the surface charging and aggregation behavior. Further, nanoparticles can interact with natural organic material (NOM), such as humic and fulvic acids, which is present in most natural waters. Adsorption of NOM affects the surface speciation and net charge of the nanoparticles and is therefore of great importance for their colloidal stability. This might alter the mobility of nanoparticles in surface waters and in soils, thus determing their bioavailability and toxicity.

The focus of the present study was to investigate the aggregation behavior of nanoparticles in aqueous solution as a function of pH, ionic strength, and in the presence of NOM. Well-characterized TiO_2 nanoparticles obtained from hydrolytic synthesis were used as test nanoparticles, and selected phenolic carboxylic compounds were used as model substances to mimic the interactions of nanoparticles with NOM. The selection of organic compounds was based on the possibility of determining the influence of various types, numbers, and positions of functional groups on the surface charging and colloidal stability of the TiO_2 nanoparticles. The aggregation and surface charging of the particles were studied by simultaneously monitoring the changes in particle size and zeta potential during the reactions.

[8]Australian National University, Canberra, Australia, Keith.Fifield@anu.edu.au

Combined $^{238}U/^{230}Th$ disequilibrium and (U-Th)/He dating of zircon [1] is a novel approach for dating young (<350 ka) volcanic eruptions. This method with great potential for the Quaternary geochronology has been successfully applied in various settings [e.g. 2,3], however its accuracy and limitations has not been rigorously tested and validated by independent methods. New Zealand's record of late Quaternary tephras provides an excellent natural laboratory for conducting such inter-calibration experiments.

In this study we apply the combined $^{238}U/^{230}Th$ disequilibrium and (U-Th)/He zircon dating to the deposits of the coeval Rotoiti and Earthquake Flat eruptions in the Taupo Volcanic Zone to investigate consistency of the method. In addition, wood sampled below and above the Rotoiti tephra is dated by high-precision radiocarbon method to provide independent constraints on the accuracy of the zircon eruption ages.

Results and Conclusion

The two independent methods revealed concordant ages, which are also in accord with the stratigraphic position of the samples. Based on these results we assign new ages of ~45 ka to the Rotoiti and Earthquake Flat eruptions. This is by ~16 kyr younger than the currently accepted age, which has implications for paleoclimatic reconstructions and volcanic hazards assessment in the Taupo Volcanic Zone. This study proves the combined $^{238}U/^{230}Th$ disequilibrium and (U-Th)/He dating of zircon reliable at late Quaternary time scale and also demonstrates demonstrates reliability of the radiocarbon dating method at higher end of its sensititvity at ~50 ka.

The Pantelleria shallow plumbing system: extreme differentiation processes and dynamics in an intraplate volcanic field

MASSIMO D'ANTONIO [1,2*], ROBERTO MORETTI[3,2], LUCIA CIVETTA[1,2], AND GIOVANNI ORSI[2]

[1]Università di Napoli "Federico II", Napoli, Italy, masdanto@unina.it (* presenting author)
[2]Istituto Nazionale di Geofisica e Vulcanologia, Sezione Osservatorio Vesuviano, Napoli, Italy
[3]Seconda Università di Napoli, Napoli, Italy

The island of Pantelleria, the type locality for pantelleritic rocks, is an active volcanic field located in the Sicily Channel Rift Zone, an intraplate setting affected by transtensional tectonics related to the complex geodynamics of the Western Mediterranean area. The island, dominated by a nested, resurgent caldera, has been affected by regional tectonism and volcano-tectonism that controlled both evolution of the magmatic system and distribution of eruption vents. The eruptions were fed through time by magmas of variable composition, typically bi-modal, both mafic and silicic. The island is divided into two sectors by a NE-SW fault system, which likely represents a crustal discontinuity along the axial ridge of the rift. The north-western sector, affected only by NW-SE crustal structures, includes most of the exposed transitional to alkaline basaltic rocks. The south-eastern sector includes silicic peralkaline rocks, variable from comenditic trachyte to rhyolite (pantellerite). Eruption of differentiated magmas and occurrence of the nested caldera, suggest that crustal magma chambers were established in this sector, probably at the intersection of the main tectonic lineaments. On the other hand, eruption of abundant mafic magmas in the north-western sector of the island suggests a deeper plumbing system linked to the mantle source region. The geochemistry of volcanics representative of the younger-than-15 ka activity has been investigated with the aim of better understand the magmatic processes governing the behaviour of the Pantelleria shallow plumbing system. The investigated volcanic rocks, products of both explosive and effusive activity, range in composition from comenditic trachyte to pantellerite, matching the typical range of evolved peralkaline composition of Pantelleria. Alkali-feldspar-rich enclaves are common in these rocks, testifying to diffuse mingling phenomena. Electron microprobe and micro-Raman analyses of interstitial glass of enclaves has revealed unusual compositions even more evolved than the host rocks. These data, integrated with recent experimental petrology results on peralkaline silicic magmas, allowed us to put forward hypotheses on the extreme differentiation processes and dynamics occurred within the Pantelleria shallow plumbing system in the past 15 ka.

Olivine record of crystal residence times and the internal dynamics of magmatic plumbing systems

LEONID DANYUSHEVSKY[1]*, ALEXEY ARISKIN[2]

[1]CODES, an ARC Centre of Excellence in Ore Deposits, Hobart, Australia, L.dan@ utas.edu.au (* presenting author)
[2]Vernadsky Institute of Geochemistry, Moscow, Russia, ariskin@rambler.ru

Analysis of the kinetics of post-entrapment re-equilibration of melt inclusions in high-Fo olivine phenocrysts in lavas suggests their common short residence times (< 6-12 months). This implies that if eruption does not happen within a few months after a primitive magma begins cooling and crystallisation within the plumbing system, early formed olivines are unlikely to be erupted as phenocrysts, being efficiently separated from the melt, and rapidly incorporated into the cumulate layers within the plumbing system.

These results suggest that in most cases erupted high-Fo olivine phenocrysts retain their original composition, which explains commonly observed large compositional variations between olivine phenocryst cores in a single sample. Short residence times imply that large unzoned cores of high-Fo phenocrysts cannot reflect diffusive re-equilibration of originally zoned phenocrysts. The unzoned cores are a result of fast efficient accumulation of olivines from the crystallising magma, i.e., olivines are separated from the magma faster than melt changes its composition. Thus, the main source of high-Fo crystals in the erupted magmas is the mush zone of the plumbing system. Olivine-phyric rocks represent mixtures of an evolved transporting magma (which forms the groundmass of the rock) with crystals that were formed during crystallisation of more primitive melt(s). Unlike high-Fo olivine phenocrysts, the evolved magma may reside in the magmatic system for a long time. This reconciles long magma residence times estimated from the compositions of rocks with short residence times of high-Fo olivine phenocrysts.

Olivines incorporated in the cumulate layers are sometimes erupted in gabbroic/ultramafic xenolith. Unlike phenocrysts in lavas, olivines in xenoliths commonly have uniform compositions, reflecting diffusive re-equilibration during long residence times.

Slow cooling rates and extensive re-equilibration within the plumbing systems results in complete re-equilibration of the cumulate crystals at near solidus temperatures. In parts of these systems where cumulate compaction and intercumulus melt migration were minimal, correlations between compositions of olivine and the bulk samples can be used to estimate the compositions of the parental magmas and the amount and composition of phenocrysts they carry. Having established the composition of parental magmas, comparing them to the bulk compositions of different parts of the plumbing system can indicate their open or closed behaviour.

Using the Dovyren magmatic system (Northern Baikal region, Siberia, Russia) as an example, we show that the parental magmas were phenocryst rich, the supplying conduits were thermally and compositionally zoned, and the large layered intrusive body of the complex represented an open plumbing system feeding the associated volcanic centres.

Are the "magnetite lava flows" of El Laco (Chile) magmatic? Comparison of trace elements in magnetite with other magmatic Fe-oxide deposits

S.A.S. DARE[1*], S.-J. BARNES[1], G. BEAUDOIN[2] AND J. MERIC[1]

[1] Université du Québec à Chicoutimi, Québec, Canada, sasdare@hotmail.com (*presenting author)
[2] Université Laval, Québec City, Québec, Canada

Magnetite forms under a wide variety of conditions, crystallizing at high temperature from silicate magmas or precipitating at low temperature from hydrothermal fluids or seawater. Trace element content of magnetite may reflect the differences in these conditions. Therefore as part of a larger project examining the trace element content of magnetite, by laser ablation ICP-MS, we have characterized magnetite in magmatic massive Fe-oxide deposits (magnetite-ilmenite, ± apatite) from layered intrusions (Bushveld and Sept Iles Complexes) and a massif anorthosite (Lac St. Jean) in order to study how magmatic processes affect the trace element compositions. We have also collected trace element data from the enigmatic "magnetite lava flows" from El Laco, Chile, in order to consider whether these magnetites are indeed of igneous origin.

Magnetite from the layered intrusions record the evolution of the fractionating silicate liquid (Fig. 1a), with those found lower in the sequence (more primitive) being richer in Cr, Mg, V and Ni whereas those found higher (more evolved) being richer in Ti, Nb and Ta. Magnetite layers from the uppermost parts of the intrusions contain apatite and this magnetite shows the most evolved composition (Fig. 1a). Magnetite from the anorthosite shows similar compositions to those of the layered intrusions. However, magnetite from the El Laco lava flow are much richer in Si (0.4 wt.%), Ca and P and poorer in Ti (<0.1 wt%), Al (<0.2 wt%) and Ga than magnetite from any magmatic Fe-oxide deposit (Fig. 1b) which raises doubts about the El Laco "magnetite lava flow" having formed by igneous processses.

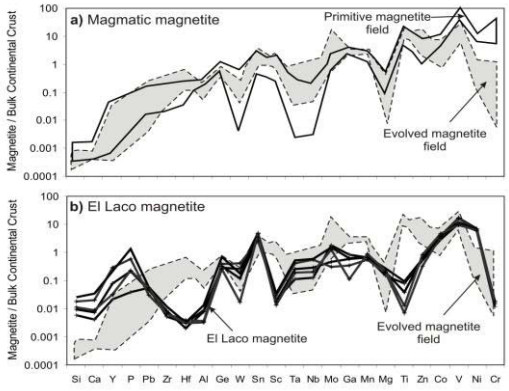

Figure 1: Trace element patterns for (a) magmatic magnetite and (b) El Laco magnetite compared to evolved magmatic magnetite. Order of elements: increasing compatibility into magnetite to the right.

Zircon U-Pb geochronology of the Nuvvuagittuq Greenstone Belt

J. DARLING[1*], D. MOSER[1], L. HEAMAN[2], W. DAVIS[3], R. STERN[2], J. O'NEIL[4], R. CARLSON[4], D. FRANCIS[5]

[1]Uni. of Western Ontario, London, Canada ([*]jdarli5@uwo.ca)
[2]University of Alberta, Edmonton, Canada
[3]Geological Survey of Canada, Ottawa, Ontario, Canada
[4]Department of Terrestrial Magnetism, Washington, DC, USA
[5]McGill University, Montreal, Quebec, Canada

The Nuvvuagittuq Greenstone Belt in northern Québec is a rare ~10 km^2 fragment of the Earth's early crust. The belt contains metamorphosed supracrustal rocks that are at least 3.77 billion years old [1,2], and amphibolites (the Ujaraaluk Unit) that may have protoliths as old as 4.3 Ga [3]. Primary contacts and relative age relationships have been obscured by multiple episodes of intensive ductile deformation, however the geological history of the belt is beginning to be unraveled via geochronology and geochemistry.

In this study we have undertaken SHRIMP U-Pb analysis of zircons from key meta-igneous and meta-sedimentary units of the belt. The analysed samples fall into three categories: (a) felsic bands (0.5 to 1 m in width) and tonalitic orthogneiss interlayered with the Ujaraaluk Unit; (b) fuchsite-bearing quartz-rich bands and a newly identified metasedimentary unit; (c) garnet-biotite amphibolite from the Ujaraaluk Unit and a meta-gabbro.

The felsic lithologies place contraints on the minimum age of the supracrustal assemblage. Oscillatory zoned zircons separated from a plag-qtz-bt schist form a discordant array with an upper intercept of 3774 ± 32 Ma, consistent with previous analyses of similar lithologies [1,2]. The tonalitic orthogneiss yields concordant zircon ages between 3740 and 3800 Ma, consistent with the observation of oscillatory zoned cores and rims from CL imaging.

Zircons from the fuchsite-bearing quartz band are subrounded and have oscillatory zonation textures very similar to the orthogneiss zircons, with little textural variation, and concordant ages of between 3750 and 3800 Ma, similar to the orthogneiss. In contrast, a quartz-albite-clinozoisite dominated metasediment identified within a lower strain domain, interfolded with amphibolites, has highly variable zircon CL textures. The zircons are dominated by concordant ages of 3630 to 3680 Ma, similar to the age of nearby tonalites [2], with minor concordant populations at ca. 3800 and 3500 Ma. Accordingly, the belt must have been exhumed following intrusion of the ca. 3660 Ma tonalite [2], and prior to high-T metamorphism and deformation.

Electron microscopy of polished thin sections was used to locate zircons within 4 samples of the Ujaraaluk Unit mafic amphibolites. Large (≤ 500 μm) zircons separated from a gt-bt rich sample, together with those from the meta-gabbro sample, are sector zoned and yield metamorphic ages of ca. 2700 Ma.

Although unequivocal constraints on the primary age of the Ujaraaluk Unit amphibolites remain elusive for now, continued geochronological studies are revealing that the belt contains a detailed record of Eoarchaean to Paleoarchaean crustal processes.

Zircon-adhering, crystallized melt inclusions in peritectic garnet from the western Adirondack Mountains, New York State, USA.

ROBERT DARLING [1*]

[1]Geology Department, SUNY Cortland, Cortland, NY, 13045, USA
robert.darling@cortland.edu (* presenting author)

Micrometer-scale, multiple-solid inclusions occur in garnet from metapelitic gneiss extracted from the hydroelectric plant on the Black River at Port Leyden, NY (western Adirondack Highlands). The garnet host grains are small (0.5-1.0 mm diameter), euhedral neoblasts that formed peritectically during biotite dehydration melting accompanying the Ottawan phase of the Grenville Orogeny (ca. 1040 Ma; [1]). Partial melting conditions of 4 to 6.4 kbar and 735°C, and a peritectic reaction of bio + sil + vapor = gar + melt, or bio + sil + qtz = gar + melt ± K-feldspar have been proposed for these rocks [1].

The inclusions are typically 10-20 μm in diameter and occur randomly in garnet. Both negative crystal and irregular inclusion morphologies are present. Many, if not all, of the inclusions contain a large (5-8 μm), often euhedral, zircon grain surrounded by finer-grained (some less than 1 μm) phases with EDX spectra consistent with biotite, K-feldspar, quartz, and albite. The inclusions are similar in size and composition to those described in garnet from other migmatites (e.g. [2], [3], [4]) and are similarly interpreted as anatectic melt inclusions.

Low Zr solubility in silicate melts [5] indicates the large zircon grain in each inclusion is a trapped phase. Therefore, it appears that micrometer-scale droplets of anatectic melt adhered to refractory zircon grains while peritectic garnet grew around them.

Spectrophotometric determination of alkalinity and pH in freshwaters

YACINE DARMOUL[1*], GIL MICHARD[1], MARC F. BENEDETTI[1], ALEXIS GROLEAU[1] AND FRANÇOIS PREVOT[1]

[1]Univ. Paris Diderot, Sorbonne Paris Cité, IPGP, Paris, France darmoul@ipgp.fr (* presenting author), michargf@noos.fr, benedetti@ipgp.fr, groleau@ipgp.fr, prevot@ipgp.fr

The different compartments of the hydrosphere are major sinks or sources of CO_2 and the role of freshwaters in the global carbon cycle has been recently reevaluated as substantial [1]. Freshwaters show variations of the carbonate system variables at hourly time scales and in a large range. A key limitation for the carbonate system studies is the necessity of accurate, *in-situ* and high frequency measurements that would provide data with suitable spatial and temporal resolutions to enlighten the processes affecting the carbonate system.

With the aim of *in-situ* and high frequency sensor development to assess the freshwaters whole carbonate system with the simultaneous measurement of the pH-Alkalinity couple [2], spectrophotometric measurement of these parameters is developped. Spectrophotometric pH measurements already exist [3] this work focuses mainly on the alkalinity (Alk) measurement, which is an original contribution. This new method, based on [4], consists to neutralize all the basic species taken into account in the Alk by a weak acid mixed with a pH sensitive dye to measure accurately the pH end point value and thus deduce the alkalinity of the sample.

The performance of spectrophotometric methods is assessed in low pH buffer solutions for pH, commercial mineral and spring waters for Alk and natural freshwaters for both, by a comparison to conventional potentiometric measurements and theoretical calculations.

pH measurements show a precision of ±0.005 and an accuracy of 0.01 pH unit; Alk measurements show a precision of ±8µM and an accuracy ranging from 19 to 2 µM. The best accuracy is obtained by downplaying the excess acid term and thus its associed uncertainty. Additionnaly, accuracy relies upon the performance of the spectrophotometer, carefully prepared and defined indicator solution and all very controlled and reliable thermodynamic constants with their temperature and ionic strength dependence. The somewhat poorer precision reported might be ascribed in a larger part to the totally handmade procedure steps that introduce more errors than an automatic device. Tests on our pH and Alk *in-situ* sensor (still in development), shows that a precision better than ±0.001 unit on pH and better than ±2 µM on Alk are expected.

This work provide a strong theoretical basis for its future use as an *in-situ* high frequency sensor, which precision and accuracy meet the requirements of scientist working on freshwaters systems.

Abstract

Osborn et al [1] recently reported 17-times higher concentrations of thermally mature methane (CH_4), consistent with production gases from the Marcellus shale, in drinking water wells within 1km of hydraulically fractured horizontal drilling sites producing from the Marcellus Shale in northeastern Pennsylvania. We employ a combination of hydrologic (groundwater age dating [^{3}H-^{3}He and fluid flow modeling]), noble gas geochemistry, and carbon isotopic composition to distinguish the potential sources of gases present in drinking water aquifers within the region. These techniques simultaneously distinguish Marcellus/Devonian gas from deeper Trenton Group/Ordovician gases and other potential sources (e.g. shallow biogenic methane, stray landfill gases, other organic-rich lithologies, and natural gas that has migrated naturally over geologic time) providing a powerful technique for delineating the source and potential for fugitive gas migration in areas active or targeted for drilling. We will present preliminary results of noble gas and isotope geochemistry for Pennsylvania and New York areas of the Marcellus fairway.

Precise Pb-Pb dating of Precambrian zircon using thermal extraction-condensation (TEC) and ^{202,205}Pb double spike

ABIN DAS[1] AND DONALD W. DAVIS[1*]

[1]Department of Geology, University of Toronto,22 Russell St., Toronto M5S 3B1 , Canada, das@geology.utoronto.ca[1], dond@geology.utoronto.ca[1*]

Method

Demonstrating reproducibility of Pb isotopic ratios in zircon is sufficient for accurate dating of Precambrian samples without the need for isotope dilution and U analysis, which require total dissolution of sample and chemical processing to remove Zr. The Kober [1,2] and Davis [3] methods of thermal extraction of Pb are simple but both provide relatively inefficient ionization and neither is amenable to double Pb isotope spiking, which limits the accuracy of ages that they can provide. We have experimented with a modification of Kober method that overcomes these limitations. Zircon is folded into a 0.03 in x 0.0005 in Re filament and thermally pre-treated at about 1450C for 30-45 min in vacuum to evaporate disturbed Pb from chemically altered domains. A condensation surface is then exposed to the sample and the zircon is heated at 1600C over 15 min to totally evaporate Pb. The condensation surface consists of either a 0.25 in wide Re ribbon (thermally cleaned using high current in a carbon coating chamber) or the inside of a 3 ml Savillex vial. Condensation of common Pb from the posts of the filament is prevented by the use of blinders welded to the posts of the evaporation filament. Operations are carried out inside a bell jar normally used for filament outgassing. Deposited silica from the zircon is subsequently removed using HF, by swabbing the Re surface using a pipette or open fluxing in the vial. The recovered Pb in the solution is dried, converted to HCl and spiked with ET2535 ^{202,205}Pb-^{233,235}U spike, then loaded onto a conventional Re filament with phosphoric acid and silica gel for conventional TIMS analysis. The vial condensator is more convenient than the wide filament but it produces relatively high blanks probably because of partial melting of a thin teflon surface layer by the hot silica. The Re condensator gives negligible blank but is less efficient for collecting Pb.

Results

The TEC method has been tested on two Precambrian zircon populations from northwest Ontario previously dated by conventional methods. One of them is from the Marmion tonalite which has a conventional U-Pb age of 3002.6 ± 1.5 Ma [4]. Four fractions of it gave an average TEC age with 2 standard deviation of 3001.9 ± 0.6 Ma. The other one consists of two zircon fractions from a rhyolite at Nevison Lake (conventional age of 2998.6 ± 0.8 Ma) with a TEC age of 2998.5 ± 0.4 Ma.

Noble gas and radionulcides study of chondrules from Dhajala and Bjurbole chondrites

J. P. DAS[1*], G. E. BRICKER[2], A. MESHIK[1], O. PRAVDIVTSEVA[1], M. W. CAFFEE[3], C. M. HOHENBERG[1], K. NISHIIZUMI[4].

[2]Dept. of Physics, Purdue University, Westville, IN 46391, USA.

[3]Primelab, Dept. of Physics, Purdue University, West Lafayette, IN 47907, USA.

[4]Space Sciences Lab, University of California, Berkeley, CA 94720, USA.

Chondrules were formed ~ 2-3 Myr after the formation of CAIs (the first solid condensates of solar system) and then accreted into large bodies with fine-grain matrix material [e.g.,1]. Chondrules might experience excess exposure to energetic solar particles and cosmic rays before their compaction. To investigate such pre-compaction exposure, cosmogenic noble gas isotopes and radionuclides were studied for individual chondrules from Dhajala and Bjurböle.

Separated individual chondrules from Bjurböle (L/LL4) and Dhajala (H3.8) meteorites were crushed to small and uniform grain size and then divided into three aliquots for composition, radionuclide and noble gas analyses. To calculate production rates of cosmogenic nuclides, major element compositions of the samples were determined by a Thermo Electron Corporation iCAP 6000 series mass spectrometer. Measurements of ^{10}Be, ^{26}Al, and ^{36}Cl were performed by AMS at Primelab, Purdue University. He, Ne and Ar measurements were carried out using noble gas mass spectrometry at Washington University in St. Louis. The cosmic ray exposure age of Bjurböle (> 8 Myr, [2]) is greater than five half-lives for all the radionuclides measured, indicating that the production rate is equal to the activity of the sample. The production rates of ^{10}Be, ^{26}Al, and ^{36}Cl were calculated based on irradiation depth using the model suggested by [3]. Estimates for the pre-atmospheric size of Bjurböle are ~ 400kg with a density of 2.28 g cm^{-3} [4]. Assuming a spherical shape, the pre-atmospheric radius of Bjurböle is ~ 35 cm. From radionuclide analysis, we find the Bjurböle samples were located from 2-5 cm inside the parent body. For Dhajala (CRE age ~ 4 Myr, [5]), ^{36}Cl and ^{26}Al activity is at the saturation point. Based on ^{26}Al, the most likely size and location of the sample is 70 cm inside a 120 cm body. At this depth, the ^{10}Be activity is saturated and the minimum CRE age is 6.8 Myr. The noble gases in chondrules are dominated by cosmogenic component however a detectable amount of trapped gases are also present. We are initially using the ^{22}Ne/^{21}Ne as a depth indicator, allowing us to calculate production rates of ^{3}He, ^{21}Ne and ^{38}Ar [6]. An alternative method is to deduce the irradiation depth based on radionuclide activity [3]. ^{3}He, ^{21}Ne and ^{38}Ar CRE ages suggest that chondrule D#10C from Dhajala and chondrule BC06C from Bjurböle were exposed to cosmic rays longer than the host matrix. The remainder of the chondrules show CRE ages similar to matrix. The excess exposure duration is within the range of earlier reports [2, 5]. Radionuclide data in this study were used to find size and depth profile of the samples; future radionuclide data will be used to quantify recent exposure history with the goal of elucidating pre-compaction exposure from the total exposure history.

Phase transformation of two-line ferrihydrite: Effects of pH, temperature, and adsorbed arsenate and molybdate

SOUMYA DAS[1*], M. JIM HENDRY[1], JOSEPH ESSILFIE-DUGHAN[1]

[1]University of Saskatchewan, Geological Sciences
sod671@mail.usask.ca (* presenting author)
jim.hendry@usask.ca
joe377@mail.usask.ca

Introduction

A dominant control on the mobility and speciation of many toxic elements from mining and milling operations is their adsorption onto the surface of iron oxy-hydroxides, of which two-line ferrihydrite (hereafter called ferrihydrite) is one of the most common and reactive. For example, tailings generated from uranium (U) mining and metallurgical operations are a potential source of As, Mo, Se, and Ra^{226} (termed Elements of Concern; EOCs) to the geosphere and biosphere. Generally, these elements are removed from oxic, acidic leach solutions (pH ~1.5) in the U mill via neutralization with lime and co-precipitation with ferric iron. Ferrihydrite starts to precipitate at pH ~3.5-4 during this neutralization process, which ultimately increases the pH to ~9.5 in the tailings prior to discharge. The EOCs subsequently adsorb onto the ferrihydrite, which thus controls their mobility in the pore waters. Because ferrihydrite is metastable and can transform to more structurally ordered oxy-hydroxide phases such as goethite and, under certain geochemical conditions, hematite, this study was conducted to assess the ability of ferrihydrite to act as a long-term sink for As and Mo in U tailings bodies. The results will also be useful in determining the long-term stability of ferrihydrite in other mine environments.

Materials and Methods

A comprehensive study was carried out to determine the rate of transformation of pure ferrihydrite (i.e., no adsorbed As or Mo) to goethite and hematite as a function of temperature (25, 50, 75, and 100°C) and pH (2, 7, and 10) via batch experiments. Subsequently, the impact of adsorbed arsenate and molybdate on the rate of ferrihydrite transformation was determined based on As/Fe (0.500-0.010) and Mo/Fe (1.000-0.010) molar ratios (to approximate elemental concentrations measured in the tailings) at pH ~10 and 75°C. These rates were extrapolated to the environmental conditions measured in the tailings (i.e., 1°C and pH=10) at Cameco Corporation's Deilmann Tailings Management Facility, Saskatchewan, Canada. Pure and transformed phases were characterized and quantified using XRD, XANES, AFM, SEM, BET, and Raman spectroscopy.

Results and Discussion

The rate of transformation of pure ferrihydrite to hematite increased with increasing temperature at all pH values considered and followed first order reaction kinetics. In the case of As adsorbed to ferrihydrite, the rate of ferrihydrite transformation decreased by two orders of magnitude as the As/Fe ratio increased from 0.010 to 0.018. No transformation was observed at higher As/Fe ratios (0.050, 0.100, and 0.500). Calculations show that the rate of ferrihydrite transformation under *in situ* conditions (~1°C; pH ~10; As/Fe ratio >0.250) is negligible and thus the ferrihydrite should continue to act as a sink for As for at least 10,000 years. Results of the ferrihydrite-molybdate testing remain to be analyzed.

Carbon solution and partitioning between metallic and silicate melts in a shallow magma ocean: implications for the origin and distribution of terrestrial carbon

RAJDEEP DASGUPTA[1*], HAN CHI[1], NOBUMICHI SHIMIZU[2], ANTONIO BUONO[3,4] AND DAVID WALKER[3]

[1]Rice University,Houston, TX, USA, (*Rajdeep.Dasgupta@rice.edu)
[2]Woods Hole Oceanographic Institution, Woods Hole, MA, USA
[3]Columbia University, Palisades, NY, USA
[4]Massachusetts Institute of Technology, Cambridge, MA, USA

Carbon in the Earth's mantle has critical influence on planetary geodynamics, chemical differentiation, long-term climate, and habitability. But how early did the bulk silicate Earth acquire its current inventory of carbon? Is the mantle carbon mostly recycled or primordial? Answering these questions requires knowledge of the element's fate during magma ocean processes and parameters such as carbon solubility and partitioning between metal and silicate during core formation are key.

Experiments were performed at 2-7 GPa, 2000-2100 °C on mixtures of silicates (tholeiitic basalt/ komatiite/ fertile peridotite) and Fe-Ni-Co-C-S mix contained in graphite or MgO capsules. All the runs produced immiscible Fe-rich metallic and silicate melts at fO_2 between IW-1.0 and IW-2.2. Carbon concentrations of basaltic glasses and non-glassy quenched silicate melts were determined using secondary ionization mass spectrometry (SIMS) and speciation of dissolved C-O-H volatiles in silicate glasses was constrained using Raman spectroscopy. Carbon contents of metallic melts were determined using both electron microprobe and SIMS. Our experiments indicate, that at reduced, core-forming, conditions, carbon in mafic-ultramafic magmas dissolves primarily as a hydrogenated species and its storage capacity remains low. The total C content in our reduced melts at graphite saturation increases with increasing melt depolymerization (NBO/T), consistent with a recent spectroscopic study [1]. Carbon behaves as a metal-loving element during core-mantle separation and D_C (metallic melt/ silicate melt) varies between ~3500 and ≥100 and increases with increasing pressure and decreases with increasing melt NBO/T.

Our data suggest that if only a trace amount of carbon (~730 ppm C; [2]) was available to participate in the early differentiation of Earth, most of it was partitioned to the core and no more than ~10-30% of the present-day mantle carbon budget (50-200 ppm CO_2) can be derived from a magma ocean residual to core formation. With core formation removing most of the carbon initially retained in the terrestrial magma ocean, explanation of the modern Earth carbon inventory requires a later replenishment mechanism. Addition of volatile-rich, late veneer and inefficient core formation both remain viable mechanisms. Alternatively, carbon ingassing by magma ocean-atmosphere interaction, soon after core formation, may also make the Earth's primordial carbon inventory similar to that of the present-day budget.

Insights on the Late-Stage Evolution of Glacial Lake Ojibway

VIRGINE DAUBOIS[1], MAXIME MÉNARD[2], MARTIN ROY[3], AND JEAN J. VEILLETTE[4]

[1,2,3] Dép. des Sciences de la Terre et de l'Atmosphère – GEOTOP, Université du Québec à Montréal, Montréal, QC, Canada

[4] Geological Survey of Canada, Ottawa, ON, Canada
[4] Jean.Veillette@NRCan-RNCan.gc.ca

Meltwater released at the southern margin of the Laurentide ice sheet during the last deglaciation led to the development of Lake Ojibway in NE Ontario and NW Quebec. The late-stage evolution of Lake Ojibway was marked by ice (Cochrane) readvances, while recent mapping of low-elevation lakeshores indicate abrupt drawdowns of Ojibway lake level prior to its final discharge into Hudson Bay ~8200 cal yr BP. Additional late-stage events are also suggested by the presence of thick (10-15 cm) bands of massive silt that truncate Ojibway rhythmites. This silt band is in turn overlain by ~1 m of rhythmites. Although this sequence suggests the occurrence of drainage episode(s), the late-stage history of Lake Ojibway remains inadequatly documented. Here we report results from the study of 12 Ojibway sediment sequences that contain the silt band.

Grain-size analyses of bulk Ojibway rhythmites (winter and summer beds) show a textural composition consisting of 73% clay (<2 μm) and 25 % of fine silt (2–8 μm), with the remaining material being composed of medium silt (8–16 μm). This contrasts with the thick silt band that consist primarily of ~54–86% of fine to coarse silt (2–63 μm), with the clay fraction typically representing < 20%. The detrital carbonate content of rhythmites samples shows values ranging from 0.72 to 2.02%, while silt band samples commonly show a slight increase with respect to the bounding rhythmites, going from 1.85 to 3.34%. Ostracods were extracted from specific sediment intervals for oxygen isotope ($\delta^{18}O$) measurements. Preliminary results indicate that ostracods from the silt band and underlying rhythmites have $\delta^{18}O$ values ranging from –23.26 to –25.04 ‰ (vs VPDB), typical of glacial metltwater. In contrast, the rhythmites overlying the silt band show $\delta^{18}O$ ranging from 10.03 to 16.62 ‰.

Interpretation of the results is still limited at this stage of the study. Nonetheless, the textural changes reported could be associated with a drainage episode(s) that was followed by a deepwater phase(s). Alternatively, this *drainage varve* (?) could represent a drastic change in the sediment supply (or source) to the lake. This appears to be supported by the increase in detrital carbonate of the silt band. Because the Ojibway basin lies primarily on crystalline bedrock, the presence of detrital carbonate in Ojibway sediments is commonly attributed to the late-glacial dynamics (metlwater runoff or ice readvances) of the decaying ice in Hudson Bay, which is underlain by carbonate rocks. Any explanation for the origin of this silt band and associated compositional changes must also take into account the sharp change in $\delta^{18}O$ composition obtained for the sediments overlying the silt band, which shows an evolution towards post-glacial values. Upcoming ^{14}C ages from the ostracods extracted from the silt bands and bounding rhythmites should also help refining our understanding of these events.

A surface complexation model for the copper-bacteria-iron oxide system

Laboratory experiments were performed to track the fate of dissolved Cu and Fe at a fixed pH of 5.2 during the gradual, incremental oxidation of dissolved Fe(II) and precipitation of iron oxide in the presence of *Anoxybacillus flavithermus* cells. The experimental data reveal significant and complex controls on Cu immobilization, related to progressive changes in 1) ratio of Cu to dissolved Fe(II) concentration, inferred to result from competition for bacterial sorption sites; 2) ratio of precipitated iron oxide to bacteria, inferred to result from desorption of Fe(II) initally associated with the bacterial surface; and 3) reaction time, inferred to result from Cu complexation by increasing quantities of biogenic dissolved organic matter. Surface complexation models were developed to describe the experimental data, with constraints on reaction mechanims provided by polarography and X-ray absorption spectroscopy. Differential pulse polarography demonstrated that Cu complexes form with dissolved organic ligands in filtered bacterial suspensions. The concentration and Cu complexation capacity of these bacterial exudates could be quantified and related to the conditions and history of the suspensions. The bacterial exudates significantly inhibited Cu adsorption onto the bacterial cells but slightly enhanced adsorption onto the iron oxide under the experimental conditions. X-ray absorption spectra were collected at the Cu K-edge on the bacterial exudates and wet pastes of the bacteria, the iron oxide, and the bacteria-iron oxide composites. The EXAFS data suggest that Cu complexation by the bacterial exudates involves binding by carboxyl or phosphate sites. The EXAFS data also show that under the experimental conditions Cu in the solid phase is associated predominantly with carboxyl structures on the bacterial cell walls, not with bacterial phophoryl structures or with binding sites on the iron oxide. This study demonstrates that the immobilization of metal cations in bacteria-bearing settings should not be examined independently of progressive oxidation, hydrolysis and precipitation of iron.

Previous studies have suggested that iron isotopes could be good tracers of redox conditions during melting [*e.g.*, 1]. However, we lack a reliable database of equilibrium fractionation factors between melts and igneous minerals such as olivine to interpret the rock record [2]. Iron equilibrium fractionation factors (or more specifically reduced partition function ratios, β) can be derived from Nuclear Resonant Inelastic X-ray Scattering (NRIXS) experiments at a synchrotron facility [3,4]. We have developed a new method (*i.e.*, the *general moment* approach), based on a Bernoulli expansion of the reduced partition function ratio, to calculate β-factors from the moments of raw NRIXS spectra [4]. The first term in this expansion corresponds to the mean force constant of the iron bonds [5], a quantity that is readily measured and often reported in NRIXS studies [6]. We have used this technique to determine the β-factors of olivine and geologically relevant silicate glasses.

At a given Fe^{3+}/Fe^{2+} ratio, the force constants of basaltic, andesitic, and dacitic glasses are almost identical. However, the force constant of rhyolitic glass is higher. For all samples, the force constant increases with the Fe^{3+} content. Thus, for mafic melts, there is little structural control on iron isotopic fractionation; redox effects seem to dominate. The relationship between force constant and Fe^{3+}/Fe_{tot} for basalt, andesite, and dacite is approximately linear. We can estimate the force constants of Fe^{2+} and Fe^{3+} in basalt by interpolating the data to $Fe^{3+}/Fe_{tot}=0$ and $Fe^{3+}/Fe_{tot}=1$. At 1,100 °C, we calculate an equilibrium $\delta^{56}Fe$ fractionation of +0.25 ‰ between the two oxidation states of iron in magmas. The olivine-melt and melt Fe^{2+}-Fe^{3+} iron isotopic fractionations derived from NRIXS data may explain the heavy iron isotopic compositions measured in MORBs.

This study provides a solid reference for interpreting Fe isotopic variations in igneous rocks. Specifically, it reveals the potential of using Fe isotopes to trace redox variations and magmatic differentiation processes in planets.

Cyclic growth layers in calcareous biominerals

YANNICKE DAUPHIN[1*], C. TERRY WILLIAMS[2], AND JEAN-PIERRE CUIF[3]

[1]Université P. et M. Curie, Paris, France yannicke.dauphin@upmc.fr (* presenting author)

[3]Université Paris Sud, Orsay, France, jean-pierre.cuif@u-psud.fr

Mollusc shells are among the best known calcareous biominerals. The calcitic prisms of *Pinna* and *Atrina* are often used because of their large size and simple geometry. As other biominerals, they are organo-mineral composites [1,2]. Thin sections observed in polarized light show they behave as monocrystals [3]. However, polished and etched sections show they are composed of growth zonations. Thickness of a growth line is about 1-3 µm. Moreover, the distribution of chemical elements is not uniform. Outer organic walls have low Mg and high S contents. Within the prisms, more or less intense zonations are visible. In both structural and chemical images, zonations are synchronous across adjacent prisms, showing the strict physiological control of the biomineralization processes. The comparison of chemical maps show that the rhythm and intensity differ according to the element.

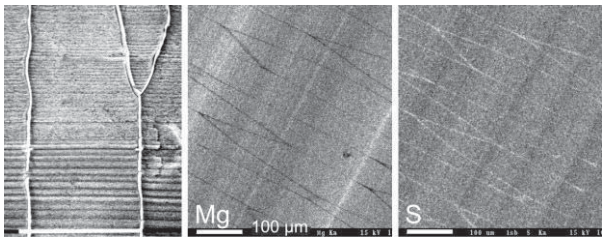

Figure: structural growth lines and chemical zonations in the calcitic prisms of *Pinna*

AFM images show that prisms are made of granules surrounded by a cortex. TEM data show that in distinct regions of a prism, granules are amorphous, while others are crystallized as subunits of a large single crystal. At the boundary of the two regions, granules display a crystallized core and an amorphous rim [4]. Such a limit probably marks out an arrested crystallization front having propagated through a previously biocontrolled architecture of the piling of amorphous micro-domains.

Such a crystallization process, developed within the organic matrix, differs from the usual model occurring within a fluid, the composition of which is assumed to be close to sea water. Such a model, used in the palaeo-climate/ geochemical areas, cannot account for any species-specific property of the calcification process. A matrix-driven crystallization within the spheroids of the growth layers provides us a reasonable way to explain the black-box of the "vital effect".

Does diopside dissolve like glass? Insights from measurements of nano- to macroscale dissolution rates

DAMIEN DAVAL[1,2*], GIUSEPPE D. SALDI[2], ROLAND HELLMANN[3] AND KEVIN G. KNAUSS[2]

[1]LHyGeS, Université de Strasbourg – CNRS UMR 7517, Strasbourg, France; ddaval@unistra.fr (* presenting author)

Whereas the dissolution rate of silicate minerals has been extensively studied at far-from-equilibrium conditions, extrapolating such rates over a broad range of solution compositions has proven challenging. In particular, a growing amount of studies have pointed out that the simplest TST-based rate-affinity dependence commonly implemented into most of geochemical codes was the source of dramatic overestimations of the actual fluid-rock interaction rates [1, 2]. Such limitations acted as a driving force for developing alternative dissolution models of solids over the past 10 years [3, 4].

Diopside was shown to belong to that category of minerals for which rate-affinity relationships do not follow a simple TST-like model, since an unexpected drop of the rate was evidenced at ΔG_r(diopside) as low as –76 kJ.mol^{-1} [5]. An examination of these data led us to envisage that two different, non-exclusive aspects were worth investigating: (i) the possible passivating ability of interfacial, nm-thick Si-rich layers developed on weathered silicate surface, and (ii) the stop of etch pits formation on crystal surface, which were found to be responsible for drops of olivine [2] and albite [3] dissolution rates, respectively. The former mechanism should be evidenced by the dependence of diopside dissolution rate on [SiO_2(aq)], whereas the latter should verify a strong anisotropy of diopside dissolution, with (h k l≠0) faces dissolving noticeably faster than (h k l=0) faces. Both of these models were tested by running either classical flow-through experiments with controlled [SiO_2(aq)], and face specific dissolution experiments. In this latter case, single crystals were immersed in solution. The dissolution features were monitored by AFM imaging and the dissolution rates were calculated by measuring the global surface retreat between masked and unmasked regions using VSI [1].

Our results show that the dissolution rate of diopside drops as SiO_2(aq) is added to the solution, consistently with a dissolution mechanism controlled by the stabilization of a passivating, interfacial Si-rich layer, as already suggested for glass [6]. On the other hand, our preliminary results on the face-specific dissolution of diopside show that the dissolution rate of faces varies following: (021) >> (110) ~ $(1\bar{1}0)$>> (010) ~ (100), which does not invalidate the etch pit nucleation control of diopside dissolution kinetics. The results of the ongoing experiment on (001) face, as well as upcoming investigations of the interfacial layers by TEM, will help to make a final decision between the two proposed models.

Differentiation and source controls along the Lesser Antilles arc

JON P. DAVIDSON[1*] AND MARJORIE WILSON[2]

[1] Department of Earth Sciences, Durham University, Durham DH1 3LE, UK, j.p.davidson@durham.ac.uk (* presenting author)
[2] School of Earth & Environment, the University of Leeds, Leeds LS2 9JT, UK, B.M.Wilson@leeds.ac.uk

The fluxes of elements into, and out of, subduction zones dictate both the composition of the crust and the heterogeneity of the mantle. Most flux estimates are predicated on the basis of the compositions of magmas erupted from arc volcanoes. However, volcanic rocks represet only 10-20% of the total magma flux from the mantle at arcs, and these magmas have undergone the maximum amount of filtering, having passed through the entire thickness of the upper plate lithosphere. In order, therefore, to realistically determine the contributions from the mantle wedge and slab (sediments and fluids) to arc magmas, it is critical to account for the effects of differentiation.

We have done this at the Lesser Antilles arc for two volcanoes; The Quill (Statia) in the north and Mt Pelee (Martinique) in the central part of the arc. An evaluation of the volcanic rocks, their constituent minerals and associated cumulate blocks allows us to show that 1) differentiation was controlled by an amphibole-plagioclase-dominated assemblage, as reflected in the cumulate blocks, and 2) differentiation was open system, involving assimilation of the arc crust.

Even though amphibole is not present in the phenocryst assemblage of the volcanic rocks, it is common in the cumulate xenoliths. Thus fractionation control is cryptic, with compositions determined largely by mineral assemblages not represented in the erupted fractionates. Indeed amphibole may be more common as a fractionating phase at arcs than has previously been appreciated [1]: By increasing SiO_2 and generating LREE enrichment, amphibole might have an important role in generating crust-like differentiates at arcs. The inferred assimilation of the arc crust modifies Pb and Sr isotope compositions in the magmas, suggesting that even at intra-oceanic arcs the isotopic compositions of erupted magmas cannot a priori be taken as indicative of their mantle source.

Once differentiation trends are established they can be back-extrapolated. When this is done, differentiation trends for The Quill and Mt Pelee do not converge on a common primitive/ parental composition, suggesting that mantle source compositions vary along the arc. The mantle sources of both volcanoes can be modlled by addition of <5% sediment or <1% sediment melt, along with LILE-bearing fluid. The differences between the sources of the two volcanoes can be explained by different sediment compositions delivered along the arc, or a slightly greater sediment contribution at Mt Pelee [2].

A Particle-Based Approach to Modelling Water Flow and Residence Times in a Small Catchment

JESSICA DAVIES[1]*, KEITH BEVEN[1,2], LARS NYBERG[3], ALLAN RODHE[2]

[1]Lancaster University, Lancaster, United Kingdom, j.davies4@lancaster.ac.uk (* presenting author) k.beven@lancaster.ac.uk

Introduction

Understanding water flow processes in the near-surface environment is crucial in determining movement of nutrients and pollutants. The majority of hydrological models used employ continuum-based expressions to derive mass flow linked with advective dispersive equations (ADEs) if transport is also considered. The appliability of these approaches to real soils which contain structural heterogeneities is questionable. Continuum-based models requires sub-grid equilibrium of potentials and fluxes, leading to impracticably fine grid-scales if the heterogeneities are to be represented, and the assumption of Brownian motion in ADEs is not representative of preferential flow features that allow solute movement at velocities much in excess of the wave celerities.

Multiple Interacting Pathways Model

The Multiple Interacting Pathways (MIPs) concept is an alternative approach to modelling transport and flow that directly acknowledges the presence of preferential flow pathways. Water in the slope or catchment is represented as a set of discrete particles, the movement of which is simulated through random particle tracking. Velocity distributions are applied to the particles, which attempt to characterise the range of pathways available to the water. These pathways are interacting as movement between them is simulated with exchange probabilities, which may also be used to simulate evapotranspiration or bedrock losses.

This concept provides unified simulation of transport and flow, allowing analysis of input/output/storage residence times and water origin, with the potential of adding chemistry to the particle interactions.

Application to Hydrometric and Isotopic Data

The MIPs model has previously been applied to simulating plot scale hydrometric and artificial tracer data at a site in Gårdsjön, Sweden with some success [1]. This modelling has been extended to simulate a catchment-scale step-change in isotopic input that occurred at the site on construction of a roof. Hypotheses are sought which provide consistent results across both spatial scales and temporal scales of transport. Having found a behavioural model, a fuller analysis is made of the input/output/storage residence time distributions suggested by the model.

Geochemical and isotopic insights into the origin of the 'Scourie' Dykes

JOSHUA H. F. L. DAVIES*, LARRY M. HEAMAN, S. ANDREW DUFRANE, KARLIS MUEHLENBACHS AND ROBERT A. CREASER.

University of Alberta, 1-26 Earth Sciences Building, Edmonton Alberta Canada. (jdavies1@ualberta.ca Presenting author)

The 'Scourie' dykes are a NNW trending dyke swarm in the Lewisian gneiss terrain of Northwest Scotland. They represent important time markers in the evolution of the Lewisian as the majority were intruded between two regional high-grade metamorphic events – the Inverian (~2.5 Ga) and the Laxfordian (~1.7 Ga). Importantly, the area around Loch Assynt was variably affected by the Laxfordian event leaving some of the dykes un-metamorphosed with primary igneous textures and minerals. The dykes therefore are perfectly placed to distinguish between the metamorphic events and provide information on the Paleoproterozoic history of the Lewisian terrain. Numerous field, geochemical and geophysical studies have been conducted on the Scourie dykes over the past 30 years, despite this the age and origin of the dykes is still poorly known.

Field relationships and geochronology indicate that there are at least four separate Paleoproterozoic dyking events intruding the Lewisian crust spanning a period of more than 400 m.y. The majority of dated dykes using high precision U-Pb zircon/baddeleyite geochronology were emplaced between 2420 and 2380 Ma, which is the time period focus of this study. Whole rock and clinopyroxene oxygen isotopic analyses have shown that some of the dykes have low $\delta^{18}O$ signatures (~2‰) whereas other dykes have normal mantle values (~5.5‰). Geochemical studies of the dykes indicate that there maybe at least two mantle sources involved in dyke genesis that are variably enriched in trace elements.

Here we combine new Sm-Nd, Rb-Sr, $\delta^{18}O$, geochronological and trace element data on the dykes to suggest a new model for the origin of the 'Scourie' dykes. Preliminary results indicate that the initial pulse of dyke emplacement (~2420-2400 Ma) was characterized by normal mantle oxygen isotope signatures and mantle source enrichment. A second period of dyke emplacement occurred subsequently (~2400-2380 Ma) in which the dykes are less geochemically enriched and contain low $\delta^{18}O$ signatures possibly indicating the involvement of subducted oceanic crust. Using the new geochemical and geochronological classifications we define the 'Scourie dyke suite' senso stricto as those emplaced between ~2420 and 2380 Ma with a concentration of these dykes in geographic proximity to the town of Scourie.

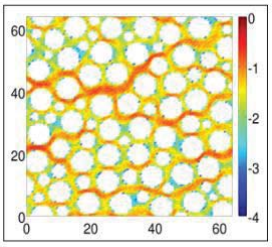
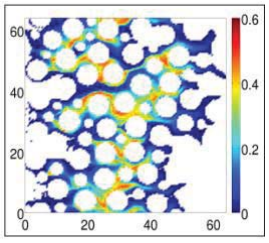
The effective reaction kinetics of chemical species transported in solution in the subsurface depends on the probability of reactants to mix. While chemical reactions ultimately occur by diffusive mixing at the molecular scale, the effective reaction kinetics can be greatly enhanced by the shear and stretching action of the flow field, which increases the surface available for diffusive mass transfer [1]. Understanding and quantifying the effect the flow field heterogeneity on the upscaled mixing and reaction rates is thus a key issue for the prediction reactive transport in the subsurface.

We use pore scale Smooth Particle Hydrodymanic (SPH) simulations to investigate effective mixing and reaction kinetics for reaction fronts where an initially resident reactant is displaced by an incoming reactant. The reaction kinetics is found to be faster than that of homogeneous diffusion-reaction fronts, for which the mass of product grows like the square root of time. At early time, the effective reaction rate is controlled by the formation of fingers of incoming reactant, which invade the porous media, rapidly increasing the reaction front area. At late time, the reaction kinetics is governed by the longitudinal dispersive growth of the mixing area and by the spatial distribution of concentration gradients in the mixing zone, which characterize a persistent state of incomplete mixing [2.3]. We discuss the effect of changing the relative contribution of advective and diffusive motions (quantified by the Peclet number) on the temporal evolution of effective mixing and reaction rates.



Pore scale flow field



Distribution of product concentration within the reaction front

[4]Royal Netherlands Meteorological Institute, P.O. Box 201 3730 AE De Bilt, The Netherlands

The thus far longest (13,000 km) complete deep ocean section of iron (Fe), aluminium (Al) and a suite of other trace elements and isotopes was realized in 2010-2011 in the West Atlantic Ocean. The more than 1200 data values reveal the major sources and processes controling Fe and Al in the oceans. Overall Fe is decoupled from Al except in the uppermost surface layer of dust input. Overall the Al shows an amazing inverse relationship with Si.

The background concentrations of Fe are quite uniform around 0.5 nM but there are several major enhancements. In the 10-30 ºN region the uppermost samples (10m depth) have maximum concentrations of Fe exceeding 2nM and Al exceeding 40 nM, respectively, due to partial dissolution of dust supply from the Sahara. This extra Fe supports N_2 fixation by diazotrophs in the Sargasso Sea, that upon sinking of plankton debris and mineralization causes a high anomaly of the nitrate/phosphate ratio in the 200-800m depth zone. The Amazon River plume provides a signal of high Fe and Mn but Al is not enhanced. Underlying the equator the strong oxygen minimum zone contains higher Fe concentrations, that by upward mixing may well be the major source of Fe to surface waters supporting plankton growth. The Confluence zone (~30 ºS) of the Brazil and Malvinas Current is a well known region of high biological productivity and chlorophyll biomass. We now find this is supported by very high dissolved Fe from below at ~3 nM or more, the supply of which may also be due to influence of the Rio de la Plata or submarine groundwater discharge. The North Atlantic Deep Water shows a very strong correlation of Al and silicate (Si) in the subArctic Gyre, yet going southwards the NADW content of Al decreases and of Si increases and far south no relationship exists anymore. This is consistent with ocean simulation modeling of steady remineralization of Si versus continuous loss of Al due to adsorptive scavenging. An enhanced Fe pool at 2000-3000m depth below and south of the equator (4ºN - 15ºS) is consistent with hydrothermal input, confirmed by higher Mn but no extra Al.

[4]Department of Ocean Sciences & Institute of Marine Sciences, University of California Santa Cruz, CA 95064, USA

Iron (Fe) is an essential trace element for all biota but the dissolved Fe in ocean waters is extremely low and limiting for phytoplankton growth in over 40% of world ocean surface waters. Indeed in the Southern Ocean extremely low dissolved Fe was found in surface waters along the Greenwich meridian, both in the Antarctic Circumpolar Current and in the most southerly Weddell Gyre adjacent to the ice-covered Antarctic continent [1]. The low dissolved Fe is maintained in solution by organic complexation [2]. The extending continental ice-sheet floating over the continental shelf is unique in largely preventing biological processes and cycling. As a consequence Antarctica is the only continent that does not supply Fe [1] and Mn [3] from shelf sediment sources into adjacent surface and intermediate waters. In contrast the shelves at both sides of the Antarctic Peninsula are a source for dissolved Fe, Mn and Al into the western Weddell Sea and southern Drake Passage, respectively. Otherwise dissolved Fe concentrations are extremely low in the entire water column of the Weddell Sea and Drake Passage. In West Antarctica the local Pine Island Glacier is a source of dissolved Fe [4] fueling intensive phytoplankton blooms [5] in the Amundsen Sea where organic complexation [6] of Fe plays a key role. In deep waters there is a significant hydrothermal plume of Fe and Mn over the Bouvet Triple Junction region. One water mass in Drake Passage also shows hydrothermal Fe and Mn associated with δ^3He anomalies originating from the Pacific Ocean [7]. In the Arctic Ocean a very strong hydrothermal Fe and Mn plume was found over the Gakkel Ridge [8, 9]. The large spatial extent of Fe of hydrothermal origin is ascribed to its stabilization in solution by organic complexation [10]. Surface waters in the central Arctic Ocean have fairly high dissolved Fe concentrations due to the Transpolar Drift bringing along coastal waters, mainly of Siberian riverine origin with high dissolved Fe contents [11]. As a result the Arctic Ocean has fairly adequate Fe abundance for phytoplankton growth, this in contrast to the very low and bio-limiting dissolved Fe in large areas of the Antarctic Ocean.

Atmospheric gases: the archaeological glasses memory

Aurore de Bigault de granrut[1*], Eric Humler[1]

[1]Laboratoire de Planétologie et Géodynamique - Université de Nantes, Nantes, France, (*aurore.de-bigault-de-granrut@univ-nantes.fr)

The atmospheric components of past climatic changes are often constrained from ice records of polar ice sheets. In temperate areas, this kind of study is more difficult to apply due to the low spatial and temporal resolution of the iced records.

In this study, we propose an alternative method based on analyses of atmospheric gases trapped in bubbles of archaeological glasses from the Western Europe and dated between the Ist century BC to the present. Indeed, during the shaping of ancient glasses, bubbles are created in glass paste, from the melting of raw materials inside furnace and glass-paste degassing, or from the step of glass working in open air. In this second case, the surrounding atmosphere could be trapped, particularly during the glass-making of ancient and medieval stained windows.

While the study of Vesicule Size Distribution (VSD) [1] of archaeological flat glasses show a bimodal size bubbles distribution in flat glasses, the distribution of the other kind of glasses (blown cup or vessel, and raw glasses) are unimodal. Geochemical analyses of major gases included in bubbles in flat glasses, show a chemical dichotomy between two groups of bubbles, independent of chemical composition of glass paste. The smallest bubbles (Ø<100-500 μm) are exclusively composed of CO_2. In contrast, the largest bubbles (Ø>250-500 μm) are N_2 rich (~80%), CO_2 poor and contained Ar (~1%), and sometimes O_2. So, the origins of the two populations of bubbles are obviously different and the largest vesicles seem to have an atmospheric origin (the Ar/N_2 ratios of these large bubbles are closed to the modern atmosphere).

Despite these gases look like an atmospheric composition, the CO_2 contents are too high and the oxygen contents are too low. The carbon excess could have different origins (mixing between atmosphere and furnace/combustion gases, and/or chemical reactions between trapped gases and particular soots). SEM analyses have shown some deposits in the inner wall of the largest bubbles (graphite, carbon oxides etc.), supporting the idea of a catch of elements as alien to glass and in-situ chemical reactions.

We need to take care of these soot-reactions and the gases diffusion rates through the glass, to estimate the initial compositions of gases included in vesicles, and to extract the atmospheric contribution from the bubbles gases set using mixing models. Finally, we suggest that the archaeological glasses could appear like a new but complex source of archeo-climatic recording.

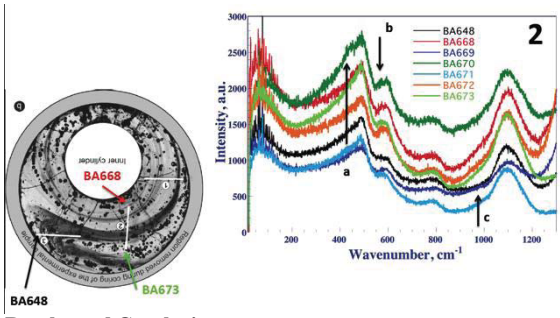
Glasses melts and magmas

A widely debated question in Geosciences is how viscous magmas with extreme viscosity contrast mix under natural conditions. In order to study how chaotic dynamics may control chemical interactions, and therefore timescales of hybridization during magma mixing, we developed a modified Journal Bearing System device [1] for experiments on chaotic mixing silicate melts at high temperature [2]. In this work we focus on preliminary Raman spectra of mixed glasses obtained by mixing two end-members at 1,673K: (i) a peralkaline haplogranite melt (HPG8N5K5), and (2) a haplobasaltic melt corresponding to the 1-atm eutectic composition of the Anorthite-Diopside (An-Di) binary system. These two compositions are intended to act as analogues for natural dry granitic and basaltic magmas. Raman spectra were obtained along two transects along filaments from the resultant glasses, next to the same points analysed for major and trace elements (microprobe and Laser Ablation ICP-MS) [3]. Experimental conditions were kept 'extreme', since most of melt fraction consisted of a high-viscosity melt (95%) and small amounts of lower viscosity mafic melt (5%).

Figure 1: Raman spectra along two transects crossing filaments of mixed haplogranite and An-Di



Results and Conclusion

We observe some changes, in particular the arrows a, b and c show changes in the Raman spectra, and they can link at changes in the polymerization network. Spectra 648 is probably more polymerized than spectra 666 (not shown in Figure 1). This observation is also confirmed for the spectra 670, consisting of the more polymerized melt. Although the changes are still subtle, these point towards changes in the polymerization degree, which are due to differential hybridization of the two stating compositions. For the preliminary results peak-changes vary with the geometry and interaction degree among filaments. Results are consistent with those obtained from microchemical studies along the same lines [3].

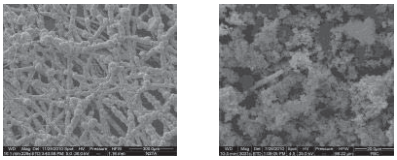
Ingurtosu mine characterization

The Ingurtosu Pb-Zn mine (S-W Sardinia) was in production for about a century until 1968. Huge amounts of tailings were abandoned, resulting in long-term heavy metal dispersion in both stream sediments and waters. Downstream from the mine wastes, the Naracauli waters discharge directly into the Mediterranean Sea. At least two biomineralization processes (Fig. 1) are known to be effective in the abatement of Zn and other heavy metals transported in solution.

In this work, many different techniques were used to study the mineralogy and geochemistry controlling the biomineralization processes. Microbial consortia within biofilm associated with seasonal precipitation of an amorphous mineral made of Si, Zn and O were examined. In addition, the load of metal dissolved in the Naracauli waters was measured using hydrologic tracers with synoptic sampling.

The results presented in this work show that a) the consortium of bacteria changes along the river, creating a cascade of processes that results in biologically mediated formation of different Zn-bearing minerals [1]; b) the changes in water chemistry along the river are moderate for the major constituents, but large changes in trace-element concentrations are observed [2]; c) the heavy metals load derives from the interaction between mine wastes and Naracauli water, and about half of the metal load comes from tributaries with high water flow but relatively low heavy metal concentrations.

Figure 1. SEM images of Naracauli biominerals: hydrozincite on the left, and Zn-Si-O phase on the right.



Conclusion

This work indicates that any remediation plan for the Ingurtosu abandoned mine must take into account the whole Naracauli basin, and water treatment is needed before river water is allowed to discharge to the sea. Finally, biomineralization processes could offer a way for a natural abatement of Zn and some other heavy metals.

Modelling the nucleation of hydroxyapatite at a collagen template

NORA H. DE LEEUW[1]*, N. ALMORA-BARRIOS[1]
[1]University College London, Department of Chemistry, London, UK
n.h.deleeuw@ucl.ac.uk (presenting author)

The biomineral hydroxyapatite nucleates at an organic collagen matrix, which controls the growth process and eventual morphology of the apatite crystallites. An important but largely unresolved issue is the way in which nature controls the nucleation, growth and morphology of the inorganic crystallites and the function of the templating biomolecules, here collagen, in these reactions. However, as it is not yet possible to study directly, by experiment alone, the molecular mechanisms of biomineralisation processes, we have employed a combination of *ab initio* and classical Molecular Dynamics simulations to investigate the early processes of the nucleation of hydroxyapatite at a collagen template, by immersing a triple-helical collagen molecule in a stoichiometric solution of Ca^{2+}, PO_4^{3-} and OH^- ions.

The average number of water molecules in the first hydration shells of the Ca ions and PO_4 groups from the classical MD simulations are all in excellent agreement between with the *ab initio* MD and experiment. Very quickly, a number of stable calcium phosphate (CaP) clusters form in solution, although preferential CaP formation occurs at the collagen matrix.

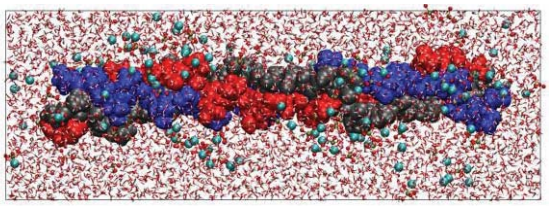

Figure 1: Graphical representation of the collagen triple helix in stoichiometric hydroxyapatite solution.

Electrostatic attractions are prevalent between calcium ions and oxygen atoms of the glycine and hydroxyproline residues, which were the starting point for the formation of the calcium phosphate clusters. At body temperature, calcium ions interact with water molecules to form stable complexes, but attracted by electrostatic forces, they coordinate to PO_4 ions and start forming clusters. Some phosphate ions form hydrogen-bonds with the hydroxy groups of hydroxyproline residues, whereas due to strong water-OH interactions most of the hydroxy ions stay in solution, although some become attached to calcium phosphate clusters. These results agree with suggestions that HA growth follows initial amorphous CaP formation.

Comparison of our results[1] with those of Kawska et al.[2] shows that fluoride ions inhibit calcium phosphate formation by competitively binding the Ca ions into calcium fluoride clusters.

Geochemical modelling of long-term mineral alteration induced by the injection of CO_2 in a saline aquifer: the Ketzin site

MARCO DE LUCIA*, ELISA KLEIN, MICHAEL KÜHN
AND THE KETZIN TEAM
Helmholtz Centre Potsdam, German Research Center for Geosciences - GFZ, delucia@gfz-potsdam.de (* presenting author)

The assessment of expected long-term CO_2-induced mineral alterations of reservoir and cap rock is crucial to ensure the long-term stability of the storage project, and to evaluate the potential carbon trapping provided by mineralization. In the first european on-shore pilot site at Ketzin, nearby Potsdam, Germany, about 60,000 t of CO_2 were injected (as of February, 2012) in a saline aquifer in a Triassic sandstone at about 650 m depth. A rich set of analyses of pristine formation fluids [1] as well as mineralogical and geochemical composition of the reservoir rock [2] made possible a precise parametrization of the reference geochemical model.

Batch 0-D simulations including reaction kinetics were run using the speciation code PHREEQC under the assumption of a constant CO_2 pressure over the simulation time of 5,000 y. The pore pressure itself was found to have a negligible impact on mineral alterations, at least in the considered range of approximately 50 to 80 bar expected for the site. The reference simulation predicts the precipitation of kaolinite, K-feldspar, and plagioclase (represented by the end-member albite) which greatly compensate the partial dissolution of illite, Fe-rich chlorite, and anhydrite cement. Of all carbonate minerals included in the model (siderite, magnesite, calcite, and dolomite), siderite is the only one which precipitates in significant amounts, and thus contributes to mineral trapping. However, the precipitation of carbonates always starts after several hundreds years in the models.

To investigate the robustness of these results, different scenarios were run, each representing a different choice for primary and secondary minerals and different hypothesis for the parametrization of mineral reactive surfaces with respect to the reference model. The simulated results are quite variable, but the simulated total relative change in pore volume after 5,000 years was always below 2%. This can be considered irrelevant in terms of influence on the hydrodynamic properties of the rock. These results are confirmed by the observations from laboratory experiments on core samples exposed to CO_2.

We examine S degassing and S isotope fractionation at basaltic volcanoes using S isotope compositions of scoria and magmatic gases from three active basaltic volcanoes in contrasting tectonic settings: Masaya and Cerro Negro (Central American Arc), and Erta Ale (East African Rift). We present S contents and S speciation of gases and melt inclusions to constrain degassing conditions. An equilibrium isotope fractionation degassing model is used to assess the S systematics considering oxygen fugacity, temperature, and pressure of degassing.

Erta Ale is a reduced system at Δ QFM ~0 [1]. Pristine scoria from Erta Ale have an average $\delta^{34}S$ value of + 0.9 ± 0.3 ‰ (n = 5) and gas samples have $\delta^{34}S$ values of + 0.7 ‰ to -1.9 ‰, spanning the MORB range of + 0.3 ± 0.5 ‰ [2] and extending to lighter values. Synchrotron micro-X-ray Absorption Near Edge Spectroscopy (XANES) analysis of an olivine-hosted melt inclusion from Erta Ale indicates that S^{2-} is the dominant S species in the melt (rather than S^{6+}). High temperature (1086°C) fumarolic gas samples have SO_2 as the dominant S species. Significantly, the scoria are isotopically heavier than the gases, which is the opposite of that expected for equilibrium conditions between S^{2-} in the melt and SO_2 gas because at equilibrium the more oxidized S species retains the heavy isotope. We interpret the low $\delta^{34}S$ values of the gas to reflect a kinetic effect that occurs as S diffuses from the melt into the gas phase (on the bubble scale) that favours the transfer of the light isotope into the gas.

Gas and scoria samples from the oxidized arc volcanoes (Cerro Negro and Masaya; ~ΔQFM +2 [3]) have a range of $\delta^{34}S$ values from + 2.2 ‰ to + 9.3 ‰. Scoria are isotopically heavier than the gases by ~3 ‰ at Masaya and by ~5 ‰ at Cerro Negro. XANES analysis of an olivine hosted melt inclusion from Cerro Negro shows that S^{6+} is the dominant S species in the melt. The negative $\Delta^{34}S_{gas\text{-}melt}$ relationship observed at Masaya and Cerro Negro is consistent with degassing of SO_2 or H_2S from a melt containing S^{6+}. However, equilibrium modelling predicts that the gas should be isotopically lighter than the melt by only 1‰ to 1.7‰ for degassing between 1 bar and 4 kbar (higher degassing pressure favours H_2S over SO_2, resulting in larger fractionation between gas and S^{6+} in the melt). The large $\Delta^{34}S_{gas\text{-}melt}$ observed at Masaya and Cerro Negro can be explained by equilibrium fractionation in addition to a kinetic effect as observed at Erta Ale. In all three cases the compositions of the gases are isotopically lighter than predicted by equilibrium modelling by 2 ‰ to 4 ‰, suggesting a common kinetic effect that favours the transfer of the light isotope into the gas phase.

Ex situ carbonate mineralization: a novel way to sequester CO_2 at the expense of saline wastewater

CATERINA DE VITO[1], SILVANO MIGNARDI[1], VINCENZO FERRINI[1] AND ROBERT F. MARTIN[2]*

[1]Sapienza University, Earth Sciences Department, Rome, Italy, cdevito@uniromal.it
[2] McGill University, Earth and Planetary Sciences, Montreal, Canada, robert.martin@mcgill.ca (* presenting author)

In situ and ex situ technologies based on carbonate mineralization offer ways to insure the permanent and safe storage of this greenhouse gas. In our opinion, both anthropogenically produced CO_2, at a cement plant, for example, and saline wastewaters can be utilized as valuable resources. The brines recovered from desalination operations and produced water associated with oil and gas exploitation are promising sources of alkalis and alkaline earths needed in the carbonation process. Our ex situ approach involves the formation of hydrated carbonate minerals (e.g., nesquehonite, $MgCO_3 \cdot 3H_2O$) at room temperature through the reaction of gaseous CO_2 bubbling in Mg (7 g L^{-1}) wastewater, similar to what is commonly available industrially [1]. The reaction rate is rapid, with carbonate deposition in about ten minutes. We have demonstrated that the method can be efficiently applied to more concentrated solutions, up to 32 g L^{-1} of Mg. The efficiency of the carbonate mineralization process ranges between 65 and 80%, depending on the salinity of the solution [2]. The thermal behavior and structural stability of the nesquehonite precipitate suggest that it will remain stable at the temperature conditions that prevail at the Earth's surface, i.e., below 600 K, the threshold of periclase nucleation [3]. Moreover, our results indicate that if this mineral is left in contact with the simulated brine or heated, it can be expected to transform to other carbonates thermodynamically more stable, up to about 650 K, e.g., dypingite $[Mg_5(CO_3)_4(OH)_2 \cdot 5H_2O]$ and hydromagnesite $[Mg_5(CO_3)_4(OH)_2 \cdot 4H_2O]$. These experimental results also provide information about the fate of secondary carbonates that form in a CO_2 injection environment.

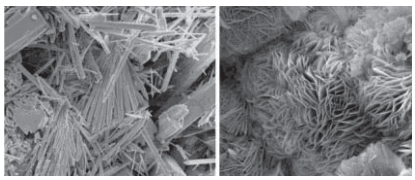

Figure 1: Nesquehonite (left), obtained by direct synthesis, and dypingite (right), obtained by transformation of early-formed carbonate.

The resulting carbonate precipitates formed in our approach can profitably be used in many applications, for example in the production of building materials. Our approach offers a complementary solution to CO_2 abatement in countries where the production of saline waste is significant.

Abstract

Few attention has been given to pre-anthropogenic signals recorded in peat bogs, especially in the Southern Hemisphere. Yet they are important to 1/ better understand the different particle sources during the Holocene and 2/ to tackle the linkage between atmospheric dust loads and climate change and 3/ to better understand the impact of dust on Holocene palaeoclimate and palaeoenvironments in a critical area for ocean productivity.

In this poster, we will present the preliminary results and the main objectives of the PARAD project, which are: 1) to provide high-resolution continuous records of natural atmospheric dust using the elemental and isotopic signature of peat cores from Tierra del Fuego, and 2) to assess the linkage between dust inputs and climate.In this project, we will explore the use of a broad range of trace elements as dust proxies (soil particles, volcanism, cosmogenic dusts, marine aerosols). Radiogenic isotopes (Pb, Nd, Hf) will be used as tracers for fingerprinting predominant sources. Coupling these findings with biological proxies (plant macrofossils, pollen) and detailed age-depth modeling, we expect not only to identify and interpret new links between atmospheric dust chemistry and climate change but also to significantly improve our understanding of peat bogs as archives of climate change, and the role of dust in both palaeoenvironmental and palaeoclimatic changes.

Non-classical pathways of mineralization: Pre-nucleation clusters and oriented attachment

Introduction

Recent investigations of crystallization in the calcium carbonate and phosphate systems have conclusded that classical concepts of crystal growth fail to predict observed pathways of nucleation. These pathways appear to start with pre-nucleation clusters and depend upon particle mediated growth processes that involve amorphous precursors. These conclusions follow upon a body of research documenting aggregation-based growth mechanisms in which primary crystalline particles are found to be co-aligned in the final crystal structure. However, little is known about the formation, structure and energetics of pre-nucleation clusters, and the mechanism by which co-alignment of primary particles occurs has not been established. Here we report results of novel simulations and experiments exploring these phenomena.

Results and Conclusion

Using replica-exchange molecular dynamics techniques previously applied to protein folding, we investigate initial formation and onset of order within hydrated calcium carbonate clusters. The clusters initiate as short linear chains that rapidly evolve into 2D and 3D structures with continued growth. Establishment of order is hindered by incomplete ion desolvation. However, in ~1 nm diameter particles, ordered motifs emerge that resemble the local order within crystalline carbonate phases. The free energy along the simulated growth pathways is currently being calculated to determine whether the clusters are thermodynamically stable or metastable with respect to ions in solution and to predict the free energy barrier that separates the cluster species from supercritical nuclei.

We investigated mechanism of oriented attachment (OA) of iron oxyhydroxide nanoparticles using high-resolution fluid cell TEM. The particles undergo continuous rotation and interaction until they find a perfect lattice match. A sudden "jump to contact" then occurs over < 1nm, followed by lateral atom-by-atom addition at the contact point. Interface elimination proceeds at a rate consistent with the curvature-dependence of the chemical potential. Translational and rotational accelerations show that strong, highly-

Vegetation uptake controlling groundwater solute evolution on a southeast Australian granite

JOSHUA F. DEAN[1,2*], JOHN A. WEBB[1,2], GERALDINE JACOBSEN[3], ROBERT CHISARI[3] AND P. EVAN DRESEL[4]

[1]La Trobe University, Agricultural Sciences, Australia, jf3dean@students.latrobe.edu.au (* presenting author)

[4]Department of Primary Industries Victoria, Australia

Groundwater geochemical signatures are typically considered derived from rock-water dissolution and weathering interactions. However, many major ions (Ca^{2+}, K^{+}, HCO_3^{-}, Mg^{2+}, S, and Si) are essential plant nutrients, and are removed from rainfall, soil-water and groundwater, where soils are depleted in these species. This in turn affects the solute composition of infiltrating water.

Conventional methods [1] of determining relative groundwater solute contributions from specific rock weathering reactions were carried out for a pair of sub-catchments in the Dwyer Granite, southwest Victoria, Australia. This method was adapted for semi-arid, southwest Victoria by standardising all ions to rainfall Cl^{-} to remove the effects of evapotranspiration. While this step is commonly omitted in high rainfall, northern hemisphere studies [2], it is important for the Australian setting, where groundwater solutes are primarily derived from the concentration of rainfall by evapotranspiration [3,4].

In a few groundwater samples in the study area, enrichment with respect to rainfall of Na^{2+} and H_4SiO_4 is ascribed to plagioclase weathering, while SO_4^{2-} enrichment is ascribed to pyrite oxidation, indicating that rock weathering reactions play a role in this setting. However, in most samples, after subtracting rainfall input (as per [1]), there is wholesale depletion of all measured ions. This prevents the use of the plagioclase, biotite and k-feldspar chemical weathering reactions in the mass-balance, as these release cations (Na^{2+}, K^{+}, Mg^{2+} and Ca^{2+}), all of which are depleted in the groundwater with respect to rainfall.

This ion depletion is not due to mineral precipitation as neither geochemical modelling nor X-ray diffraction analyses show evidence of this occuring. Nor is it due to ion exchange as there is no balancing import of ions or significant acidification of the groundwater. Having already ruled out evapotranspiration effects through Cl^{-} standardisation, the depletion is instead attributed to vegetation uptake, which has been identified as a significant process elsewhere in the region [5], causing depletion of recharge solutes.

Abstract

The lithium isotope system holds great allure as a tracer of recycled subducted materials in the Earth's interior, owing to the striking isotopic contrast between lithium at the Earth's surface and that in the mantle, combined with the presence of Li at measurable quantities in mantle minerals. Unfortunately, measurements of lithium isotope ratios in mantle xenoliths have proven difficult to interpret. Mantle xenolith data compiled from samples worldwide have revealed that lithium elemental and isotopic distribution between olivine and clinopyroxene is highly variable. At high temperatures such as those found in the mantle, the isotopic fractionation factor $\alpha_{ol/cpx}$ $[=(^7Li/^6Li)_{ol}/(^7Li/^6Li)_{cpx}]$ is expected to approach 1, and experimental constraints on equilibrium partitioning show that the partition coefficient ($D^{Li}_{ol/cpx}$) is between 1.5-2. Many xenolith samples exhibit equilibrium behavior with respect to both isotopic fractionation and equilibrium partitioning, but some samples do not. Xenoliths with apparent $D^{Li}_{ol/cpx} < 1$ trend toward isotopically lighter Li in clinopyroxene relative to olivine, with $\Delta^7Li_{ol\text{-}cpx}$ $[=\delta^7Li_{ol} - \delta^7L_{cpx}]$ ranging from 3 - 25‰. A physical process explaining this relatively extreme isotopic fractionation between co-existing mantle phases has yet to be satisfactorily demonstrated. One proposed hypothesis to explain the apparent Li isotopic disequilibrium in mantle xenoliths is that upon exhumation, closed system redistribution of Li between mantle minerals occurs as a function of cooling, meaning the partition coefficient is temperature dependent. Richter et al. (2003) have shown potential for considerable kinetic isotopic fractionation of Li during diffusion. Thus if Li is redistributed under dynamic conditions preceding or concurrent with eruption, kinetically driven isotopic fractionation might be "locked in" to the mantle minerals upon reaching closure conditions. We have conducted a series of piston cylinder experiments at 1.5 GPa and 700-1100 ˚C, the results of which show that $D^{Li}_{ol/cpx}$ is 2.0 ± 0.2 regardless of temperature over this range. It seems that a new explanation is needed to explain the Li signature in mantle xenoliths. Mantle olivine contains some amount of iron (~10% FeO*), and the ambient $fO2$ controls the relative amount of Fe^{+2}/Fe^{+3}. Variation in the amount of Fe^{+3} could potentially influence the incorporation of Li^{+} into the octahedral site of olivine by providing a charge-balancing mechanism. This could allow for a redistribution and isotopic fractionation of Li in response to changing fO_2. Experiments at 900°C and 1.5 GPa with solid state fO_2 buffers of Re-ReO, Ni-NiO, and Mo-MoO are currently underway to determine whether oxygen fugacity plays a role in controlling Li partitioning.

The progressive μ^{142}Nd decrease in early Archean rocks from +20 to 0 between 3.9 to 3.6 billions years (Gyr), with rocks younger than 3.5 Gyr showing no μ^{142}Nd anomalies, is thought to indicate the efficient remixing of the first primitive crust into the Archaean convecting mantle that ultimately produce a well-mixed present-day convecting mantle with μ^{142}Nd = 0 [1]. The implied long mixing time of ~1 Gyr from the Hadean to Archaean for the whole mantle is paradoxical on several levels. This is much longer than the rapid mixing time (<100 Myr) inferred for the Archean due to vigorous mantle convection related to Earth's hotter thermal regime [2], and similar to the mixing time inferred for the present-day Earth's mantle [3].

Here we report a resolvable positive ^{142}Nd anomaly of μ^{142}Nd = +7 ± 3 ppm relative to the modern convecting mantle in a 2.7 Gyr old tholeiitic lava flow from the Abitibi Greenstone Belt in the Canadian Craton. Our result effectively extends the early Archean convective mixing time to ~1.8 Gyr, i.e. even longer than present-day mantle mixing timescale [3], despite a more vigorous convection expected in the Archean. Different hypotheses have been examined to explain such a protracted mixing in the Archean, such as mantle overturn, two-layer convection or the existence of a dense layer at the bottom of the mantle. We postulate that the requirement of a delayed mixing in a strongly convective mantle is best explained by long periods of stasis in the global plate system, with scarce episodes of subduction throughout the Hadean and Archean [4].

Our numerical model confirms that in absence of continuous plate tectonics, the convective mantle mixing is relatively inefficient in erasing the chemical heterogeneities inherited from the primordial differentiation of the early Earth. This constrains the tectonic regime of the Hadean and Archean to a stagnant-lid regime with episodic subduction. In this case, the timing for the onset of continuous modern plate tectonics can only occur shortly before or after 2.7 Gyr.

The effect of aqueous organic ligands on forsterite dissolution rates

JULIEN DECLERCQ[1*], OLIVIER BOSC[2], ERIC H. OELKERS[2]

[1]Geoscience environnement Toulouse (GET), Toulouse, France, declercq@get.obs-mip.fr (* presenting author)
[2]GET, Toulouse, France, bosc@get.obs-mip.fr
[3]GET, Toulouse, France, oelkers@get.obs-mip.fr

Forsterite is an abundant mineral which reacts exothermically with CO2 to form secondary minerals including carbonates. As such it is viewed as the most promising source material for the divalent metals required for mineral carbonation [1]. Mineral carbonation could potentially be accelerated if catalyses that accelerate forsterite dissolution can be identified. This study was initiated to determine if common aqueous organic ligands can accelerate forsterite dissolution rates. Aqueous organic species have long been considered as potential catalyses for enhancing silicate mineral dissolution rates (e.g. [2], [3]).

Forsterite dissolution rates were measured at 25 ºC in 10-2 M NaCl using mixed-flow reactors as a function of pH and concentration of 13 organic ligands (acetate, alginate, oxalate, Na-glutamate, citrate, EDTA, L-glutamic, humic, malic, malonic salicylic, tartaric and L-aspartic). Stoichiometric dissolution was observed. Selected measured dissolution rates as a function of organic ligand concentration is presented in figure 1.

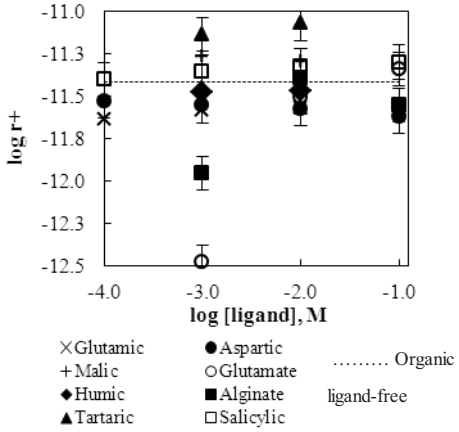

Figure 1: Summary of pH 3 olivine steady-state dissolution rates as a function of ligand concentration.

As depicted in Fig. 1, aqueous organic ligands in general have weak effects on pH 3 forsterite dissolution rates. Humic, salicylic and aspartic acid have no detectable effect on these rates, while the tartaric and malic acid decreases these rates.

Overall, results of this study demonstrate that organic ligand do not affect sufficiently forsterite dissolution rates at mildly acidic conditions. As these pH conditions likely to be characteristic of the fluids at carbon storage sites due high CO2 pressure carbon storage, it seems likely that organic additives will not accelerate substantially forsterite carbonation.

Crustal versus source processes on the Northeast volcanic rift zone of Tenerife, Canary Islands

DEEGAN, F.M.[1*], TROLL, V.R.[2], BARKER, A.K.[2], HARRIS, C.[3], CHADWICK, J.P.[4], CARRACEDO, J.C.[5], AND DELCAMP, A.[6]

[5]Dept. de Física, Universidad de Las Palmas de Gran Canaria, Spain
[6]Dept. Geography, Vrije Universiteit Brussels, Belgium

The Miocene-Pliocene Northeast Rift Zone (NERZ) on Tenerife is a well exposed example of a major ocean island volcanic rift. We present elemental and O-Sr-Nd-Pb isotope data for dykes of the NERZ with the aim of unravelling the petrological evolution of the rift and ultimately defining the mantle source contributions.

Fractional crystallisation is found to be the principal control on major and trace element variability in the dykes. Differing degrees of low temperature alteration and assimilation of hydrothermally altered island edifice and/or sediments elevated the primary $\delta^{18}O$ and the Sr isotope composition of many of the dykes, but had little to no discernible effect on Pb isotopes. Minor degrees of sediment contamination, however, may be reflected in the Pb isotope composition of a few samples that plot to slightly higher $^{207}Pb/^{204}Pb$ values.

Once the data are screened for alteration and shallow level contamination, the underlying isotope variations of the NERZ reflect a mixture essentially of Depleted Mid-Ocean Ridge-type Mantle (DMM) and young High-μ (HIMU, where $\mu = {}^{238}U/{}^{204}Pb$)-type mantle components. Furthermore, the Pb isotope data of the NERZ rocks ($^{206}Pb/^{204}Pb$ and $^{207}Pb/^{204}Pb$ range from 19.591-19.838 and 15.603-15.635, respectively) support a model of initiation and growth of the rift from the Central Shield volcano (Roque del Conde), consistent with latest geochronology results [1]. The similar isotope signature of the NERZ to both the Miocene Central Shield volcano and the Pliocene Las Cañadas central edifice suggests that the central part of Tenerife Island was derived from a mantle source of semi-constant composition through the Miocene to the Pliocene. This can be explained by the presence of a discrete "blob" of HIMU material, ≤ 100 km in vertical extent, occupying the melting zone beneath central Tenerife throughout this period. The most recent central magmatism on Tenerife appears to reflect greater entrainment of DMM material, perhaps due to waning of the blob with time.

Uranium mineralogy and factors of stability in the mill tailings of the COMINAK mine at Akouta (Niger)

ADRIEN DEJEANT[1,2*], LAURENCE GALOISY[1,2], GEORGES CALAS[1], NICOLAS MENGUY[1], VANNAPHA PHROMMAVANH[3] AND MICHAEL DESCOSTES[3]

[1]Institut de Minéralogie et de Physique des Milieux Condensés, Université Pierre et Marie Curie, Paris, France, dejeant@impmc.upmc.fr ([*]presenting author), calas@impmc.upmc.fr, menguy@impmc.upmc.fr

[3]AREVA, BG Mines, R&D, Paris la Défense, France, vannapha.phrommavanh@areva.com, michael.descostes@areva.com

The world's largest uranium underground mine, at Akouta (Niger), has been mined for more than 30 years. Since that time, around 14 million tons of mill tailings were accumulated on site. After the processing of the ore, with an extraction process efficiency reaching ~95%, some U is left within the mill tailings. Some U reconcentrations may be observed in the storage heap, pointing out potential migrations. This study aims at an assessment of U mobility for revaluating/rehabilitating mill tailings stored in heaps and preventing any U releases in the environment.

The ore deposit occurs in continental lower Carboniferous sandstones, containing quartz and feldspar with detrical clays and organic matter. Pitchblende is associated with minor coffinite, U-Ti and U-Mo oxides, with an average U concentration of 4‰ associated to trace metals (V, Zr, Mo…). Ore processing is based on an oxidative dissolution in sulfuric acid. As a result, a gypsum-indurated duricrust is formed at the upper surface of the tailings heap, referred to as a gypscrete crust.

Gypscrete samples were analyzed using different mineralogical methods: SEM, TEM, electron microprobe, XRD and cathodoluminescence. Micrometer-size U-bearing phases are observed: UO_2, U-Ti oxides (brannerite-type) and secondary phases such as uranyl phosphates. At the nanometer scale, supposedly neoformed U phases are associated with clay minerals, together with evidence of U sorption.

Brannerite-type minerals are most likely inherited from the ore, as they are more resistant than uraninite to the process. Such as UO_2 included in quartz grains, they appear as stable hosts for U. The main source of U^{VI} may rather come from more accessible U-rich phases which have suffered from oxidation and solubilization. The formation of secondary U minerals, in association with U sorption on clay minerals, may delay U^{VI} transport. The comparison of ore samples with their associated tailings sampled before their storage, provides complementary data on the processes governing U mobility.

Monitoring dynamics of species and adsorption reactions at the corundum-oxalate-solution interface by *in situ* ATR-FTIR spectroscopy

MIRELLA DEL NERO[1*], CATHERINE GALINDO[1], GUILLAUME BUCHER[1] AND REMI BARILLON[1]

[1]Institut Pluridisciplinaire Hubert Curien, UMR 7178 UdS/CNRS, Strasbourg, France
mireille.delnero@iphc.cnrs.fr (* presenting author)

Introduction

We addressed the molecular level description of the interactions occurring at low pH between oxalate ions and the surface of corundum colloids, for oxalate in the low concentration range relevant to freshwater (1-50µM). We monitored the dynamics of species at the corundum- solution interface during the oxalate sorption process by using a highly sensitive technique, namely Attenuated Total Reflectance – FTIR spectroscopy, joint to a method of layer deposition of corundum particles on the ATR crystal [1-3].

Results and conclusion

Examining changes in IR spectra during the oxalate sorption process, for frequency regions characteristics of oxalate, surface hydroxyls and ClO_4^- electrolyte ions, has revealed the existence of two types of sorption mechanisms dependent on the oxalate concentration.

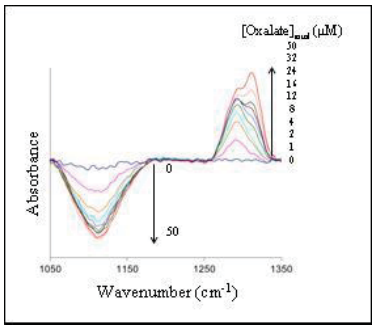

Figure 1: In situ ATR-FTIR monitoring of the corundum-solution interface during gradual increase of $[Ox]_T$ at pH 4.7, 0.01M $NaClO_4$.

In the trace level concentration range, the uptake of oxalate is accompanied by removal of ionisable surface hydroxyls and weakly adsorbed ClO_4^-. This is direct spectroscopic evidence that a reaction of surface ligand exchange controls the oxalate sorption. The other sorption reaction involves no surface hydroxyls or counter-ions and it exists in a wider range of oxalate concentration, indicating weak sorption of hydrated oxalate via H-bonds. Our study suggests that the sorption of oxalate at the trace level influences surface reactivity and charge of oxides in soils, as well as colloid aggregation and mobility.

Laser spectrometry for tracing evaporation in a Mediterranean wetland (Rhône delta, France)

HÉLÈNE DELATTRE[1], CHRISTINE VALLET-COULOMB[1*], AND CORINNE SONZOGNI[1]

[1]CEREGE, CNRS, Aix-Marseille Université, Aix en Provence, France,
delattre@cerege.fr,
vallet@cerege.fr (* presenting author),
sonzogni@cerege.fr

Context

Evaporation from wetlands may contribute significantly to local atmospheric moisture, and may thus provide an additional water source to regional precipitation. In the context of global change, the distribution of wetlands is expected to vary, making necessary to better understand the influence of wetlands on climate. Isotopic tracing ($\delta^{18}O$, δD) is an efficient tool for detecting the contribution of local vapor to the atmospheric component of the water cycle, because the fractionation that occurs during evaporation induces a modification of the deuterium excess [1].

Results and conclusions

We performed continuous measurements of the isotopic composition of the atmospheric vapor during summer 2011, near a lagoon located in the Rhône delta, using wavelength-scanned cavity ring-down spectrometer (WS-CRDS). Calibrations were regularly performed with 3 different water compositions, and for mixing ratio varying between 4 to 33 g/kg. Linear calibration results were obtained, except for mixing ratio higher than 25 g/kg. Laser spectrometer measurements were compared to atmospheric vapor samples collected by cryogenic trapping (65 samples). The difference between results from the two methods was acceptable for $\delta^{18}O$ (±0.36‰ on average), while the laser spectrometer slightly overestimated δD, by 4.3‰ on average. Based on hourly-averaged time series, we evidenced a clear difference in deuterium excess between day-time and night-time data (Figure 1), resulting from the influence of local evaporation. Further work is under way to elucidate the shift in deuterium measurements. Preliminary attempts for a quantitative interpretation of deuterium excess variations in terms of evaporation fluxes [2] will be discussed at the meeting.

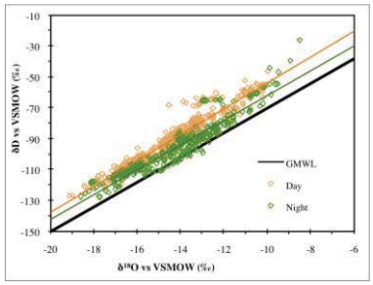

Figure 1: Isotopic composition of atmospheric water vapour between 2011/07/19 and 2011/08/13. Data are hourly averaged. Solid lines represent linear regressions (orange: $\delta^2H=8.3x\delta^{18}O+30.1$; green: $\delta^2H=8.0x\delta^{18}O+18.5$), with the Global Meteoric Water line in black.

Fissured karst aquifers are vulnerable resources that react very sensitive to the dynamics of recharge events

The description of water and tracer flow in fissured aquifers and recharge event integration are generaly roughly depicted. In fact, there are characterized by multiple water transit velocities ranging from fast flow through fissured network to slow water infiltration in porous media.

An experimental field site located in French Burgundy under a topographic hill with well recognized boundaries has been monitored in-situ (head, temperature, conductivity, discharge flow), continously sampled for stable isotopes and major ion analyses on several sites (springs and boreholes) since two years. This long time monitoring allow us both to define baselines and discuss the impact of recharge events on groundwater dynamics.

The tracers $\delta^{13}C$, ^{14}C, $\delta^{2}H$, $\delta^{18}O$ and major chemical constituents have been used to describe the temporal response of the water flow through the unsaturated zone. The geochemical signals have been monitored at different levels of the system (precipitation, boreholes and springs) during several rainfall events. The preliminary results highlight a wide distribution of transit velocities during a recharge event.

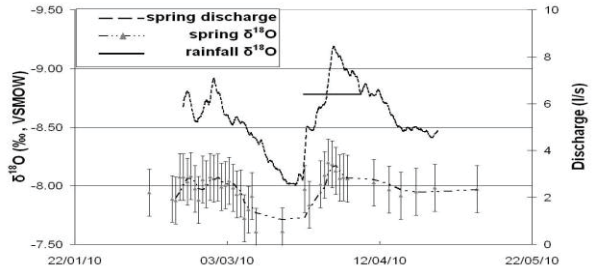

Figure 1: Times series of discharge and $\delta^{18}O$ at R14 spring.

Specific velocities or residence times of the different reservoirs as determined by recharge event characterisation, can be supported by tracers as ^{85} Kr, ^{39}Ar, ^{3}H, ^{3}He, CFCs, SF6 [1]. A recharge event will be monitoring (February 2012) on 2 springs and 1 boreholes. Tracers will allow to realize a geochemical deconvolution and to obtain the water residence times in the fractures and the matrix of this fissured aquifer.

Biogeochemical dynamics related to seasonal changes and biomass-density patterns in rhyzosphere sediments of a *Zostera noltii* meadow

MARIE LISE DELGARD[1*], BRUNO DEFLANDRE[1], EMERIK KOCHONI[1], FLORIAN CESBRON[2], GUILLAUME BERNARD[1], CELINE CHARBONNIER[1], DOMINIQUE POIRIER[1], SABRINA BICHON[1], EDOUARD METZGER[2], JONATHAN DEBORDE[1], AND PIERRE ANSCHUTZ[1]

[2] Univ. d'Angers, UPRES EA 2644, BIAF, Angers, France

This study was conducted in the Arcachon bay that shelters the largest *Zostera noltii* meadow in Europe [1]. A severe but non-homogeneous decline of this meadow coverage has been recently observed. In this context, we investigated seasonal changes and short-scale spatial variability of sediment biogeochemistry in a tidal mudflat of this lagoon colonized by a stable eelgrass meadow. Cores were collected at low tide on vegetated and unvegetated sediment over an annual cycle from autumn 2010 to summer 2011. Additional sediment cores were collected along a density-biomass gradient of seagrass in autumn and summer. Concentrations of major redox species were measured in sediment porewaters. In sediment solid-phase, two reactive fractions of Fe and P were extracted. Total oxygen fluxes were determined under light and dark conditions and used to calculate the benthic gross primary productivity (GPP).

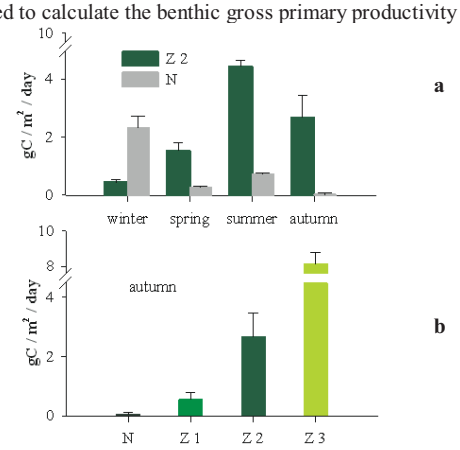

Figure 1: Daily GPP calculated for vegetated (Z) and unvegetated sediments (N) over an annual cycle (**a),** and in autumn 2010 (**b**) along a density-biomass gradient of *Z. noltii* (Z1 to Z3) (*n=4 - 6*).

Some redox species such as dissolved iron did not show significant seasonal changes and along the biomass gradient. For other parameters, e.g. DIP or GPP, the variability observed along the biomass gradient was higher than the one observed between seasons (Fig.1). Results suggest that the effect of seagrass on sediment biogeochemistry can be strongly dependent on the plant biomass, which highly vary with seasons but also on short and large space scales. Hypothesis to explain how this component influences the biogeochemistry of superficial sediments are proposed.

The record of human impact in the sedimentary record at *Portus*, the harbor of ancient Rome

H. DELILE[1, 2]*, J. BLICHERT-TOFT[2], J.-P. GOIRAN[3], J.-P. BRAVARD[1] AND F. ALBAREDE[2]

[1]Université Lumière Lyon 2, 69676 Bron, France
(*correspondence: hdelile@gmail.com)
[2]Ecole Normale Supérieure de Lyon, 69007 Lyon, France
[3]CNRS – UMR 5133 Archéorient, 69365 Lyon, France

The present study focuses on the analysis of palaeo-pollutions and the sedimentary environments in which they were trapped in the Roman *Portus* harbor. *Portus* received heavy-metals pollution both from local foundries, fulling, and tanning and from distal upstream development in Rome. Rome wastewaters, which accounted for up to 3 percent of the total Tiber discharge, were forwarded to *Portus* through a network of canals (*Canale Romano* and *Canale Trasverso*) connecting the river to the sea. In this manner, harbor basins accumulated both allochthonous and autochthonous heavy metals.

We determined major and trace element concentrations as well as Pb isotope compositions in a high-resolution set of samples from sediment cores recovered in the *Portus* area. Principal component analysis of elements that are less prone to the influence of human activities, such as Ca, Mg, Mn, Zr, K, Al, Ti, Na, Sr, and Mn, was used in conjunction with metallic elements to break down the sedimentary load into local and regional components.

The record of Pb concentrations and isotopic compositions reveals an overall general trend on which other signatures are superimposed. The geochemical background of the Tiber catchment (24.7-26.2 ppm Pb and $^{206}Pb/^{207}Pb$ ~ 1.198) represents geologically young (model age T_m <50 Ma) Pb derived from natural runoff over young sediments and volcanics in the Latium. From the 1st century AD to the end of the roman period, the harbor regime evolved from a dominant fluvial (enriched in Al, Ti, Mg, K, and Zr) to a more marine influence (high Ca/Mg, Na/Al, Sr, and $CaCO_3$) in the upper part of the harbor unit. "Imperial" Pb (90.5-35.4 ppm Pb and $^{206}Pb/^{207}Pb$ ~ 1.187-1.192) requiring the prevalence of Hercynian (T_m >200 Ma) Pb, probably imported from central or northern Europe, gets progressively diluted with time. The transition from the roman to the medieval period is characterized by a closed environment (high Ca/Mg, Na/Al, Sr, and $CaCO_3$) with a spike of unradiogenic $^{206}Pb/^{207}Pb$ (~ 1.184). Either an alluvial plug formed, which blocked fresh water entry into the harbor from the *Canale Trasverso*, or the harbor burned, causing melting of the ancient waterworks. Finally, the upper part of the sediment cores consists of overflow deposits enriched in Al, Ti, K, Mg, and Mn associated with the return of the pre-anthropogenic geological background (18.9-28.2 ppm Pb and $^{206}Pb/^{207}Pb$ ~ 1.196-1.201). In this post-roman sedimentary unit pollution signatures shift to a mix of heavy metals dominated by Co, Cr, Ni, and Zn, whereas during the roman period elements such as Pb, As, Fe, Cu, and Sn were predominant.

The fractionation of Lithium isotopes during continental weathering: clues from the Amazon and Mackenzie rivers

M. DELLINGER[1*], J. GAILLARDET[1], V. GALY[2], P. LOUVAT[1], J.-L. BIRCK[1], J. BOUCHEZ[3]

[1]IPGP- Géochimie et Cosmochimie, 75238 Paris, France

[2]Woods Hole Oceanographic Inst., Woods Hole, MA 02543, USA
[3]GFZ (German Centre for Geosciences), 14473 Potsdam, Germany

Numerous studies on river systems have shown that Lithium isotopes are fractionated during chemical weathering as ^6Li is preferentially retained in solid secondary phases whereas dissolved fractions are enriched in ^7Li. In this study we investigate the Li isotope composition of Suspended Particulate Matter (SPM) and bedload transported in two of the largest world river systems having drastically differing climate conditions: Amazon and Mackenzie rivers. In order to separate the effects of hydrodynamic sorting and chemical weathering, Li isotope were measured along river depth profiles to capture all the SPM grain size variability.

We find that Li content and isotope composition display a strong variability in relation with grain size within a single water column in both Amazon and Mackenzie Rivers. Li content in SPM increases by a factor up to 3 from coarse (river bed) to fine (channel surface) particles, ranging from 30 to 90 ppm. All bedloads and SPM samples have Li/Al molar ratios higher that of the mean Upper Continental Crust (UCC), despite the fact that 10 to 20% of total Li in both rivers is transported in the dissolved load.

River sediments Li isotopic composition (δ^7Li) ranges between -3.5 to 5‰ and displays an inverse relationship with grain size. δ^7Li is also well correlated (R^2>0.9) to the weathering index Na/Al, further illustrating the fact that weathering products are isotopically fractionated toward low light δ^7Li values. Amazon river-sediments δ^7Li values are more than 1‰ lower than those of the Mackenzie for a given Na/Al value. We interpret these relationships between Li content, δ^7Li, Na/Al and grain size as a binary mixing between a coarse-grained, relatively Li-poor, high δ^7Li component (δ^7Li~5‰) and a fine end-member having low δ^7Li and high Li concentrations. The low δ^7Li value of the fine component could be the result of either present day light-Li co-precipitation/adsorption into secondary minerals or of the recycling of fine-grained silicate sedimentary rocks or a combination of both processes. These results have important implications for establishing global mass budgets of erosion and for using lithium concentrations and isotopes as a tracer of sedimentary recycling.

Introduction

Kerguelen basalts contain abundant mantle xenoliths, including mantle peridotites and deep magmatic segregates equilibrated in the granulite facies [1]. Lithium chemical and isotopic distribution were measured in two-pyroxene granulites in using the Cameca IMS 1270 Ion probe at CRPG, in order to define their signature and describe the Li behavior during the lower crust formation process.

Samples description

The studied xenoliths display close mineralogical compositions, bearing Mg81-92 Al-diopside, Mg-78-93 enstatite and labradorite or bytownite. Spinel and garnet are observed in 2 of them, and they all are type II xenoliths [1,2]. The xenoliths range along a regular magmatic cristallisation trend, with decreasing Mg content.

Li and δ^7Li distribution

On the whole rock scale the Li contents increase from 1,5 up to 9 ppm, following the cristallisation trend with the Li content increasing during the cristallisation. At the sample scale Li contents is higher in Cpx compared to Opx and to plag, with a ratio Opx/Cpx of 0.8-0.9 and a ratio Plag/Cpx of 0.2-1. At the grain scale, Li displays an homogeneous distribution in most minerals, at the exception of few depleted or enriched Cpx rims.

The δ^7Li values measured on Cpx and Opx range in between -9 and +20, normalized to lsvec . The Cpx Li depleted rims display enriched δ^7Li values, associated to Li diffusion isotopic fractionation. Most xenoliths display relatively homogenous δ^7Li distibution, with only few per mil scatters, and only one Li poor xenolith display δ^7Li values scattered on a large range, from -9 to +14. A general observation is that Cpx display higher δ^7Li values than Opx (+2 to +3 ‰), and that the values are more scattered in Opx than in Cpx. There is positive correlation between the Li contents and the δ^7Li values, both at the mineral and whole rock scales, pointing out a melt-mineral isotopic fractionation for Li, with the melt being enriched in ^{7}Li compared to the residue.

Conclusions

The bulk value for these granulite samples is in agreement with a direct derivation from the mantle (5-8 ppm, d^7Li≈+5), but at the sample scale, Li content and Li isotopic composition is strongly dependent on the melt-solid fractionation during crystallization in the granulite facies. The large scatter observed on the Li poor sample could result from the partial re-equilibration of this early formed granulite with late enriched fluid.

Weathering conditions in the Mesoarchean are poorly constrained. Recent studies have shown that neoformation of secondary clay minerals are associated with large Si isotope and Ge/Si fractionation in response to desilication processes and the weathering degree [1, 2, 3, 4]. Here, we present the first application of these weathering proxies on a 2.95 Ga paleosol profile and coeval shales. The paleosol is developed on andesite and shows a well defined mineralogical and chemical differentiation. δ^{30}Si values are lighter (down to -0.44‰) and Ge/Si values higher (up to 3.2µmol/mol) than parental andesite values (-0.14‰ and 2.1µmol/mol, respectively). Such trends support the formation of secondary minerals that preferentially incorporate light Si isotopes and Ge relative to Si, as observed during modern weathering [1, 2, 3, 4, 5]. However, less pronounced fractionation relative to modern soils with neoformation of kaolinite can be potentially explained by mineralogical control on δ^{30}Si with the formation of Fe-rich smectite, reported with heavier Si isotope composition than kaolinite [6]. In contrast, the top of the paleoprofile shows a return to heavier δ^{30}Si values (up to -0.11‰) and lower Ge/Si ratios (down to 1.1µmol/mol). This may be explained by a preferential release of light Si isotopes and Ge during partial dissolution of Fe-rich smectite to form kaolinite. This transformation is thought to have been governed by drainage conditions with fast drainage favoring kaolinite, implying moderate rainfall and/or poor-drainage conditions during weathering. In addition, we demonstrate that the combination of δ^{30}Si and Ge/Si tracers in 2.95 Ga Archean shales can reflect the relative proportions of primary rocks and secondary minerals. Moreover, a kaolin-rich or -poor nature of secondary clays can be evaluated. Therefore, combining δ^{30}Si and Ge/Si ratio as paleoweathering tracers opens new perspectives in quantifying Archean superficial weathering dynamics with potentially important paleoclimatic implications.

[3]LMV, Clermont-Ferrand, France, J.L.paquette@opgc.univ-bpclermont.fr

During the Late Cretaceous and Paleocene, intense magmatic activity along the Toquepala arc resulted in the building of a continuous relief along the Peruvian margin. This arc growth coincided with the only known significant uplift along coastal southern Peru [1] and can thus be considered to have been a major factor in this uplift.

Our study has focused on a batholith segment extending in the Arequipa area over 60x40 km for a ≥7 km thickness. We confirm that granitoids were emplaced mainly between 90 and 60 Ma, into the Proterozoic basement, a dominantly mafic Liassic (200-175 Ma) plutonic suite, and Jurassic strata. The Late Cretaceous–Paleocene suite consists of numerous plutons, dykes and sills with compositions varying from gabbro to granite.

We analysed trace elements, and Sr and Nd isotopic ratios on a collection of 100 samples principally located along 3 cross-sections of the batholith. The obtained geochemical compositions are in good agreement with data available from the literature [2]. Given the large lithological range, covering a wide spectrum of chemical compositions, Rb-Sr systematics was used to identify two magmatic suites. Samples represent either the Liassic or the Late Cretaceous-Paleocene suite, which are easily distinguished in a Rb-Sr isochron plot. Samples plotting along the 60 Ma isochron were separated and their measured $^{87}Sr/^{86}Sr$ isotopic ratios were used to determine LLD (liquid lines of descent) for gabbro-granite series within the batholith. Using $^{87}Sr/^{86}Sr_m$ as an indirect proxy for fractional crystallization, we propose a simple but powerful method to estimate the nature and compositions of primitive magmas in a plutonic environment.

These results are critical to estimating crustal growth and thickening in the Arequipa area. They will also be analysed in terms of magmatic flux for a better understanding of the mantle vs. crustal contribution to Andean arc magmatism.

Unravelling glacial sediment provenance through soil chemistry in the north of Ireland.

MICHAEL DEMPSTER[1*], PAUL DUNLOP[1], ANDREAS SCHEIB[2], AND MARK COOPER[3]

[1]School of Environmental Sciences, University of Ulster, Coleraine, Northern Ireland, dempster-ml@email.ulster.ac.uk (* presenting author)
[2]British Geological Survey, Keyworth, England, ascheib@bgs.ac.uk
[3]Geological Survey of Northern Ireland, Belfast, Northern Ireland, mark.cooper@detni.gov.uk

Background and method.

Reconstructing palaeo-ice sheets provides important information on how they respond to and drive climatic changes over long timescales. Traditional approaches to reconstructing palaeo-ice sheets rely heavily on geomorphological evidence. However, recent work on ribbed moraines [1] and drumlins [2], which are used to reconstruct ice flow direction, major ice flow pathways and drainage conduits, indicates that using geomorphology alone can potentially produce misleading results if small areas are investigated. Furthermore, ascertaining ice flow direction in regions where no bedforming events have occurred can present difficulties. An alternative approach to investigating former ice flow direction is to use geochemistry to determine glacial sediment provenance, from which transport direction can then be established.

This study presents results from the first regional geochemical investigation of glacial sediment provenance in Ireland using soils developed in areas of till superficial geology. The soil samples were gathered as part of Geological Survey of Northern Ireland's Tellus survey [3] which collected soil samples at a density of 1 sample per $2km^2$ accross all of Northern Ireland. The Tellus samples were supplemented by an additional 81 samples taken at a density of approximately 1 sample per $4km^2$ around the margins of the Tellus survey where no previous sampling had occurred. Bulk geochemistry was determined by X-ray Fluorescence from which 28 lithophile and rare earth elements were selected. Principal Component Analysis (PCA) was then applied to these elements using 3917 soil samples from across the entire region. PCA is a variable reduction procedure that allows groups of elements to be identified, and is used here to infer underlying till geochemistry. Since till geochemistry is a product of its parent materials, the PCA groupings can aid identification of the original bedrock source and thus the sediment provenance and ice transport direction.

Results and conclusion.

The results show that most till deposits in the study area are closely related to local bedrock, with changes of geochemical composition occurring across lithological boundaries. This suggests that the majority of tills have been locally derived and that till transport in this sector of the British-Irish Ice Sheet was low, with rapid comminution and low evacuation rates of entrained debris.

Controls on seawater ^{231}Pa, ^{230}Th and ^{232}Th concentrations along the flow path of major deep-water masses in the Southwest Atlantic

FEIFEI DENG[1*], ALEX L. THOMAS[1], GIDEON M. HENDERSON[1] AND MICHA J.A. RIJKENBERG[2]

[1]Department of Earth Sciences, University of Oxford, Oxford, OX1 3AN, United Kingdom (*feifei.deng@earth.ox.ac.uk)

12b. Pa and Th distributions in the ocean: controlling mechanisms

Pa-231 and ^{230}Th are naturally occurring radionuclides in the ocean, produced through the α-decay of dissolved U. Once produced, the two radionuclides are adsorbed onto particles and removed from seawater as the particles settle to the sediment. Due to its higher particle reactivity, ^{230}Th is readily removed from seawater once produced, while less particle-reactive ^{231}Pa can be advected by deep ocean circulation to high-productivity areas to be subsequently removed. Therefore, a fractionation between ^{231}Pa and ^{230}Th takes place in seawater, making the ^{231}Pa/^{230}Th ratio a potential water-mass proxy to reconstruct past ocean circulation. However, factors such as particle flux and composition also play a part in the oceanic distribution of ^{231}Pa and ^{230}Th. To make use of ^{231}Pa/^{230}Th as a paleo-circulation tracer therefore requires a thorough understanding of the controls on the distribution of the two nuclides in seawater. Despite a growing knowledge of water-column ^{231}Pa and ^{230}Th concentrations, rather little is known about the distribution of the nuclides in the South Atlantic Ocean. This basin has recently been the focus of down-core ^{231}Pa/^{230}Th records [1], but is characterised by a more complex pattern of deep-water circulation than the North Atlantic, with multiple water masses flowing in different directions.

In this study, we present high-resolution dissolved ^{231}Pa, ^{230}Th and ^{232}Th data for twelve profiles in the Southwest Atlantic collected during GEOTRACES cruise GA02s (JC057) in March, 2011. The data capture all the main Atlantic water masses along their meridional flow paths and cross a gradient of productivity and dust input. Concentrations of dissolved ^{230}Th range from 0.0060~1.27 dpm/1000l and show a nearly linear increase with increasing water depth as a result of reversible scavenging process [2]. Concentrations of dissolved ^{231}Pa range from 0.0094~0.37 dpm/1000l and show an increase with depth in the upper water column with more variable concentrations at depth. ^{231}Pa/^{230}Th ratios characterise the three deep water-masses (AAIW, NADW, AABW) and show an evolution along flow paths. There is, however, also an obvious decrease in ^{231}Pa/^{230}Th near the equator, potentially due to higher productivity in this region. We will discuss the impact of these observations on the use of ^{231}Pa/^{230}Th to assess past ocean circulation. Concentrations of ^{232}Th are low but appear to provide information about detrital inputs to the region from dust and from the Rio Plata.

[3]Key Laboratory of Nuclear Techniques in Geosciences, China

[4]Third Geology and Mineral Resources Exploration Academy of Gansu Province, Lanzhou, China

X-ray fluorescence (XRF) can be used directly to analyze contents of ore-forming elements in a gold mine and other characteristic indicator elements such as Zn, Cu, Pb, As, Sb, Fe, etc. in the field. It will make contributes to delineate the favorable areas for mineralization of gold mine, and quickly obtain the location and distributional pattern of gold mine geochemical halo.

Due to the polytropism of geological samples and the differences of analytical methods, the results of chemical analysis are quite different from the results of XRF analysis. As a result, specific standard samples corresponding to each kind of elements are requested in different lithology for each mine. And then the standard curve of best sample linear can be made.

Dashui Gold Deposit in Maqu, Gansu, which was found in west Qinling mountain area, is a type of gold deposits with unique mineralization. On the basis of geochemical exploration and actual situation of the deposit, the representative 3530 m and 3490 m middle sections of No.103 exploration line of Dashui Gold Deposit were selected for measuring. The measuring device is CIT-3000SMP. The design spacing is 3 m, and the analyzing time is 120 seconds per point. Five limestone and six diorite porphyrite samples with chemical analysis results had been used to fit standard curves and establish standard database respectively by the linear fit of the peak area and contents combining with the inverse computation of software. Then multi-element analyses had been down on the survey middle sections to delicate the favorable areas for mineralization of gold mine, and quickly obtain the location and distributional pattern of gold mine geochemical halo. The results demonstrate that:

1. Au, As, Cu, Fe, Mn, Ag, Sb, Ti, Sr, etc. appear high strength anomalies on the known middle sections, meaning that they can be treated as the indicating elements for Dashui Gold Deposit.

2. There is a high anomaly area in and near the contact zones of diorite porphyrite and hematite limestone of known ore body in 3490 m middle section. The width of the anomaly is about 33m. Combining with the geological situations of other middle sections, this area is delineated as level one prospective area. This area might be formed by the combination of two narrow gold veins, and it connects with other ore veins of the higher and lower middle sections.

CALCIUM ISOTOPES: KEYSTONE FOR UNDERSTANDING ISOTOPIC FRACTIONATION AND PLANETARY MATERIAL PROCESSES

DONALD J. DEPAOLO

Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA 94720, djdepaolo@lbl.gov

Non-traditional elements like Ca, Mg, Li, Fe, Mo and others have proven to be valuable for assessing the mechanisms and magnitude of non-equilibrium isotopic fractionation processes. These so-called kinetic effects are important not only for low-temperature processes, but also for hydrothermal and magmatic conditions. Theory and experiments are progressing rapidly and are leading to a new level of understanding and a roadmap for further experimental work. This presentation will focus mainly on Ca isotopes, but the principles and effects are applicable to other elements. With respect to mineral growth from aqueous solution, the essential insight is that equilibrium growth can occur only if the molecular exchange fluxes at the mineral-solution interface are large in comparison to the rate of growth. For typical minerals growing at Earth surface temperature, this is unlikely to be the case, the consequence being that the kinetics of the forward reaction strongly influence isotopic fractionation, causing precipitated solids to be enriched in light isotopes. A rough estimate of surface exchange fluxes can be derived from mineral dissolution rates, but more detailed ion-by-ion growth models can be used to develop a more comprehensive description of the forward and backward reaction rates. For calcite, not only solution oversaturation, but also the Ca:CO3 ion ratio in solution can strongly affect both growth rate and Ca isotopic fractionation. Ionic strength and other aspects of solution composition also modify isotopic fractionation, and analogous models can account for trace element partitioning as well. Preliminary data suggest that Ca isotopic fractionation in calcite and epidote also occurs at hydrothermal temperatures of 150 to 400C, with fractionation factors similar in magnitude to those for calcite at 25C. In magmatic systems, isotopic fractionation can be deduced by both chemical diffusion and thermal gradients in silicate liquids. The magnitude of Ca isotopic fractionation due to chemical diffusion has been shown to be dependent on silicate liquid composition, with high-Si, high-viscosity liquids producing larger fractionations than low-Si liquids. Diffusion in the solar nebula is probably responsible for some Ca isotopic variations observed in carbonaceous chondrites. Both phenocrysts in magmas and nebular condensates are likely to have kinetic fractionation effects if they grow under transport-limited or high oversaturation conditions. Current efforts are directed at experimental testing of model predictions, and modeling the coupling between growth inhibition/catalysis and isotopic fractionation.

A comparison of shale weathering rates inferred from catchment solute mass balance versus soil profile chemistry at Plynlimon, Wales

ASHLEE L. DERE[1]*, BRIAN REYNOLDS[2], TIMOTHY S. WHITE[3] AND SUSAN L. BRANTLEY[4]

[1]Penn State University, University Park, USA, ald271@psu.edu*

[2]Centre for Ecology and Hydrology, Bangor, Wales, UK, br@ceh.ac.uk

[3]Penn State University, University Park, USA, tsw113@psu.edu

[4]Penn State University, University Park, USA, sxb7@psu.edu

In an effort to quantify the influence of climate on shale weathering rates, a transect of study sites has been established on Silurian shales along a climatic gradient in the northern hemisphere as part of the Susquehana Shale Hills Critical Zone Observatory, PA (USA). The coldest and most northerly site of this transect is the Hafren watershed in the headwaters of the River Severn, at Plynlimon, Wales, UK. The watershed, which is approximately 24 km from the west Wales coast, has an area of 357 ha and is 70% covered by Sitka spruce plantation forestry. The watershed has been extensively studied with continuous measurements of precipitation and runoff since 1968 and weekly monitoring of rain and stream water chemistry since 1983. These data provide an ideal opportunity to compare weathering rates derived from watershed mass balance to those derived from soil geochemical profiles. Annual solute mass balances over the past 25 years were determined by subtracting stream output fluxes from precipitation input fluxes using Cl as a conservative tracer. Annual mass balance estimates for dissolved elements such as Si are relatively consistent over time (mean value 23.2 ± 0.7 kg Si ha^{-1} yr^{-1}) while those of Na are more variable (mean value 2.69 ± 1.2 kg Na ha^{-1} yr^{-1}) and show influence of variations in sea salt input. Area-weighted release rates of Mg (mean value 5.36 ± 0.3 kg ha^{-1} yr^{-1}) are indicative of weathering rates of the dominant shale minerals illite and chlorite. Weathering rates were also estimated from soil geochemical profiles, where elemental depletions relative to parent shale chemistry were used to calculate a weathering rate over the last 10 ka. Mg release estimates from soil ridgetop samples (5.16 kg Mg ha^{-1} yr^{-1}) are in close agreement with the watershed mass balance calculations. Conversely, the estimated Si weathering flux derived from soil profiles of 6.6 kg ha^{-1} yr^{-1} is much smaller than the watershed mass balance flux estimate. This may imply that the watershed mass balance estimates for Si are influenced not only by weathering processes in the augerable regolith but also in the fragmented shale bedrock underlying the soil profile. Si cycling through the Sitka spruce trees must also be evaluated. The weathering rates obtained from the two methods at Plynlimon will be placed in context with our observations for the overall shale climosequence, where weathering rate estimates at the other locations are restricted to geochemical profiles alone.

Distribution of GDGTs in tropical sediments from Guadeloupe (French West Indies): implications for application of MBT/CBT and TEX_{86} proxies

S. DERENNE[1*], A.HUGUET[1], I. BELMAHDI[1], C. FOSSE[2], AND V. GROSSI[3]

[1] BioEMCo, CNRS/UPMC UMR 7618, Paris, France, sylvie.derenne@upmc.fr (* presenting author)

[3] PEPS, UMR 5125 CNRS–Univ. Lyon 1, Lyon France

Glycerol dialkyl glycerol tetraethers (GDGTs) are lipids of high molecular weight present in membranes of Archaea and some bacteria. Archaeal membranes are composed predominantly of isoprenoid GDGTs, with acyclic or ring-containg biphytanyl chains. The amount of isoprenoid GDGTs with cyclopentyl moieties was shown to increase with water temperature and variations in surface water temperature can be determined via the TEX_{86} proxy. Recently, another type of GDGTs, with branched instead of isoprenoid alkyl chains, has been discovered in peat. Branched GDGTs were suggested to be produced in soils by still unknown bacteria. The degree of methylation of branched GDGTs, expressed in the MBT, was shown to depend on air temperature and to a lesser extent on soil pH, whereas the relative abundance of cyclopentyl rings of branched GDGTs, expressed in the CBT, was related to soil pH. The MBT/CBT proxies are increasingly used as paleoclimate proxies. The aim of this study was to investigate the distribution of GDGTs in tropical sediments from Guadeloupe (French West Indies). Surficial sediment samples were collected in four coastal water ponds: two located in Grande-Terre and two in a smaller island named La Désirade, 10 km east from Grande-Terre. GDGTs either present as core lipids (CLs; presumed of fossil origin) or derived from intact polar lipids (IPLs; markers for living cells) were analysed. Interestingly, the distribution of archaeal and bacterial GDGTs differed between the four sites, as shown by the higher values of the TEX_{86} and MBT in sediments from La Désirade than in those from Grande-Terre. These differences were also reflected in the TEX_{86}- and MBT/CBT-derived temperatures. Temperature estimates derived from GDGTs present in La Désirade sediments were consistent with temperature recorded in the area (annual air temperature 26 °C), whereas temperature estimates derived from Grande-Terre sediments were much lower than expected values. The variability in archaeal GDGT distribution between the four water ponds might be due to different archaeal communities between Grande-Terre and La Désirade. Bacterial GDGTs seem to be essentially derived from surrounding soils in La Désirade. In contrast, in Grande-Terre, a substantial proportion of bacterial GDGTs might be produced in the water pond in addition to being produced in surrounding soils, as revealed by the high relative abundance of bacterial IPLs vs. CLs downcore. Our results suggest that caution should be exercised when interpreting MBT/CBT-derived temperatures in aquatic environments, as they might be largely biased by in situ microbial production.

Weathering of voclanics and the geological carbon cycle

LOUIS DERRY

Cornell Uninversity, Dept. of Earth & Atmospheirc Sciences, Ithaca, NY, USA, derry@cornell.edu

Weathering and volcanic rocks

Weathering rates in granitic and cratonic terranes have been well studied, yet information on weathering in volcanic terranes remains sparse. Available data suggest that mafic – intermediate volcanic terranes play a disproportionately large role in the carbon cycle. They have high abundances of Ca and Mg silicates, the weathering of which results in much greater CO_2 consumption rates than the weathering of the alkali silicates typical of continental crust, which is an inefficient CO_2 sink. They also have mineralogy and texture that weather much faster than those typical of most cratonic terranes. Additionally, most active volcanic centers are associated with arcs and hotspots that are adjacent to oceans where marine moisture and orographic effects can lead to high runoff and erosion rates, and many of the active island arcs today are located in the wet tropics. All of these features suggest that weathering and CO_2 consumption rates of volcanics should be high. While there are relatively few published data from streams draining active arcs that permit estimation of CO2 consumption rates, there is growing evidence to support the hypothesis that arc weathering is an important CO2 sink [1, 2]

The contribution of arc terranes to global weathering budgets is poorly known in part because rivers in these settings tend to be small and have not been sampled systematically (or in most cases at all) for geochemical purposes. Unlike major continental regions, where a single large river can give information about a large fraction of both the continental surface and total runoff, island arcs are a type of "non-point source" problem. Many smaller streams deliver large loads per unit basin area, and the aggregate flux can be quite large, but no one stream samples a large region.

The srtontium isotope ratios of arc and hot spot weathering is low, reversing the common relationship beteen silicate weathreing and changes in seawater 87Sr/86Sr. Changes in the rates of arc weatheirng can be important drivers of the long term carbon cycle

Open-system behavior of U-series in carbonates: what we can learn from old limestones

P. DESCHAMPS[1*], C. HILLAIRE-MARCEL[2], B. HAMELIN[1], B. GHALEB[2]

[1]CEREGE, UMR Aix-Marseille Univ. - CNRS - IRD, Aix-en-Provence, France, deschamps@cerege.fr
[2]GEOTOP, Montreal, CANADA, hillaire-marcel.claude@uqam.ca

Conventional U/Th age determination assumes closed-system behavior. This criterion is violated in most Pleistocene fossil corals as evidenced by unreliable ages, ^{226}Ra offsets with respect to radioactive equilibrium with parent ^{234}U, as well as variable initial coral ^{234}U/^{238}U ratio, that are in most case substantially higher than that of modern seawater. The source of excess ^{234}U (and ^{230}Th) in fossil corals and its relationship to U-series age determinations remains an open issue in U-Th geochronology. Many investigators [2,3] consider that open-system behavior results from an enhanced alpha-recoil mobility of U-series nuclides (^{230}Th, ^{234}Th and consequently ^{234}U).

The premise of this study is that alpha-recoil-related processes evoked for open-system behavior of fossil corals, should also be active in "old" carbonates. Here we illustrate this issue with precise and accurate measurements of ^{234}U/^{238}U ratios in borehole core samples from deep, low-permeability Mesozoic formations of the Paris basin, France [3]. The initial objective of the study was to investigate the behavior of naturally occurring uranium isotopes as a means to assess the long-term safety of radioactive waste disposal in a clayey formation of Callovo-Oxfordian age targeted by the French Agency for nuclear waste management (ANDRA). Special attention was paid to U-series disequilibria within over- and underlying Mesozoic carbonate formations. All samples associated with pressure-dissolution features (stylolites) depicted systematic ^{234}U/^{238}U disequilibria at the centimetric scale, thus illustrating some uranium mobility during the last 2 Ma. This finding illustrates an unusual and unexpected mechanism of uranium remobilisation implying relocation and fractionation processes, since U was supposed to be practically immobile under the reducing conditions and low porosity and permeability characterizing the host sedimentary formations. We intend to discuss here the mechanisms responsible for uranium mobility in such deep sedimentary rocks and will make a comparison with mechanisms that have been proposed to drive U mobility in fossil corals.

Impact of remediation design on arsenic leaching from historic gold mine tailings

S.L. DESISTO[1*], M.B. PARSONS[2], J.L. KAVALENCH[3] AND H.E. JAMIESON[1]

[1]Department of Geological Sciences and Geological Engineering, Queen's University, Kingston, Ontario, Canada, desisto@geoladm.geol.queensu.ca (* presenting author), jamieson@geol.queensu.ca

[3]AMEC Earth and Environmental, London, Ontario, Canada, Jennifer.Kavalench@amec.com

Secondary As minerals can reduce metal(loid) mobility in mine wastes, but may dissolve under changing geochemical conditions during or after remediation. The objective of this study is to optimize remediation strategies for As-bearing tailings from abandoned gold mines in Nova Scotia. A logical clean up plan at these publicly accessible sites would be to place a cover on the tailings, a method often successful at limiting sulphide oxidation and thus, preventing acid production and metal(loid) release. However, due to the heterogeneous nature of these strongly weathered mine wastes, this may lead to dissolution of some As-bearing minerals and an influx of As to local waters. The challenge of remediating such tailings lies in the different Eh-pH niches in which Fe-arsenates (oxidizing, acidic), Ca-Fe-arsenates (oxidizing, alkaline), and sulfides (reducing) are stable. Since these mine wastes are mineralogically complex and associated with variable pH and redox conditions, a one-size-fits-all remediation approach will be difficult to achieve.

To assess the geochemical changes induced by various remediation scenarios, the following options have been tested: (1) unremediated tailings in the field, (2) unremediated tailings in the lab, (3) a simulated limestone cover, (4) a simulated vegetative cover, and (5) a soil cover. For scenario 1, four field bins were filled with one of each tailings end member (hardpan tailings, oxic surface tailings, wetland tailings, or high Ca/As tailings). Leachate from the bins was sampled bi-weekly for two years. Scenarios 2-4 involved a set of three columns per tailings end member that were leached weekly with one of three input solutions: synthetic rainwater, synthetic rainwater equilibrated with $CaCO_3$, or a weak organic acid solution, respectively. Scenario 5 consisted of one column of each tailings end member topped with a 30-cm-thick soil cover that was leached with synthetic rainwater.

Results from Scenarios 1-4 show the As mineralogy in the tailings is the primary control on As mobility. Under field conditions, both hardpan and wetland tailings produced acidic, metal(loid)-rich drainage over time, and only the high Ca/As tailings remained near-neutral throughout the tests. In the lab, column leachates for a given tailings end member showed similar pH values and concentrations of sulphate, As and Fe despite the range in input solution pH (from 4.6 to 10). The scenarios tested so far have not proven to be effective mitigation strategies against As leaching. Reducing water and oxygen availability may be the best way to minimize As release and prevent acid generation.

Stablization of mercury in riverbank sediments of the South River, Virginia (U.S.A.)

KRISTA DESROCHERS [1*], CAROL PTACEK [1], DAVID BLOWES[1] RICHARD LANDIS [2], JAMES DYER[2], WILLIAM BERTI[2], NANCY GROSSO[2]

[1]Earth and Environmental Sciences, University of Waterloo, Waterloo, ON, CA
k2desroc@uwaterloo.ca (* presenting author)
[2]E.I du Pont de Nemours and Company, Wilmington, DE, USA

Metal-bearing sediment particles from eroding riverbanks can be an ongoing source of bioavailable mercury (Hg) to aquatic ecosystems. Hyporheic zones in particular can be important sources of both inorganic and organic-complexed Hg, which can be rapidly transported to adjacent surface waters. The objective of this study was to investigate the release and treatment of dissolved and particle-bound Hg in water derived from the riverbank sediments of the South River, Virginia. A profile of sediment was collected along a riverbank. Samples were characterized to assess the potential for Hg release as both dissolved and particulate forms. A series of resuspension experiments was conducted to simulate erosion of the riverbanks into the river. Mechanisms controlling transport of Hg during a riverbank inundation event were evaluated through column leaching experiments, which were conducted under variable flow conditions. Carbon-based amendments were applied in batch experiments to limit the release of Hg from sediment containing either 70 mg kg^{-1} or 280 mg kg^{-1} of Hg. Continuous flow-through column experiments were conducted to evaluate the potential for treatment of both dissolved and particulate Hg under transport conditions.

Elevated concentrations of Hg were observed in the river water during the resuspension experiments. The highest concentrations of Hg released (up to 80 μg L^{-1}) were observed for sediment samples collected from near the top of the riverbank profile. Mercury release during the resuspension experiments showed a non-linear response as the mass of sediment was increased, suggesting a possible solubility control on aqueous Hg concentrations. In column experiments, Hg concentrations in the in the 0.45 μm-filtered fraction of the effluent varied from 0.15 μg L^{-1} for samples collected from the base of the riverbank to 8 μg L^{-1} for samples collected from the top of the riverbank. Filter size-fractionation of water column effluent suggested approximately 50% of the leached Hg was present in the dissolved phase, with the remainder in particulate form.

Results from batch and column experiments indicated that the addition of reactive media resulted in lower aqueous concentrations of Hg. The co-blending of carbon-based adsorbent to sediments resulted in decreases in aqueous Hg ranging from 43 to 89% in the South River water. The adsorption of Hg ranged from 32 to 202 ng Hg per g reactive material. Decreases of 98% of Hg in column effluent were observed following 35 pore volumes of flow, and 91% after 100 pore volumes of flow. Results from laboratory-based experiments indicated that the addition of reactive media resulted in lower concentrations of both dissolved and particulate Hg in the river water. The potential application of carbon-based amendments to the riverbank sediment may be an alternative approach to reduce Hg flux in the South River.

Use of stable (HOCN) and radiogenic (Sr) isotopes to determine the geographic provenance and traceability of artisanal cheeses of Quebec, Canada.

S. DESROCHERS*, R. K. STEVENSON, J-F. HÉLIE, A. POIRIER

GEOTOP et, Science de la Terre et de l'Atmosphère, Université du Québec à Montréal, P.O. Box 8888, Station Centre-Ville, Montreal, Qc, Canada, H3C 3P8
(*correspondence:ldesrochers.steph@gmail.com)

Analysis of stable isotopes has often been used to determine the traceability of different food products [1]. The light stable isotope ratios in dairy products such as cheese can provide information for tracing geographical origin [4]. The province of Quebec is Canada's largest cheese producer and artisanal cheeses are becoming a larger part of this market. In this context, we selected artisanal cheeses from six different regions of the province of Quebec to study the applicability of light stables isotopes and radiogenic isotope (Sr) ratios as descriminants to provide geographic traceability.

The cheese samples were analysed for light stable isotope ratios (HOCN) which are mainly influenced by altitude, distance from the sea, use of fertilizer, rainfall, food type, temperature, longitude and latitude [2,3,6]. The Sr isotope analyses are indicative of the geology of the type of substrate of the grazing areas [5]. Prelininary results yeild $^{87}Sr/^{86}Sr$ ratios that vary from 0.70978 to 0.71347 for both winter and summer cheeses. These values reflect soils composed largely of glacial tills derived from either the Canadian Shield or Appalachain Orogen. Furthermore, we observed a direct correlation of the $^{87}Sr/^{86}Sr$ ratios of cheese, milk and soil from the grazing area. Stable isotope δD values vary beteween -107.57‰ to -56.38‰, and $\delta^{18}O$ beteween -18,64 ‰ to -6,45‰ for both winter and summer cheeses. Water and milk δD and $\delta^{18}O$ results are similar to chesse results but with and enrichment in $\delta^{18}O$ values. Stable isotope $\delta^{13}C$ values vary between -27.12‰ to -21.40‰ and $\delta^{15}N$ beteween 4.66‰ and 6.21‰ wich is representative of C_3 plant CO_2 fixation. These results allow us to conclude that the use of stable and radiogenic isotopes can provide geographical provenance and traceability of the artisanal cheese of Quebec.

The climate sensitivity of oceanic oxygen

CURTIS DEUTSCH*[1], TAKA ITO[2]

[1]University of California Los Angeles, Los Angeles, USA, cdeutsch@atmos.ucla.edu (* presenting author)
[2]Georgia Institute of Technology, Atlanta, USA, taka.ito@eas.gatech.edu

The warming of Earth's climate is expected to lead to a widespread loss of oxygen from the ocean, exacerbating the localized effects of coastal eutrophication. The mechanisms responsible for climate-forced deoxygenation – changes in gas solubility, ventilation of the ocean interior, and respiration of organic matter – are spatially heterogeneous, so the susceptibility to oxygen loss varies greatly among water masses. Moreover, the wide range of time scales involved in the adjustment of the oceanic oxygen distribution, coupled with the presence of strong internally generated variability greatly complicate the detection and attribution of trends. This talk will synthesize the current evidence for and understanding of changes in oceanic oxygen from model simulations, modern ocean observations, and the geologic record. A central conclusion is that the low latitude ocean, where the biological constraints from low oxygen are most profound, are also intrinsically most sensitive to climatic perturbations. Given the long transit times from thermocline outcrops to the tropical oxygen minimum zones, the response of oxygen in those regions to climate warming must either be slow to arrive, or else driven by local rather than remote climate trends. This suggests that if an expansion of the tropical oxygen minimum is already underway, its climatic origin is likely to be found in tropical winds rather than high latitude stratification. The major uncertainties and implications for ecosystems and biogeochemical cycles will also be discussed.

Benthic nitrogen fluxes and denitrification in Bering Sea shelf sediments.

ALLAN DEVOL[1*], RAHCHEL HORAK[1], DAVID SHULL[2], CALVIN MORDY3 AND HEATHER WHITNEY[1]

Abstract

Benthic-pelagic coupling is hypothesized to be quite strong in the in the highly Bering Sea shelf ecosystem and primary production of the system is thought to be nitrogen limited[1]. Nevertheless, sedimentary denitrification and benthic nutrient fluxes and their seasonal trends are poorly characterized. Through the Bering Sea Ecosystem Study (BEST) program, we measured benthic fluxes of N_2 and dissolved inorganic nitrogen species, the extent of coupled nitrification/denitrification, and the water column nitrate deficit (using N**[2]) on the Bering Sea shelf in the spring and summer 2009 – 2010. We found that sedimentary denitrification is widespread over the shelf and is fuelled mostly through coupled nitrification/denitrification, the net balance of sedimentary DIN flux is negligible over the shelf, and that water column N** varies widely according to season and year. In the summer, N** appeared to be strongly affected by non-Redfieldian uptake of inorganic nutrients by phytoplankton in the spring bloom; in the winter, N** was strongly affected by sedimentary denitrification. Our findings indicate that the estimate of total N loss in the Bering Sea shelf should be revised upwards by at least 50% to 5.2 – 6.2 Tg N y^{-1}. In addition sediments appear not to be a large source of remineralized nutrients for primary production over the shelf, hence sedimentary denitrification exacerbates N-limitation of the ecosystem.

Monte-Carlo modeling

The Monte-Carlo modeling of the corrosion of glasses by water makes it possible taking into account both the chemical reactivity at the atomic level and the morphology of the altered surface film at the mesoscopic scale. The method was mainly applied to borosilicates in relation to the durability of the nuclear waste confinement glasses. The effect of substituting silica for more (B, Na) or less (Al, Zr) oxides was studied [1, 2].

The model leads to three major predictions. First, the initial dissolution rate is controlled by the surface area of the porous layer produced by the departure of the most soluble oxides. Second, the corrosion blocking that frequently occurs in static conditions is due to the restructuring of the altered film, which leads to the densification of the external layers and to the closure of the pores (Fig 1). Third, the presence of insoluble oxides in the glass composition paradoxically increases the degree of corrosion, since it prevents the layer reconstruction.

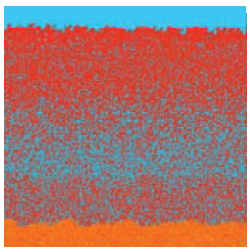

Figure 1: Cross section of the reorganized gel showing the densification of the external layers and the closure of the pores [3].

Experimental studies

All these predictions were broadly confirmed by experimental studies of the kinetics of corrosion and by the characterization of the corroded films by various techniques including NMR, gas adsorption and spatially resolved mass spectroscopy [3, 4]. Especially, the gel reconstruction was probed by small angle X-ray scattering and the porosity closure was evidenced by neutron scattering with solvent index matching. An inverse correlation between the initial dissolution rate and the final degree of corrosion was demonstrated both as a function of pH, and glass composition when silica is replaced by zirconia, or Na_2O by CaO [4].

Continental growth through the sedimentary reservoir: Hf in zircon & Nd in shales records

BRUNO DHUIME[1,2*], CHRIS HAWKESWORTH[1], PETER CAWOOD[1]

[1]University of St Andrews, Department of Earth Sciences, St Andrews, UK, b.dhuime@bristol.ac.uk (* presenting author)
[2]University of Bristol, Department of Earth Sciences, Bristol, UK

~7% of the present-day exposed crust consists of rocks of Archean age, yet models of continental growth suggest that 20-100% of the present-day volume of the continental crust had formed by 2.5 Ga ago [e.g. 1]. These models rely on understanding the balance between the generation of new crust and the reworking of old crust, and how these have changed with time. For that purpose, the variations in radiogenic isotope ratios in detrital rocks and minerals are a key archive.

We considered two different approaches to model the growth of the continental crust: (i) the variation of Nd isotopes in continental shales with various deposition ages, which requires a correction of the bias induced by preferential erosion of younger rocks through an erosion parameter 'K' [2-3]; and (ii) the variations in U-Pb, Hf and O isotopes in detrital zircons sampled worldwide. These two approaches independently suggest that the continental crust appears to have been generated continuously, but with a marked decrease in the continental growth rate at ~3 Ga. The >4 Ga to ~3 Ga period is characterised by relatively high net rates of continental growth (~3.0 $km^3.a^{-1}$), which are similar to the rates at which new crust is generated, and destroyed, at the present time [4]. Net growth rates are much lower since 3 Ga (~0.8 $km^3.a^{-1}$), which may be attributed to higher rates of destruction of continental crust. The inflexion in the continental growth curve at ~3 Ga indicates a change in the way the crust was generated and preserved. This change may be linked to onset of subduction-driven plate tectonics and discrete subduction zones.

[3]University of Cambridge; Dept. of Earth Sciences; Cambridge, UK

Magnesium isotopes are a powerful tracer of low temperature geochemical processes [1, 2]. However, widespread application of Mg isotopes in geochemical studies is limited due to the relative amount of Mg required for high precision measurements, high procedural blanks, artificial fractionation induced by chromatographic methods, and low matrix tolerance [1, 2]. The improved method for Mg isotope ratio (δ^{25}Mg & δ^{26}Mg) determination has low mass consumption (5 ng-Mg) with high precision (± 0.1‰, 2s) and high matrix tolerance using Neptune® MC-ICP-MS. A single step chromatographic method is used to quantitatively (100.0% ± 0.2%) separate Mg from matrix elements with low blanks and no column induced fractionations. Quantitative separation of other matrix elements (Li, Na, Ca, and Sr) was also achieved with > 99% recovery (Fig. 1). This procedure is optimal for natural carbonates and seawater samples with high matrix loads.

Preliminary MC-ICP-MS analyses of CAM1, DSM3, and seawater fall in the published range ($\Delta^{25}Mg_{Cam1}$ and $\Delta^{26}Mg_{Cam1}$ relative to DSM3 are 1.47‰ and 2.67‰, respectively) (Fig. 2). Internal reproducibility ranges from 0.029‰ to 0.144‰ / AMU (1σ, n=105), while external reproducibility obtained on pure Mg solutions is 0.009‰ / AMU (1σ). These new analytical methods will be used to investigate relationships between $^{7/6}$Li, $^{(26/25)/24}$Mg, and $^{(88/87)/86}$Sr ratios in natural carbonates to asses their viability as indicators of weathering and endmember mixing in carbonate systems.

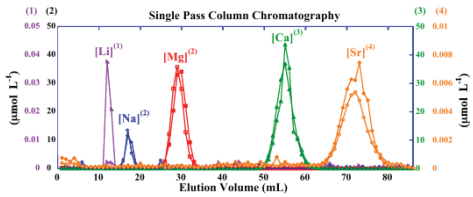

Figure 1: Quantitative separation of alkali and alkaline earth elements.

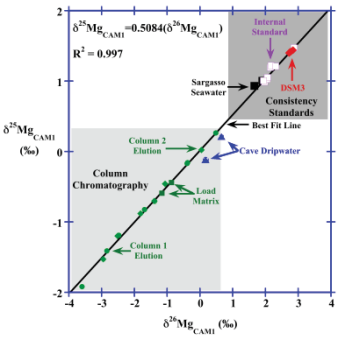

Figure 2: δ^{25}Mg vs. δ^{26}Mg for elution matrices, seawater, cave dripwater, DSM3, and internal isotope standards. Error bars (2σ) are contained within data symbols. The slope of the best-fit line through all data is δ^{25}Mg = 0.5084 (δ^{26}Mg) R^2 = 0.997.

Effect of Nanoparticles on the Displacement Pattern of CO_2 Injection in Porous Media

D. A. DICARLO[1*], B. AMINZADEH[1], D. H. CHUNG[1], M. ROBERTS[1], C. HUH[1], AND S. L. BRYANT[1]

Introduction

The patterns that emerge from a displacement process depend greatly on the mobility ratio between displaced and displacing phases. When a less viscous fluid (e.g. CO_2) displaces a more viscous fluid (e.g. brine) the displacing fluid fingers through the porous media, causing it to travel faster and longer distances. Spontaneous formation of foam during the displacement may be an effective solution to stabilize the displacement. Surface treated nanoparticles have been shown to stabilize CO_2 in water foam by adhering to the surface of CO_2 bubbles and preventing their coalescence [1]. However, the large adhesion energy suggests that mechanical work must be applied to bring the nanoparticles from bulk phases to the CO_2-water interface [2]; Co-injection of CO_2 and nanoparticle solution at high rates is known to provide sufficient energy. Here, we study the foam formation during a fluid/fluid displacement at low shear rate.

Methodology

In order to capture the efficiency of the nanoparticle foam flood, we inject CO_2 and CO_2 analogue fluids into sandstone cores preloaded with either brine or brine with suspended nanoparticles. We use CT scanning to measure the saturation profile and flow pattern during a displacement, and pressure transducers to measure the overall mobility.

Results and Conclusion

Even at small flow rates (low shear rate) the presence of nanoparticles acts to control the CO_2 mobility. The displacement front is more spatially uniform and breaks through later in the presence of nanoparticles compared to displacements without nanoparticles (Fig. 1). Pressure measurements during the displacement are consistent with generation of a viscous phase such as an emulsion. These observations suggest that nanoparticle stabilized emulsion is formed during the displacement which acts to suppress the viscous instability. We argue that generation of droplets of CO_2 occurs at the leading edge of all drainage displacements; however, the droplets are preserved only in the presence of nanoparticles.

Introduction

Primitive olivine cumulates; dunite, troctolite, and olivine gabbro associated with mantle peridotite are common features of oceanic core complexes away from fracture zones. They are broadly interpreted as from the crust-mantle transition zone, formed where melt transport focused beneath a 2nd order ridge segment. Mapping at Kane Megamullion on the MAR shows local magmatic centers may form anywhere beneath a ridge segment: existing for several hundred thousand years before magmatism focused elsewhere [1].

Olivine-rich troctolites form by melt-rock reaction with the mantle, in a sequential reaction between peridotite and migrating melt, forming first dunite, then troctolite, then olivine gabbro. This occurs due to solidification-by-reaction between melt and the mantle [2]. Such reactions may continue in the lower crust until olivine is eliminated. Ol-rich troctolites in IODP Hole U1309D appear to have this origin [3-5]. Rafting of troctolites to higher levels likely due to tectonic rollover wgeb the lower crust supports a shear stress at low magmatic budgets. Thus a portion of the lower crust may be hybridized mantle.

Ol-rich troctolites also occur within a mantle section at Godzilla Megamullion in the Parece Vela Basin [3]. They include both Ol-rich (Ol > 60 vol.%) and plagioclase-rich (Pl > 60 vol.%) troctolites. The latter likely formed by local dissolution of a plagioclase matrix, and crystallization of olivine, Cpx and new plagioclase by melt produced by mixing high-MgO melt residual to Ol-troctolites formation with melt crystallizing cumulus plagioclase in a melt transport conduit.

We find olivine nickel contents can constrain the formation environment of Ol-rich rocks in the lower crust and mantle, the nature of the formation process, and the magma budget. Comparison to the nickel contents of other troctolite and gabbro occurrences in oceanic and ophiolite settings reveals a set of relationships generally consistent with our interpretations. Notably, the olivine gabbros from the 1500-m Hole 735B Atlantis Bank gabbro section have low nickel contents, while those from the 1400-m Hole U1309D Atlantis Massif gabbro section have high nickel. This is consistent with less-reacted infiltrating melt at the latter, strongly supporting the idea that U1309D represents a deeper section of the lower crust near the crust-mantle transition, while the former have been shown to represent the dike-gabbro transition and underlying gabbros.

Godzilla troctolites and gabbros have clear similarities to EPR troctolites and gabbro segregations drilled in dunites crosscutting mantle peridotites at Site 895 at Hess Deep. These represent multi-stage crystallization of stagnant melts in conduits beneath the EPR. Thus, it appears that the processes that formed the Godzilla troctolites occur beneath ocean rises across the spreading rate spectrum.

THIN CRUST OVER THE MARION RISE: MELTING A HETEROGENOUS MANTLE FROM BENEATH GONDWANA

HENRY DICK[1*], HUAIYANG ZHOU[2]

[1*]Woods Hole Oceanographic Institution, hdick@whoi.edu (* presenting author)

[2]Tongji University, State Key Laboratory of Marine Geology, zhouhy@tongji.edu.cn

The Marion Rise stretches ~ 3100 km along the SWIR from its shoalest point at 850 m, 250-km north of Marion Island, to 5600-m just west of the Rodriguez TJ. By any measure it has essentially the same relief as the Icelandic/Reykjanes Rise, but is twice as long. Cut by numerous large-offset transforms, which would likely dam sub-axial asthenospheric flow, it is unlikely that the rise can be supported by a mantle plume beneath the Marion Hotspot. The hotspot, however, traces back to the Karoo volcanic event at 185 Ma near the time of the breakup of Gondwana, and formation of the SWIR. Hence the mantle substrate beneath the SWIR likely comes from beneath southern Africa, representing the residue of the Karoo event.

We compiled new and existing data on SWIR dredge and dive samples, and find that large peridotite exposures occur throughout, including the Marion Rise crest. In the absence of significant gabbro representative of a lower crustal section, and the presence of near-amagmatic spreading segments along the rise, we conclude that the crust over the Marion Rise, in sharp contrast to the Reykjanes Ridge, is relatively thin and discontinuous. At the same time, analysis of peridotite spinel shows a systematic increase in mantle depletion up the Marion Rise correlating to the composition of spatially associated basalts and ridge depth. Hence the degree of mantle depletion increases towards the rise crest. In the absence of significantly thicker crust, this must be in large part the consequence of an earlier mantle melting event – presumably coinciding with the Karoo volcanism – but possibly including a yet earlier mantle depletion.

This, then, provides an explanation for the Marion Rise other than a simple thermal anomaly attributable to sub-axial asthenospheric flow fed from a mantle plume beneath the Marion Hotspot. Harzburgite in the garnet stability field is significantly less dense than lherzolite, and hence the systematically higher degree of mantle melting required by the Marion Rise basalts and peridotites likely reflects a major density anomaly beneath the SWIR centered on Marion Island 250 km to the south. Thus the Marion Rise may exist due to an isostatic response to an earlier mantle depletion event predating the present day volcanism.

Basalts isotopic compositions along the Marion Rise are highly variable, reflecting a heterogenous mantle consistent with interactions and entrainment of a heterogeneous continental lithosphere and crust in the asthenosphere as Africa migrated northward during the opening of the SW Indiaan Ridge [1-3].

Thermodynamic properties of aqueous phenanthrene and isomers of methylphenanthrene at high temperature

JEFFREY DICK[1*], KATY EVANS[2], ALEX HOLMAN[1], CAROLINE JARAULA[1] AND KLITI GRICE[1]

[1]WA Organic and Isotope Geochemistry Centre, Department of Chemistry, and [2]Department of Applied Geology, Curtin University, Bentley WA, Australia, Jeffrey.Dick@curtin.edu.au (* presenting author)

Polycyclic aromatic hydrocarbons, including monomethylated phenanthrenes (MP), are common components of bitumen associated with sediment-hosted ore deposits. Their relative abundances are often interpreted as indicators of thermal maturity and hence may help constrain models for the transport and deposition of metals sharing a genetic history with the organic compounds. A high degree of thermal maturation yields products in chemical equilibrium [1], but a lack of thermodynamic data for aqueous MP at high temperature has precluded a quantitative interpretation of their origin in hydrothermal settings. Values for the standard molal Gibbs energy and enthalpy, entropy, and heat capacity were generated for aqueous phenanthrene and the MP isomers methylated at the 1-, 2-, 3-, 4- and 9-positions on the phenanthrene structure. These values were derived from reported thermodynamic properties of the crystalline compounds [2], their solubilities and enthalpies of solution, and relative properties of the MP isomers from quantum chemical simulations [3] at 25 °C. Preliminary extrapolations to higher temperature were carried out using a constant heat capacity difference between the isomers. At 25 °C, 2-MP is highly favored over 1-MP. With increasing temperature, however, the difference in stability between the two diminishes, eventually crossing over to higher stability of 1-MP at temperatures greater than ~400 °C. The calculated equilibrium ratios of 2-MP to 1-MP (MPR) are consistent with two independent constraints: (1) maximum reported values for mature source rocks (~160 °C), and (2) MPR observed in Archaean rocks exposed to temperatures of 200–300 °C [4].

These comparisons indicate that relative abundances of methylphenanthrenes can be used to infer thermal conditions and sources of bitumen found in ores and host rock. At the Here's Your Chance (HYC) Pb-Zn-Ag deposit (McArthur River, Northern Territory, Australia) bitumen in the ore zones has a lower MPR than unmineralized shale samples. The range of values in the bitumen associated with the ore is consistent with temperatures of isomeric equilibration of ~350–400 °C. The source of MP, therefore, could reasonably have been a hot brine that cooled as it reached the ore zone. The offset in the relative abundances of MP between the ore and shale layers suggests a different degree of interaction of the brine with these layers. Since phenanthrene has a higher average oxidation state of carbon than its methylated counterparts, consideration of their relative abundances in a thermodynamic framework could place constraints on redox conditions in the ore-forming system.

A series of anerobic experiments have been conducted to study the mechanism of Fe^{2+}-mediated ferrihydrite transformation. At pH 6.5 and 7 and in the presence of 5 mM dissolved $Fe(II)Cl_2$, freshly formed, 2-line ferrihydrite rapidly exchanges isotopes with Fe^{2+} in solution (75% equilibration within 10 minutes). During the first 2-3 hours of reaction, X-ray pair distribution function (PDF) analysis and transmission electron microscopy shows evidence of increasing size of ferrihydrite particles and coherent scattering domains, but minor or no mineral transformation. After this lag phase, more rapid transformation commences to major end-phases lepidocrocite (pH 6.5) and magnetite (pH 7).

Extensive isotope exchange for ferrihydrite without significant phase transformation indicates that interfacial electron transfer and crystal conduction leads to oxidation of adsorbed Fe(II), resulting in Fe(III)-oxide growth, and reductive dissolution of Fe(III) at a different site, similar to what was initially observed for hematite [1]. In contrast to the lag phase observed for 2-line ferrihydrite, transformation of 6-line ferrihydrite to magnetite commences immediately at pH 7. More rapid conversion of larger and presumably less soluble ferrihydrite is inconsistent with recrystallisation by classical dissolution/reprecipitation. Rather, it suggests solid state transformation with magnetite nuclei forming either inside the ferrihydrite or at its surface.

With X-ray diffraction, materials subjected to ultrasonification during reaction display much weaker Bragg peaks from goethite, lepidocrocite and magnetite than those observed from material synthesised in regular experiments and the coherent scattering domains of the phases are smaller in PDF. This indicates that particle contact enhances crystal growth. Such a feature could reflect growth by 1) oriented attachment, which has been observed for ferrihydrite conversion to goethite [e.g. 2], or 2) electronic coupling between crystals, leading to Fe^{2+} electron donation and crystal growth on one particle, then transfer of the electron to an adjacent particle where interfacial reduction and dissolution occur.

Monazite is considered to be resistant to diffusive Pb loss at high temperatures and thus, it is particularly adapted to record various stages during a sequence of high-temperature geological events. This study focuses on Grt-Ky gneisses from the lower part of the metamorphic pile in the central part of the Rhodope Metamorphic Complex, in the areas of Chepelare (Bulgaria) and Sidironero (Greece). The outcrops of both regions have experienced a polycyclic evolution during Alpine times, with at least two stages of high temperature metamorphism. According to P-T estimates, the first event involved granulite facies dehydration melting that produced peritectic garnet and kyanite together with a K-rich melt. The second event relates to widespread fluid-assisted partial melting. The latter is well known in adjacent rocks, where it is dated at ~36-50 Ma, but is poorly expressed in our samples, which well preserve the early granulite facies assemblages. Monazite is present in all samples, included in early porphyroblasts such as garnet and kyanite or in the matrix. Matrix monazites are associated with white mica, rutile and biotite (Greek part) and sillimanite and biotite (Bulgarian part). Matrix monazite grains show fluid-assisted dissolution-recrystallisation features with pronounced Y-zoning correlated to age domains. Y-poor domains, dated by LA-ICPMS method ($^{208}Pb/^{232}Th$ ages) between 130 and 155 Ma, represent the largest part of each grain, while Y-rich domains, dated between 40 and 50 Ma, occur either as thin discontinuous rims (< 15 µm) or as small single grains surrounding the Mesozoic grains or filling white mica cleavages. The low P and REE-content of the surrounding minerals suggests that the Cenozoic domains essentially crystallized at the expense of the Mesozoic domains. In addition, garnet being the Y-richest mineral in the samples, its fluid-assisted resorption is the most likely mean to provide Y involved in the Cenozoic domains. The origin of the fluid is not clearly defined: external fluid infiltration or fluid produced by the recrystallisation of H_2O-bearing minerals. Regardless, this fluid interaction was responsible for the partial dissolution of Mesozoic monazite grains, as well as for garnet resorption, and the precipitation of newly-formed Y-rich monazite during mid-Cenozoic times.

Low-*P*, clockwise metamorphism of the Aus granulite terrane, Namibia

JOHANN F.A. DIENER[1*] AND RICHARD W. WHITE[2]

[1]Geological Sciences, University of Cape Town, South Africa, johann.diener@uct.ac.za (* presenting author)
[2]Institute of Geoscience, University of Mainz, Germany, rwhite@uni-mainz.de

Introduction

Intermediate *P-T* metamorphism has been inferred to indicate the initiation and operation of collisional orogenesis from the Palaeoproterozoic to the present [1]. However, the Precambrian also preserves examples of anomalously hot, likely collisional, orogenies that do not occur in the Phanerozoic. These orogenies are characterised by low-*P*, high-*T* metamorphism, high apparent geotherms and clockwise or anticlockwise *P-T* paths [2], and have been suggested to form during continental back-arc inversion involving juvenile and weak crust [1].

Regional Geology

The Aus granulite terrane of southern Namibia forms part of the Namaqua metamorphic complex that has been metamorphosed and migmatised in a hot orogenic environment during the Kibaran. The terrane consists of older TTG basement gneisses, a high-grade metamorphic supracrustal sequence, and syn-tectonic garnet leucogranite gneisses formed through anatexis of the surrounding rocks. Residual metapelitic rocks preserve assemblages of g-sill-cd-bi-ksp-pl-q-ilm that equilibrated in the presence of silicate melt. Sillimanite mats occur as large, blocky prisms interpreted as pseudomorphs after prograde andalusite. Sillimanite is included in garnet and rimmed by cordierite, indicating consumption of sillimanite to form garnet and cordierite at prograde to near-peak metamorphic conditions.

Results and Conclusions

Pseudosection modelling of metapelitic and metapsammitic residuum compositions constrain peak *P-T* conditions to 825°C and 5.5 kbar. The replacement of sillimanite by garnet-cordierite suggests that the rocks experienced heating with minor decompression to peak metamorphic conditions. The retrograde path likely involved decompression-cooling, as isothermal decompression would have led to the introduction of orthopyroxene, whereas isobaric cooling would have re-introduced sillimanite, neither of which occurred in these rocks. Pseudosections for melt-reintegrated estimates of the protolith composition show that andalusite stability along the prograde path is restricted to *P* below 4 kbar at 550-600°C. This indicates that prograde metamorphism occurred along a high apparent geotherm of 40°C/km, yet the textures suggest that the rocks evolved along a clockwise path at peak *P-T*. Retrogression occurred along a similar geotherm, suggesting that exhumation was slow, and dominantly occurred through erosion, rather than tectonic processes, and that elevated crustal temperatures outlasted the duration of orogeny.

The origin of such a long-lived heat source is enigmatic, particularly as direct evidence for mantle involvement, such as contemporaneous mafic magmatism, is absent. Metamorphism could have involved initial magmatic underplating that led to widespread crustal melting and the redistribution of melt and heat producing elements to higher crustal levels, thereby maintaining an elevated geotherm during the latter stages of orogeny.

Melt Rheology and Glass Formation

DONALD BRUCE DINGWELL [1]

[1] Earth and Environment, LMU – University of Munich, Theresienstr. 41/III, 80333 Munich, Germany, dingwell@lmu.de

Melt Rheology

The rheology of molten silicates has been the subject of a century of investigation. Current empirical models for Newtonian melt viscosity are adequate for many applications in petrological and volcanological modelling. Structure-based models have been proposed but no one has delivered yet a complete validation of any of these models.

In detail - potentially in petrologically important detail - the rheology of silicate melts contains a number of features that are not yet sufficiently well modelled. In particular, the high viscosity – high pressure regime of silicate melts will require detailed mapping before the grand conclusions of silicate melt viscosities can be developed.

Glass Formation

The departure of molten silicate from the viscous state forms the central event of explosive volcanism. The glassy products of all eruptions can shed light on the conditions of eruptions themselves. Tracking the path of glass formation in molten silicates has revealed a wide range of phenomena in the petrogenesis of these rocks and many new frontiers await exploration.

Some of the currently identifiable areas of progress in both areas will be reviewed. Some potential next steps will be presented.

Dynamics of organic carbon sedimentation and bottom oxygen and their impact on phosphorus retention in Lake Simcoe: reactive-transport modeling and experimental study.

M. DITTRICH[1*], A. CHESNYUK[1], J. MCCULLOCH[1], A. GUDIMOV[1], G. ARHONDITSIS[1], J. YOUNG[2], J. WINTER[2], AND E. STAINSBY[2]

[1]Department of Physical and Environmental Sciences, University of Toronto Scarborough, 1265 Military Trail, Toronto, Canada, M1C 1A4, mdittrich@utsc.utoronto. ca (* presenting author)

Introduction

Lake Simcoe experiences cultural eutrophication associated with point and non-point loading sources. Efforts to reduce total phosphorus (P) inputs to Lake Simcoe since the 1990s, have resulted in significant annual load reductions to the lake [1]. This lake still suffers from excessive growth of filamentous algae, macrophytes, and low hypolymnetic oxygen concentration. Despite a good understanding of the total P budget, our knowledge about the potential for bioavailable P loading from the sediments is limited. The impact of dynamic conditions at sediment–water interface, such as organic carbon flux and oxygen concentration, on phosphorus retention remains unknown. In this study, phosphorus sediment retention in three basins, that experienced distinct sedimentation dynamics, has been investigated experimentally and theoretically. Using diagenetic reaction-transport modeling and sediment core analysis, we investigated the effects that variations in the organic carbon loadings and oxygen bottom concentration, had on the availability of sediment P.

Methods and Results

We performed phosphorus sequential fractionations of sediments during summer stratification and under ice-cover. Phosphorus binding forms have been divided into four operational groups: apatite-bound-P, organic P, inorganic redox-sensitive P (iron-hydro-oxides-bounded) and loosely-bound P, that is in equilibrium with P dissolved in pore water.

The following rank was determined for the P in the sediment apatite-P > organic-P > redox-sensitive-P > loosely bound-P. It was found that the largest amount of P is bound in the sediment as apatite-P, essentially stable in respect to redox conditions. The model results are in agreement with the measured flux of total phosphate to the system and the fractionation data of phosphorus binding forms. A sensitivity analysis was undertaken to identify the most significant parameters, demonstrating that variations in sedimentation rate, and bottom water oxygen concentration, have the largest impact on P diagenesis.

Abstract

The potential of stable chromium (Cr) isotopes as a tracer for the biogeochemical Cr cycle depends on understanding the fractionation Cr isotopes experience. Here we present Cr isotope analyses of different Cr reservoirs to elucidate the Cr isotope fractionation occurring during oxidative weathering in a natural system from Sukinda Valley, India.

Pristine chromite seams show Cr isotope composition similar to mantle inventory rocks [1]. Weathered chromites, highly weathered ultramafic rocks and soils consistently display light Cr isotope composition, indicating that oxidative weathering have preferentially leached and mobilized heavier Cr isotopes. The surface waters display variable Cr isotope signature. However, total dissolved Cr concentration correlate with Cr isotope composition so that high Cr concentration waters (<2.6 mg L^{-1} Cr) show lighter Cr isotope values, possibly reflecting the presence of Cr in colloids, while low Cr concentration waters (>17 µg L^{-1} Cr) have heavier Cr isotope values, reflecting dissolved Cr(VI).

These results show that heavy Cr isotopes are preferentially leached during oxidative weathering. The overall consistency between data indicate that oxidation of Cr(III) to Cr(VI) and subsequent mobilization leads to considerable Cr isotope fractionation, enriching the waters in the heavier isotopes. Contrary, reduction of Cr(VI) during transport enriches the produced solid phases in the lighter isotopes and the remaining solution, in heavier isotopes [2]. The variability of the Cr isotopic composition of natural samples including soil, rock and water samples demonstrates that significant fractionation is associated with Cr biogeochemistry in the environment.

[3]Università degli Studi di Napoli (Federico II), Naples, Italy, bdevivo@uninia.it

The Aeolian Islands are an arcuate chain of submarine seamounts and volcanic islands, lying just north of Sicily in southern Italy. The eruptive products on the second largest of the islands, Salina, exhibit a wide compositional range, from basaltic lavas to rhyolitic pumice. The eruptions that produced the Grey Porri Tuffs (GPT) during the opening stages of the Monte dei Porri eruption cycle were among the most explosive in the history of the Aeolian Islands. Recent advances in microanalytical techniques permit quantification of the pre-eruptive volatile contents of magmas through analysis of silicate melt inclusions (MI). These data, in turn, provide valuable insights into magma dynamics and evolution, including the role of volatiles in controlling the style of eruption. To this end, lapilli pumice and scoria fragments were collected from the GPT and analyzed to determine the pre-eruptive volatile contents of the magmas as well as their compositional evolution.

Electron Microprobe Analysis (EMPA) of 38 naturally quenched (glassy) MI hosted in olivine, plagioclase and pyroxene define a complicated evolutionary history. Bulk-rock analyses identify the GPT host units as andesitic pumice (SiO_2 59.9 wt %) and high-silica basaltic scoria (SiO_2 53.4 wt%). MI hosted in the GPT pumice unit have basaltic compositions (SiO_2 46.2 wt%) and MI hosted in the scoria unit have basaltic andesite (SiO_2 56 wt%) compositions.

Secondary Ion Mass Spectrometric (SIMS) analysis of 23 inclusions reveals a similar bimodal distribution in volatile contents between the GPT scoria and pumice units. Olivine-hosted MI from the GPT pumice unit have higher average H_2O and S contents (4.53 wt % and 3790 ppm, respectively) compared to olivine-hosted MI from GPT scoria unit (2.7 wt % and 1772 ppm, respectively) but slightly lower F contents (659 ppm in pumice-hosted MI and 875 ppm in scoria-hosted MI). Cl contents are fairly uniform, averaging 3339 ppm in scoria-hosted MI and 3559 ppm in pumice-hosted MI. The higher H_2O contents of MI from the pumices compared to scorias is consistent with more explosive nature of eruptions that produced the pumices, compared to the less-explosive scoria eruptions.

Analysis of several spots within individual, large olivine-hosted MI shows CO_2 abundances of approximately 187-492 ppm in the GPT pumice unit and 233-576 ppm in the scoria unit. If the melt was saturated in CO_2 at the time of MI entrapment, CO_2/H_2O ratios indicate that the olivine in the pumices crystallized at approximately 6.5 km, whereas those in the scorias formed at 4.8-6.2 km.

Black carbon in Arctic snow and sea ice: The big picture through the details

SARAH J. DOHERTY[1*]

[1]JISAO, Univ. of Washington, Seattle, WA, USA, sarahd@atmos.washington.edu (* presenting author)

Overview

Model studies have indicated that black carbon (BC) in snow and sea ice may be producing significant warming in the Arctic and contributing to accelerated sea ice loss. All of these studies indicate that even small concentrations of BC may lead to large climate forcing because positive feedbacks, such as the snow albedo feedback, amplify the initial forcing. However, the magnitude of the forcing reported by different studies varies.

This talk will review our current state of knowledge regarding climate forcing by BC in Arctic snow and sea ice. The range of modeled estimates to date will be presented and reasons for differences between them explored. A recent Arctic-wide measurement study of snow and ice (BC) concentrations and sources will also be presented. This data set can be used to test modeled transport, deposition and in-snow concentration changes. However, the climate impact of BC in the cryosphere also depends strongly other factors such as snow cover, baseline snowpack radiative properties, cloud cover, in-snow redistribution of black carbon, and the presence of other light absorbing constituents. I will review what we know and what we still need to explore in order to understand whether black carbon is making a significant contribution to recent Arctic warming.

Benthic $\delta^{18}O$ signature of dense brine from sea ice formation in the North Atlantic

TROND M. DOKKEN[1,2*], ABDIRAHMAN OMAR[1,2], CAMILLE LI[1,2]

[1]Bjerknes Centre for Climate Research, Bergen, Norway, trond.dokken@uni.no (* presenting author)

[2]Uni Bjerknes Centre, Uni Research, Bergen, Norway

Abstract

Sea ice is thought to be an important factor for explaining abrupt North Atlantic climate changes during the last ice age. Reconstructing past variations in sea ice cover remains a challenge, in large part because of the complicated and indirect relationships between sea ice proxy indicators and actual sea ice conditions. One approach is to use the idea that the isotopic signature of dense brines produced via salt rejection during the formation of sea ice may be detected in benthic foraminifera records [1]. Brine formation is an active process in the Arctic and Antarctic shelf regions today [2], [3], [4]. In the Southern Ocean in particular, large quantities of dense brines are generated in polynyas and contribute an isotopically light $d^{18}O$ signature to Antarctic Bottom Water [5]. To date, it has been unclear whether North Atlantic and Arctic brines formed from isotopically light surface waters can become dense enough to penetrate to the depth habitats of benthic foraminifera. Storfjorden, located in the southeastern Svalbard Archipelago, is a site of active winter brine formation due to a recurrent polynya. Each winter, dense, brine-enriched waters fill the depressions of the fjord to its sill level and subsequently descend as a gravity current following the bathymetry towards the shelf break [6]. Observations from a September 2000 cruise reveal the presence of cold, salty, brine-enriched seawater sitting in the deepest channels (> 100 m depths) of Storfjorden, with isotopically light $d^{18}O$ values corresponding to the $d^{18}O$ values of the surface water in the region. These results are useful in better characterizing the signature of brine-enriched seawater and brine formation processes, and suggest a way forward for reconstructing sea ice variability from paleoclimate records.

Fixation and remediation of trace elements associated with coal fly ash

RONA J. DONAHOE[1*], SIDHARTHA BHATTACHARYYA[1], GHANASHYAM NEUPANE[1], KENNETH E. LADWIG[2], AND DAN V. PATEL[3]

[1]University of Alabama, Geological Sciences, Tuscaloosa, AL rdonahoe@geo.ua.edu
[2]Electric Power Research Institute, Palo Alto, CA keladwig@epri.com
[3]Southern Company Services, Birmingham, AL dvpatel@southernco.com

Introduction

Fly ash is the dominant component of solid waste produced by coal combustion. Only 38% of the total fly ash generated in 2010 was used for beneficial purposes, primarily due to concerns about potential leaching of trace elements to the environment [1]. In this study, bench-scale batch and column experiments were performed to test treatment methods aimed at reducing the mobility of trace elements associated with coal fly ash.

Results and Conclusions

Chemical fixation of fly ash using a ferrous sulfate (FS) treatment was tested at various solid:liquid ratios for a range of fly ash compositions. The best results were obtained for the 1:30 FS treatment, which successfully reduced the mobility of oxyanion trace elements in all of the fly ash samples studied. Sequential chemical extractions of treated and untreated coal fly ash showed that much of the As, Cr, Mo, Se and V associated with the acidic (Class F) fly ash samples was transferred from mobile to more stable, reducible fractions. Although reduction in trace element mobility was similar for alkaline (Class C) fly ash, FS treatment was less effective in reducing the mobility of As and Se. These elements showed significant reductions in mobility during long-term leaching, suggesting that this treatment method could increase the beneficial use of fly ash.

Older, unlined disposal facilities may serve as sources of trace elements to the environment if meteoric water interacts with the fly ash, creating leachate. Surfactant-modified zeolite (SMZ) has the potential to adsorb both cationic and anionic trace elements from aqueous solutions, but has not previously been tested for remediation of trace elements in fly ash leachate. Bench-scale batch and column experiments were performed to test the ability of SMZ to remediate trace elements in fly ash leachate. Batch experiments showed SMZ affected modest decreases in the concentrations of all oxyanion trace elements in leachate generated from both Class F and Class C fly ash, but was more effective for removal of Cr. Column experiments designed to simulate the use of SMZ as a permeable reactive barrier (PRB) at a CCP disposal facility showed large reductions in leachate trace element concentrations, but indicate that the effective lifetime of a SMZ PRB in the ash disposal environment would be relatively short.

An isotopic record of mercury in San Francisco Bay

PATRICK M. DONOVAN[1]*, JOEL D. BLUM[1], DONALD YEE[2], GRETCHEN E. GEHRKE[1]

[1]Department of Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI, USA (*presenting author: pmdon@umich.edu)
[2]San Francisco Estuary Institute, Richmond, CA, USA, donald@sfei.org

San Francisco (SF) Bay is an urban estuary that has been subjected to extensive pollutant inputs over the past 150 years. Potentially important sources of mercury (Hg) to SF Bay include Hg mining, placer gold mining, agriculture and industrial activity[1]. A previous study of Hg stable isotopes from intertidal surface sediment showed a geographic gradient in δ^{202}Hg from south (higher δ^{202}Hg) to north (lower δ^{202}Hg)[2]. To constrain background Hg isotopic composition and understand possible changes in Hg sources to SF Bay through time, we analyzed samples from eight dated sediment cores from SF Bay for total Hg concentration (HgT) and Hg isotopic composition. Sediment cores were collected at six open water sites (water depth: 2.3 to 7.8 m) and two wetland locations. At least three sediment intervals (pre-anthropogenic, ~1960, surface) were analyzed from each core. Sediment was also collected downstream of placer gold mines in the Yuba River, CA. HgT was measured by CV-AAS and Hg isotopic composition was determined by CV-MC-ICP-MS.

In all cores analyzed, HgT in pre-anthropogenic sediment is between 39 and 73 ng/g, which is within the range of expected background HgT[3]. In 1960-dated sediment, HgT varies from 239 to 532 ng/g in SF Bay open water cores and is significantly higher in wetland cores (3657 and 4777 ng/g). Surface sediment HgT in the eight cores range from 200 to 640 ng/g. HgT in the sediment derived from gold mine tailings is between 3180 and 6821 ng/g.

In all of the SF Bay cores, the pre-anthropogenic isotopic composition of Hg is similar: δ^{202}Hg = -1.00‰ (2SD = 0.14, n=6), Δ^{201}Hg = 0.09‰ (2SD = 0.08, n = 6) and Δ^{199}Hg = 0.18‰ (2SD = 0.07, n = 6). The 1960-dated sediment in the open water cores show a geographic trend similar to that reported by [2] for intertidal surface sediments: the southernmost location has the highest δ^{202}Hg (-0.32‰), the south-central locations have lower δ^{202}Hg (-0.40‰) while further north in San Pablo Bay δ^{202}Hg is lowest (-0.62‰). In surface sediment, δ^{202}Hg shows little geographic variation [δ^{202}Hg = -0.52‰ (2SD = 0.07, n = 6)]. In the sediment derived from gold mine tailings δ^{202}Hg = -0.57‰ (2SD = 0.21, n=2).

The results demonstrate that the isotopic composition of pre-anthropogenic Hg in SF Bay is different than Hg input from anthropogenic sources. A geographic trend in δ^{202}Hg is observed in sediment from ~1960, but δ^{202}Hg of SF Bay open water surface sediment does not vary geographically. It appears that intertidal surface sediments retain an isotopic memory of distinct Hg sources to SF Bay, whereas open water surface sediments have been homogenized, obscuring distinct signals of Hg source.

Fluid inclusion size, depth and shape: aspects of re-equilibration

GERALD DOPPLER*, MIRIAM BAUMGARTNER AND RONALD J. BAKKER

University of Leoben, Resource Mineralogy, Austria
gerald.doppler@unileoben.ac.at (* presenting author)

Introduction

In recent decades of fluid inclusion research potential evidences of post-entrapment changes of fluid inclusions have been increasingly noticed. Several studies of re-equilibration experiments have already been published with complex multi-component fluid mixtures. This series lacks experiments with relative simple one-component fluid systems, where the result of alteration processes, such as diffusion, can be directly related to the activity of one fluid component. Specific re-equilibration experiments are currently performed by using pure H_2O and pure D_2O. The interaction of distinct fluid inclusions attributes such as the inclusion depth below the crystal surface, the inclusion size and the inclusion shape appear to be essential for post-entrapment compositional changes.

Performing re-equilibration experiments

For this study pure H_2O fluid inclusions are synthesized in Brazilian quartz crystals which are then exposed to pure D_2O during the re-equilibration process. Fluid properties of D_2O and H_2O are approximately similar, as evidenced with specific equations of state at our experimental conditions. However, diffusion coefficients through quartz will be slightly higher for H_2O than D_2O. Both, synthesis and re-equilibration are carried out under hydrothermal conditions without a pressure gradient. The initial synthesis and the subsequent re-equilibration are performed each at the same experimental conditions.

To clarify the emphases of the above mentioned fluid inclusions attributes two different series of re-equilibration experiments are performed, as examined: **1)** time-dependent series, i.e. different experimental running-times; **2)** temperature-dependent series, i.e. different formation and re-equilibration temperatures.

Results

The gradient in the chemical potential of the entraped H_2O and the external D_2O is a driving force for diffusion of these species through the quartz crystal at constant *P-T* conditions. Fluid inclusion size and depth play an important role in relative short experiments. Fluid inclusion shapes change from irregular to regular and equant in all experiments. The diffusion of H_2O and D_2O increases rapidly between 400 and 500 ˚C at 337 MPa. At a geological time scale, fluid inclusions in deep rock should re-equilibrate instantanously to new pore-fluid conditions, if the grain that contains these inclusions is completely enclosed by the pore-fluid.

High resolution reservoir age reconstructions from cold-water corals in the North-eastern Atlantic during the Holocene (~ 1700 – 4800 cal yr BP)

MELANIE DOUARIN[1(*)], MARY ELLIOT[1], DANIEL SINCLAIR[2], STEVEN G. MORETON[3], STEPHEN R. NOBLE[4], DAVID LONG[5], J. MURRAY ROBERTS[6]

[5]British Geological Survey, Edinburgh, Scotland, UK dal@bgs.ac.uk
[6]School of Life Sciences, Heriot-Watt University, Edinburgh, Scotland, UK J.M.Roberts@hw.ac.uk

Coupled U-series and radiocarbon dating were performed on cold-water corals (*Lophelia pertusa*) from the North-eastern Atlantic. The coral fragments come from 2 sediment cores (+56-08/929VE and +56-08/930VE with 3.61 m and 5.25 m recovery, respectively) retrieved from shallow inshore coral reefs from the Mingulay Reef Complex (~56°N, 7°W and 120-190 m water depth).

The 40 U-series dates show that coral fragments within the cores are in chronological order and span the mid-late Holocene (1700 - 4800 yr BP). The sediment cores show exceptionally high accumulation rates around 5 - 6 mm yr^{-1} which is higher than those estimated for reefs along the Norwegian shelf (2 - 3 mm yr^{-1}) and an order of magnitude greater than from the coral carbonate mounds of the European continental margin (~ 0.2 mm yr^{-1} for the Holocene).

Reservoir ages were reconstructed from 18 paired U-series and ^{14}C dates measured on the same coral fragments. This high resolution dating, about one analysis every 150 yrs, allows reconstructions of high frequency changes in ventilation and ocean circulation patterns in this region. The reservoir ages estimated range from 240 yrs to 700 yrs with a mean value around 400 years. Our results also suggest cyclic circulation changes in the North-eastern Atlantic: 3 periods, around 2800, 3300 and 3700 yr BP, are characterized by lower values 240, 260 and 290 yr, respectively. One prominent increase of reservoir age is observed at about 3250 yr BP with values reaching 700 yr. The lower reservoir ages are relatively well correlated with lower $\delta^{18}O$ values recorded by planktonic foraminifer *G. bulloides* and reduced coral reef accumulation rates within the Mingulay Reef Complex.

This study suggests that cyclic circulation changes occurred in the North-eastern Atlantic during the mid-late Holocene every 400 - 500 yrs. Further studies with records of similar resolutions would be needed to determine if these changes in reservoir ages are related to local and/or global environmental changes. This study demonstrates that cold-water corals constitute a powerful alternative to provide accurate reservoir ages with unprecedented temporal resolutions.

A clumped isotopes perspective on sea surface temperatures in the Eocene southern high latitudes

PETER M. DOUGLAS[1*], LINDA C. IVANY[2], ALAN G. BEU[3], CHRISTOPHER J. HOLLIS[3], ALEXANDER J. P. HOUBEN[4], APPY SLUIJS[4] AND HAGIT P. AFFEK[1]

[4]Utrecht University, Utrecht, The Netherlands

Recent studies of high southern latitude sea surface temperatures during the Eocene Epoch have suggested that very warm temperatures, possibly exceeding 30° C, extended to the Antarctic margin[1,2]. These results could have profound implications for understanding polar amplification of greenhouse warming. However, there are large uncertainties associated with the temperature proxies applied in these studies, due either to unconstrained seawater chemistry (in $\delta^{18}O$ or Mg/Ca) or ambiguity in selecting the appropriate TEX_{86} calibration. Clumped isotopes paleothermomtery is a thermodynamically controlled temperature proxy that does not depend on the isotopic compositions of seawater, and presents a novel opportunity to reduce uncertainties in Eocene SST estimates.

We measured clumped isotopes in Eocene bivalves from two southern high latitude localities: Seymour Island, Antarctica (~65° S paleolatitude) and the South Island of New Zealand (~55° S). Middle to late Eocene (45 to 35 Ma) paleotemperatures at Seymour Island range from 18 to 11°C. Analyses of New Zealand bivalves indicate a temperature decrease from ~26°C to ~20°C between the early and middle Eocene (49 to 40 Ma). These temperature estimates are most consistent with TEX_{86} paleotemperatures from New Zealand and the East Tasman Plateau calculated using the $TEX_{86}L$ calibration[3], supporting the use of this calibration in the Eocene southwest Pacific and possibly other high latitude regions.

Clumped isotope paleotemperatures suggest that New Zealand was approximately 7°C warmer than Seymour Island during the middle Eocene. This difference points either to a sharp meridional temperature gradient or to zonal heterogeneity in southern high latitude SSTs related to different paleocurrent systems influencing the southwest Pacific and southern Atlantic. Paleotemperatures from the East Tasman Plateau suggest that this temperature difference persisted into the late Eocene.[1]

Coupled clumped isotope and $\delta^{18}O$ measurements in bivalves also provide an estimate of the oxygen isotope composition of coastal seawater. At Seymour Island $\delta^{18}O_w$ values are generally within error of the ice free latitude-corrected value of -1.2‰[4]. However a marked decrease to values less than -3‰ around 41 Ma suggests a pronounced hydrologic change. In New Zealand, mean $\delta^{18}O_w$ estimates increase from -1.4‰ in the early Eocene to -0.8‰ in the late Eocene. This shift could suggest an increase in coastal salinity to normal marine conditions, either due to decreased continental runoff or a change in surface paleocurrents.

Refertilisation of the Hawaiian oceanic lithospheric mantle

JASON DOULL[1*], GREGORY YAXLEY[1], MARC NORMAN[1], HUGH, O'NEILL[1], PAOLO SOSSI[1], IAN SMITH[2]

[1] Research School of Earth Sciences, Australian National University, Canberra, Australia, jason.doull@anu.edu.au, (* presenting author)
[2] School of Environment, Auckland University, Auckland, New Zealand

A suite of fresh spinel peridotite xenoliths from the Island of Kaula, Hawaii erupted ~3 Ma ago and offer the opportunity to characterise the composition of the oceanic lithosphere and its metasomatic history. Peridotite xenoliths from continental and oceanic lithosphere often indicate early partial melting in which "basaltic" components were removed from the system, followed by varying degrees of metasomatic enrichment in incompatible trace elements.

Depletion of basaltic components in the Kaula samples is well demonstrated by the whole rock major element chemistry. Whole rock MgO wt% ranges from 40.52-45.24 and has strong negative correlations with basaltic components such as Na_2O (0.10-0.33 wt%), CaO (0.69 – 2.41 wt%) and Al_2O_3 (0.78-2.46 wt%) and a positive correlation with Ni (2129-2454 ppm). In particular, the low CaO and Al_2O_3 (<2.5 wt%) indicate relatively refractory compositions, compared with fertile peridotite.

In contrast, trace elements in clinopyroxenes show strong positive correlations between HFSE such as Ti and the HREE. Samples that depart from this trend have elevated LILE contents, in particular Ba (>1 ppm *vs.* an average of 180 ppb) and Pb (>1 ppm *vs* an average of 300 ppb).

The enrichment in trace elements and the relationships between them suggest two distinct types of mantle metasomatism that are possibly related to localised refertilisation of the lithosphere by low degree partial melts of crustal components, within a broader scale metasomatic overprint linked with plume magmatism.

"Natural toxicant" is not an oxymoron. Earth and health scientists need to meet.

STEPHANIE L. DOUMA [1*], R.A. KLASSEN[2],

[1]Associate of Nova Tox Inc.,Population Health Risk Assessment and Management , Geochemistry, Ottawa, Canada, douma@novatox.ca; stdouma@gmail.com

[2]Retired NRCan Geological Survey of Canada, Ottawa, Canada r.klassen@sympatico.ca

Large parts of Canada may be characterized by natural enrichments in toxicants having a potential to harm health. Originating in bedrock and environmentally re-distributed in air, water, and soil, such toxicants include metals (e.g., Cr, Ni, Cd, Hg), metalloids (e.g.,As), radioactive elements (e.g., Rn, U) and organic compounds (e.g., coal, PACs). Large areas in Alberta, Ontario, New Brunswick, Nova Scotia and Newfoundland with elevated natural arsenic in lake sediments and water. Fluorite elevated in Waterloo, Ontario. Sporatically across Canada areas underlain by chromium and nickel bearing rocks enriching soils and drinking water. Arsenic and uranium in lake sediments (water) on Melville Peninsula in Inuit hunting grounds.

Far from trivial, these naturally occurring toxicants have the potential to cause morbidity (carcinogenic and non-carcinogenic disease) that exceed those that would develop from 'a pack a day' smoking habit.

Despite its potential to inform on the nature and extent of natural toxicants, and their health costs, the earth sciences remain poorly integrated with current approaches to environmental, ecological and human health protection.

All of these toxicants are naturally occurring, present in the environment at levels that will cause harm to human health and despite each toxicant being listed Health Canada's Priority Substance List 1, there is little research in their occurrence. Health officials are not aware they exist, earth scientists are unaware of the implications of their existence. It is time for earth and health scientists to meet.

Evidence of ocean acidification viewed by boron isotopes and B/Ca in scleractinian corals

ERIC DOUVILLE[1*], CECILE GONZALEZ-ROUBAUD[1], PASCALE LOUVAT[2], JEROME GAILLARDET[2], GUY CABIOCH[3] PAOLO MONTAGNA[1], NORBERT FRANK[1], MARION GEHLEN[1]

[3] IRD, Nouméa in New Caledonia and Bondy in France

The monitoring of ocean acidification (seawater pH fall due to rising anthropogenic CO_2 in the atmosphere) is mainly based on three 20-30 years long pH records: ALOHA at Hawaii in the central North Pacific, BATS at Bermuda in the west North Pacific and ESTOC at Canary Islands in the eastern North Atlantic. The current acidification rate of the surface waters deduced from these records is well established at -0.018 ± 0.001 pH-units/yr [1]. This trend is in good agreement with model projections. However the impact of ocean acidification on marine biology and ecosystems, in particular on key marine species such as foraminifera, corals, pteropods, bryozoan and molluscs still remains poorly constrained and further quantification of pH fall and its impact is needed for the high latitudes and the deep environments. While ocean acidification, since the start of the industrial era, was estimated at around -0.07 pH-units for tropical surface waters, the pH decrease since 1870 could reach values higher than 0.15 pH-units at high northern and southern latitudes.

It has been suggested that the isotopic composition of boron trapped in marine biogenic carbonates can be used to infer the pH of the ambient seawater [2]. Since the publication of this pioneering paper, a number of studies have 1) investigated the existing relationship between boron isotopic composition of carbonates (foraminifera, corals) and seawater pH in order to "calibrate" boron isotopes as pH-proxy and 2) used boron isotopes to reconstruct paleo pCO_2 over the Quaternary and further, for the whole Cenozoic. With the development of analytical techniques to measure precisely B-isotopes by MC-ICPMS, intense studies become feasible to precisely quantify ocean acidification over the industrial era using corals.

With the aim to reconstruct the major carbonate chemistry changes of the ocean, we analyzed the B-isotopic composition of long-lived sub-equatorial Pacific surface corals (*Porites* sp.) and Atlantic mid-depth dwelling cold-water corals (*Lophelia pertusa* and *Madrepora oculata*). Boron isotopes were here measured using MC-ICPMS. Our results demonstrate that boron isotopes in scleractinian corals are sensitive to small ambient seawater pH changes and can thus be reliably used to quantify past ocean acidification. The B-isotope results will be discussed together with B/Ca ratios to enlighten the crucial role of temperature in the paleo-pH reconstructions. Finally, a few examples of quantification of the anthropogenic pH fall during the twentieth century will be presented and compared to expected trends for the surface waters of the Pacific Ocean and for the intermediate waters of the North Atlantic. This research was supported by the European integrated project EPOCA and the French INSU/LEFE/CYBER project PHARE.

The influence of mineralization pathway on composition and isotope signatures in calcite

PATRICIA M. DOVE[1*], ANTHONY J. GIUFFRE[1], NIZHOU HAN[1], JAMES J. DE YOREO[2], ALEX C. GAGNON[2]

[1]Department of Geosciences, Virginia Tech, Blacksburg, USA, dove@vt.edu (* presenting author);
[2] Earth Sciences Division, LBNL, Berkeley, CA, USA.

Chemical proxy models are based upon the assumption that isotopic signatures and concentrations of minor and trace elements reflect equilibrium fractionation processes that occurred during mineralization. This picture is rooted in the fundamental assumptions of BCF crystal growth theory— a thermodynamic-based model that was derived for step growth at very near equilibrium conditions. However, the applicability of these assumptions are being called into question with the realization that many carbonate biominerals form by non-classical processes. Here, mineralization begins with accumulation of amorphous calcium carbonate (ACC) in a localized environment that subsequently transforms to the crystal/organic composites we know as skeletal structures. It is not yet known 1) if the transformation involves classical microscopic dissolution-reprecipitation or an altogether different type of process and 2) the consequences of this process for composition and isotopic signatures.

This study investigates the influence of the ACC to calcite pathway on the Mg content and isotopic signature of calcites. For low solution levels of Mg/Ca, Mg content is insufficient to inhibit step growth and ACC transforms into crystallites of Mg calcites that exhibit the expected linear fractionation with Mg/Ca of initial solutions (0-20 mol% $MgCO_3$). In contrast, when initial Mg levels are above the threshold for step growth, ACC transforms to nanoparticle aggregates of very high Mg calcite (30-50 mol% $MgCO_3$). The Mg content of calcites formed by this process is independent of solution chemistry, without evidence of fractionation. The data suggest mineralization is biased to the alternative pathway when the Mg level in the local environment is too high for significant calcite growth beyond nanoparticle sizes. This pathway is allowed because high levels of supersaturation render thermodynamic barriers to nucleation less significant than the larger kinetic barriers. Thus, the alternative pathway is a consequence of interplays between kinetic and thermodynamic factors.

Parallel experiments used enriched isotope labels (43Ca and 25Mg) to distinguish dissolution-reprecipitation from direct conversion during the ACC to calcite transformation. When solution Mg/Ca is low calcite assumes the isotopic label of the growth media consistent with a dissolution-repreciptiation pathway. In contrast, very high Mg calcites that grow from high Mg solutions retain a portion of the ACC isotope signature. This suggests the transformation of high Mg ACC occurs by an alternative pathway that involves a substantial fraction of direct transformation. Collectively our data show that mineralization pathway dramatically affects composition. This type of mechanistic understanding of mineralization processes will be necessary to explain proxy behavior and more accurately reconstruct past environental conditions.

Constraining dehydration rates during regional metamorphism, Townshend Dam, Vermont, U.S.A.

BESIM DRAGOVIC[1*], MATTHEW GATEWOOD[2], ETHAN F. BAXTER[1], HAROLD STOWELL[2], DAVID M. HIRSCH[3] AND ROSE BLOOM[3]

[1]Boston University, Deparrtment of Earth Sciences, Boston, MA, U.S.A, dragovic@bu.edu (* presenting author), efb@bu.edu

[3]Western Washington University, Department of Geology, Bellingham, WA, U.S.A., hirschd@geol.wwu.edu, bloomr3@students.wwu.edu

Progressive dehydration during regional metamorphism can result in pervasive or channelized fluid flow. Given sufficient fluxes, fluid flow may have profound effects on rheological properties of the rock, bulk rock composition, stable and radiogenic isotope compositions, mineralogy, and the kinetics of mineral reactions. Many published studies have used petrologic and stable isotopic data to constrain time-integrated syn-metamorphic fluid fluxes. Here, an integrated geochronologic and thermodynamic anaylsis is used to estimate the dehydration rate and flux during metmorphism of a pelitic schist from Townshend Dam, Vermont.

Microdrilling based on Mn growth zoning, from large (1-3 cm) garnets from one sample, provides information on the rate and duration of garnet growth. Three to six concentric zones (depending on crystal size) of garnet, were sampled for ID-TIMS Sm-Nd geochronology. A partial dissolution procedure was utilized in order to remove inclusion phases from garnet fractions which were analyzed as NdO+ with Ta_2O_5 activation. This yielded clean garnet, with $^{147}Sm/^{144}Nd \leq 3.18$. Garnet-matrix isochron ages of individual garnet zones have been previously reported [1], with the duration of garnet growth across the sample ranging from 5.5 to 11.7 Ma, and an average duration of 7.8 Ma.

Garnet growth may be linked directly to dehydration during regional metamorphism. Thermodynamic analysis of this reaction allows calculation of the stoichiometric ratio between garnet formation and water release. The garnet:water ratio depends on the growth reaction, and the P-T path during growth. In our sample, the average water:garnet molar production ratio is 3.3:1 over the duration of garnet growth. Early garnet growth involves the consumption of chlorite, resulting in initially higher water:garnet ratio. Both thermodynamic and textural analysis have determined that ~ 5.5 vol% garnet was formed during the age span stated above. This equates to a release of 1 wt% (or 2.8 vol%) water during garnet formation, similar to water volumes estimated in previous studies from southeastern Vermont [2]. Using the duration of growth (5.5 to 11.7 Ma), a time-averaged dehydration rate of 1.3 to 2.8 x 10^{-10} moles of water/ cm^3 of rock/ year can be calculated.

Global-scale changes in Hg cycling during glacial-interglacial transitions

PAUL DREVNICK[1*], CARL LAMBORG[2], AND GRETCHEN SWARR[2]

[1]INRS-ETE, Université du Québec, Quebec City, Canada, paul.drevnick@ete.inrs.ca (* presenting author)
[2]Woods Hole Oceanographic Institution, Woods Hole, USA, clamborg@whoi.edu

Abstract

Records of Hg in ice cores from Dome C indicate elevated Hg deposition to Antarctica during cold periods (glacials, stadials) of the Late Quaternary [1, 2]. Hypotheses to explain this phenomenon ultimately center on coincident increases in deposition of soil dust (of South American origin). Vandal et al. [1] suggested dust-driven increases in productivity of the Southern Ocean resulted in increased oceanic Hg^0 evasion, whereas Jitaru et al. [2] argued cold conditions facilitated efficient scavenging of atmospheric Hg onto dust particles. We will present data from additional geologic archives (sediments, ice) that challenge these hypotheses and, further, indicate glacial-interglacial transitions resulted in global-scale changes in Hg cycling. A 40,000-year sediment record from Lake Titicaca (Bolivia/Peru) (corrected for detrital Hg inputs) shows elevated Hg deposition during the Last Glacial Maximum – in remarkable agreement with the extent and timing of the Dome C record. However, there is not enough Hg in the atmosphere and surface ocean even today that could be redistributed to account for the absolute increase in deposition to Lake Titicaca. An additional source of Hg to the system is required, and one possibility is the massive reservoir of Hg in the solid earth. Volcanism was initially dismissed as a source of Hg to Dome C, based on an inadequate amount of non-seasalt sulfate in glacial ice to explain Hg increases [1, 2]. During the Last Glacial Maximum, however, lowered sea level could have acted to depressurize shallow volcanic and hydrothermal systems, encouraging greater activity [3]. Submarine volcanism would add Hg to the ocean, which could later be mobilized to the atmosphere, decoupling it from sulfate and other non-volatile tracers of volcanic activity. We will explore this hypothesis by constraining Hg fluxes from submarine volcanism during glacial and interglacial periods, as well as by comparing the records from Dome C/Lake Titicaca to other Late Quaternary records (reconstructions in progress for GISP-2, Cariaco Basin, Lake Baikal). This work may provide the basis for using Hg as a paleo-proxy of large-scale geophysical/climate change.

Construction of a Fully Searchable Soils Database Integrating Soil Characterization Data and Whole-Soil Geochemical Data

S.G. DRIESE[1], L.C. NORDT[1], G.E. STINCHCOMB[1], K. KUIJPER[1]

[1]Department of Geology, Baylor University, One Bear Place 397354, Waco, TX 76798 USA

Paleopedological studies rely heavily on the use of contemporary soil characterization and whole-soil geochemical data [1, 2, 3]. These soil science resources serve the needs of paleopedologists who reconstruct ancient climate and soil systems using models to relate modern physical/chemical soil characterization data, whole-soil geochemical data, and climate parameters [3, 4, 5]. The (paleo)pedologist currently faces a "data overload" problem due to a number of global and continental-based soil geochemical databases becoming widely available. The overwhelming nature of the available data makes model construction difficult and time-consuming. The emerging field of data analytics addresses the overload problem by providing a systematic process for data acquisition, cleaning, initial analysis and main analysis. We used a data analytics approach to construct the Baylor Paleosol Informatics Cloud (BU-PIC). The BU-PIC uniquely combines: (1) USDA-NRCS pedon data, (2) PRISM-based climate parameters, (3) NLCD land-cover attributes, and (4) published paleosol data. This aggregation of data will allow paleopedologists to upload standardized geochemical data and test and refine soil-derived paleoclimate proxies and paleopedotransfer functions. Although BU-PIC development is in the initial stages of data cleaning, preliminary analysis shows promising results. For example, variations in whole-soil weight % Fe_2O_3 explain approximately 76% of the variance in % Fe_d (pedogenic iron) in all soil horizons spanning 4000 pedons, and variations in whole-soil weight % CaO explain approximately 86% of the variance in $CaCO_3$% in 865 pedons (A and B horizons only, no gypsum). This may be useful for paleopedologists interested in determining the amount of pedogenic iron and pedogenic carbonate within a lithified paleosol. Binning by specific soil orders and soil textural classes suggests that proxies can be improved by separation rather than aggregation seeking "universal" proxies. We believe the success of BU-PIC will rely on building rapport with modern soil scientists while seeking their consultation during the developmental stages. Towards reconstructing climate and ecosystem for paleoVertisols using bulk geochemistry

S.G. DRIESE[1], L.C. NORDT[1], G.E. STINCHCOMB[1], K. KUIJPER[1]

[1]Department of Geology, Baylor University, One Bear Place 397354, Waco, TX 76798 USA
*Correspondance: Steven_Driese@baylor.edu

Whole-rock molecular oxides, especially the Chemical Index of Alteration Minus Potassium (CIA-K) have been popularly used in the paleosol community for reconstructing climate, especially mean annual precipitation (MAP) [1, 2]. Initial approaches were universal, aggregating soil geochemical data from widely disparate soil types (e.g., soil orders, soil textural classes, soil ages, etc.). Because CIA-K ($Al_2O_3/(Al_2O_3+CaO+Na_2O)*100$) is fundamentally an index of clay formation and base loss related to feldspar weathering, it is inappropriate for one soil order that is especially well-represented in the rock record as paleosols, namely, the Vertisols, which are high clay-content soils (typically smectite mineralogy) that have a high shrink-swell potential, and commonly form from alluvium that has been "pre-weathered". Recent advances in developing MAP proxies specific for paleo-Vertisols, such as the new CALMAG index ($Al_2O_3/(Al_2O_3+CaO+MgO)*100$), have not only improved MAP estimates [3, 4], but have lead to understanding potential use of bulk geochemistry and modern soil characterization data to develop pedotransfer functions for reconstructions of colloidal soil properties such as pH, CEC, Base Saturation, etc. [5]. Carrying this a step further are ecosystem reconstructions of paleosols that evaluate soil conditions influencing net primary productivity using geochemical proxies [6]. Noteworthy is reconstruction of organic C and N in paleo-Vertisols using pedotransfer functions developed using ppm Pb in modern Vertisols [7]. The limits of application of bulk geochemistry to paleosols are as yet unknown, but it is clear that our approach for analyzing separate soil types has merit. We are currently developing a soil database that contains over 1500 US pedon and 6000 soil horizon records that can be queried using different soil wet-chemical and geochemical (whole-soil) parameters to predict specific conditions. Our initial attempts with circa 40 US Vertisol pedons to develop several new proxies specific to paleoVertisols provide more uniform MAP estimates than using CIA-K, as demonstrated by specific examples from Mississippian, Triassic, and K/T boundary paleosols. Wind-driven diurnal variability in freshwater surface microlayer biogeochemistry

CHRISTOPHER DRUDGE[1*] AND LESLEY WARREN[1]

[1]McMaster University, School of Geography and Earth Sciences, Hamilton, Canada, drudgecn@mcmaster.ca (* presenting author), warrenl@mcmaster.ca

Introduction

Understanding the compositional dynamics of the surface microlayer (SML) at the air-water interface of surface waters is critical because of its role in regulating the exchange of matter between the atmosphere and hydrosphere [1,2]. Temporal variability in SML biogeochemistry is poorly understood, particularly with respect to changing physico-chemical conditions. The objective of this study was to examine the geochemical and microbial composition of the SML and underlying water column (0.5 m depth) in two contrasting freshwater environments (Sunnyside Beach, Lake Ontario, a littoral hard water environment heavily impacted by anthropogenic inputs; Coldspring Lake, a pelagic environment in a small (<1 km^2) and relatively pristine soft water lake) over a diurnal timeframe during the summers of 2010 and 2011.

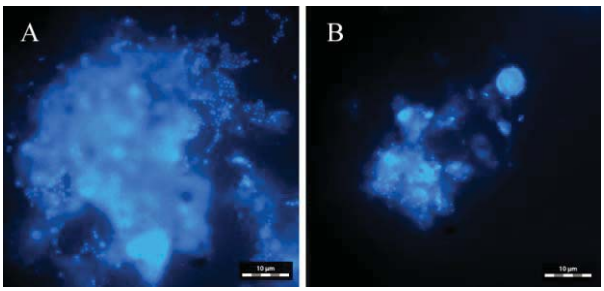

Figure 1: Fragmentation of SML microbial aggregates with increasing wind speed (from A to B, DAPI stained).

Results and Conclusion

Diurnal variability in SML biogeochemistry was closely linked to wind speed in both environments. The visual fragmentation of microbial aggregates (Fig. 1), a reduction in prokaryotic cell numbers, and an increase in dissolved organic carbon accompanied the diurnal transition from relatively quiescent to windy conditions. These changes were not observed at 0.5 m. In both environments, SML enrichment in total particulate matter and particulate iron was negatively correlated with wind speed. Particulate iron decreased in the SML and increased at 0.5m from morning to afternoon with increasing wind speed.

Collectively, these results suggest that particulate matter, including organic carbon and iron, is enriched in the SML under quiescent conditions and undergoes fragmentation over the course of a day in concert with increased wind speed. Further, wind-driven diurnal changes in SML biogeochemistry appear to be (a) conserved between contrasting freshwater environments, and (b) distinct from changes occurring at a depth of 0.5m, highlighting the unique characteristics of the SML.

Calcium isotope fractionation as a function of solution stoichiometry in groundwater

JENNIFER L. DRUHAN[1,2*], CARL I. STEEFEL[2], KENNETH H. WILLIAMS[2], LAURA C. NIELSEN[1,2], AND DONALD J. DEPAOLO[1,2]

[1]University of California Berkeley, Earth and Planetary Science, jennydruhan@berkeley.edu (* presenting author)
[2]Lawrence Berkeley National Laboratory, Earth Science Division,

While modeling predictions have suggested fluid calcium to carbonate ratio may influence the calcium isotope fractionaton factor as well as the net rate constant during calcite growth, field evidence of the macroscopic effects of solution stochiometry on precipitation rate and isotopic fractionation has been difficult to observe. Here we present some of the first evidence of solution stoichiometry influencing the fractionation in $\delta^{44}Ca$ of groundwater in a series of clogged well bores during organic carbon ammended uranium bioremediation of a contaminated aquifer in western Colorado. Secondary mineral formation induced by carbonate alkalinity generated during the bioremediation process lead to substantial permeability reduction in multiple electron-donor injection wells at the field site. These conditions resulted in removal of aqueous calcium from a backrgound concentration of 6mM to >1mM while $\delta^{44}Ca$ enrichment ranged from 1‰ to greater than 2.5‰ [Figure 1].

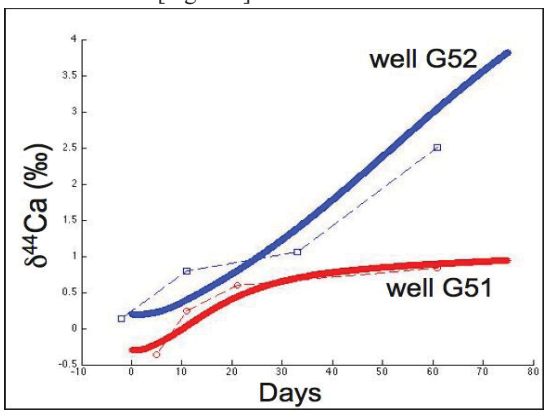

Figure 1: Data and models of $\delta^{44}Ca$ fractionation in clogged well bores as a function of time.

The variation observed in $\delta^{44}Ca$ between wells is attributed to the difference in carbonate alkalinity generated in each well bore, presenting some of the first field evidence supporting theoretical models of calcium isotope fractionation as a function of fluid Ca^{2+}:CO_3^{2-} ratio. Where the Ca^{2+}:CO_3^{2-} ratio remains >30 the $\delta^{44}Ca$ fractionation is accurately modeled by precipitating Ca-40 and Ca-44 as independent species in a TST-style model with carbonate formation calculated as a solid solution [Figure 1 red line]. However reproducing the observed $\delta^{44}Ca$ trend where Ca^{2+}:CO_3^{2-} <30 is only accomplished by utilizing a newly developed analytical model for calcium isotope fractionation as a function of solution stochiometry [Figure 1 blue line].

Constraining late Miocene seawater composition: a multiproxy approach

ANNA JOY DRURY[1*], CÉDRIC M. JOHN[1], ANNE-LISE JOURDAN[1]

[1]Department of Earth Science and Engineering, Imperial College London, London SW7 2AZ, United Kingdom.
a.j.drury10@imperial.ac.uk (* presenting author), cedric.john@imperial.ac.uk, a.jourdan@imperial.ac.uk

The late Miocene (11.61–5.33 Ma) was one of the most climatically stable periods of the past 60 Myr. However, superimposed on the stable long-term trend, short-term, 40 kyr high-amplitude changes in $\delta^{18}O$ are observed that suggest Milankovitch forcing of seawater $\delta^{18}O$ composition, temperature, or both. Understanding seawater composition evolution during this time could offer insight into the natural variation of important climate parameters, such as ice volume and sea surface temperatures.

The goal of our study is to reconstruct seawater $\delta^{18}O$ composition at different levels in the water column across the late Miocene (3.50-8.50 Ma). The study site is located in the Eastern Equatorial Pacific (Site U1338), and samples were collected during IODP Expediton 321. Understanding temporal changes in Equatorial Pacific seawater temperature and compostion is critical due to the importance of the low-latitude regions for global ocean circulation. Reconstructing $\delta^{18}O_{seawater}$ will be achieved by combining multiple geochemical proxies on benthic and planktic foraminifera. Here we present preliminary $\delta^{18}O$ and $\delta^{13}C$ data from the benthic foraminifera *Cibicidoides mundulus*. The data's long-term trends reflect global patterns, which implies the site is suitable for a high-resolution seawater composition study. Our ultimate target resolution is 3-4 kyr, which allows resolution of ~20 kyr orbital cycles. As $\delta^{18}O_{calcite}$ from benthic foraminifera is a function of both $\delta^{18}O_{seawater}$ and calcification temperature, the $\delta^{18}O_{calcite}$ will be combined with Mg/Ca and Li/Ca measurements, both temperature proxies, to reconstruct $\delta^{18}O_{seawater}$.

A second component of future work is to reconstruct temporal changes in surface water $\delta^{18}O$ and Mg/Ca by combining traditional stable isotope and trace element measurements with a novel proxy called clumped isotopes. The 'clumped isotope themometer' Δ^{47} reflects the amount of rare, heavy stable isotopes ^{13}C and ^{18}O bound together in the carbonate crystal lattice. Δ^{47} shows an inverse relationship with temperature, as more ^{13}C-^{18}O bonding occurs at lower temperature. The initial T-Δ^{47} calibration was based on inorganic calcite, however a recent study has shown that foraminiferal and coccolithophore calcite shows the same T-Δ^{47} relationship and is not affected by 'vital effects'.

We will present initial data comparing Δ^{47} measurements on the fine fraction (predominantly consisting of coccolithophores) to Mg/Ca and $\delta^{18}O$ measurements on planktic foraminifera (*Globigerinoides sacculifer*). By measuring Δ^{47} on samples consisting mainly of planktic material, we will be able to deconvolve sea surface temperature from secular changes in Mg/Ca and $\delta^{18}O$ seawater values measured in planktic foraminiferal calcite.

Geochemical modeling of lung fluid-mineral interactions: Highlighting fundamental knowledge gaps

GREG K. DRUSCHEL[1*], MICKEY E. GUNTER[2], AND ANNE E. TAUNTON[2]

[1] Indiana University-Purdue University Indianapolis, Indianapolis, Indiana,USA, gdrusche@iupui.edu (* presenting author)
[2] University of Idaho, Moscow, Idaho, USA, mgunter@uidaho.edu

Minerals respired into lungs are known, from a number of epidemiological studies and historical accounts, to have significant human health effects when the dose is high. These health effects often have latency periods of tens of years before symptoms manifest. Geochemists and mineralogists can contribute towards an understanding of how these diseases work in considering mineral interactions in the lung as a fluid-mineral interaction problem. We have performed a series of fluid-mineral interaction models utilizing the Geochemist's Workbench modeling platform, considering thermodynamic, kinetic, and fluid flow parameters towards the dissolution of a set of commonly encountered minerals. Employing rate laws from the literature, we calculated possible residence times of minerals in the lung and found that those times and possible mineral reactions products were sensitive to dose, particle size, lung fluid composiiton, and the flushing rates of fluid across particles in the lung [1].

These calculations bring into light some fundamental parameters that are poorly defined but are important in our ability to define how minerals behave in human lungs over decadal scales. While some reaction rates for minerals are defined in fluids of similar composition to lung fluids [2], many mineral rate laws are not well defined for these conditions. The composition of lung fluid itself is also not well defined with respect to some fundamental chemical speciation, noteably the speciation of phosphorus, and the organic speciation of many key cations for whose activity these calculations of mineral reactivity need to be defined. Additionally the physiological role of fluids flushing past minerals is largely undefinined in the human lung, and may have a significant role in the biodurability of minerals.

Within this context as well we can consider how mineral reactivity may be linked to cellular damage and the initiation of fibrotic diseases and cancers. Mineral reactivity can affect cells directly or can affect the biochemical environment cells function in through possible surface reactions that generate reactive molecules (often readicals), sorption of key biomolecules, or changes in the surrounding pysicochemical environment these cells reside in. Some of these reactions may be quite different if we consider the immediate reactivity of a mineral when it enters the lung and becomes whetted by lung fluid v. the reactivity of a mineral and potential secondary minerals forming on dissolution of that mineral over decades. We will discuss the results of our modeling study and what they have brought us to consider about the future state of mineral reactivity and lung fluid interactions.

Effect of fertilizing soil with Selenium on trace element uptake by kenaf (*Hibiscus cannabinus*)

GIJS DU LAING[1*], RAMA VENKATA SRIKANTH LAVU[1] AND FILIP M.G. TACK[1]

[1]Laboratory of Analytical Chemistry and Applied Ecochemistry, Ghent University, Ghent, Belgium, Gijs.DuLaing@UGent.be (* presenting author)

Fertilizing food and feed crops with Selenium (Se) fertilizers can result in an increased uptake of Se by the crops, which may be beneficial for humans and animals consuming these crops. However, assessing nutritional quality of Se-enriched crops includes not only studying uptake of Se by the crops, but also how the uptake of other trace elements is affected by fertilizing the soil with Se fertilizer. Therefore, we fertilized three types of soils with two types of Se (Selenate and Selenite, 1 mg Se kg^{-1} added to the soil) and studied the uptake of Se, Cd, Cu, Mn, Ni, Pb, Al, Fe, and Zn by kenaf (*Hibiscus cannabinus*), an indicator plant species for Se, grown on these soils. The three soils were clayey, loamy and sandy, and originally contained 0.50, 0.28 and 0.29 mg Se kg^{-1} dry mass, respectively. Afterwards, we conducted this experiment again on loamy soil using different application doses (0.5, 1, 2 and 4 mg Se kg^{-1} added to the soil).

Applying Selenate resulted in the highest increase of Se concentrations in the crop, with the highest accumulation being obtained on sandy (477 ± 77 mg kg^{-1}) and loamy (518 ± 97 mg kg^{-1}) soil, whereas Selenite performed best on a sandy (107 ± 17 mg kg^{-1}) and a clayey (122 ± 23 mg kg^{-1}) soil. Applying Selenate affects also significantly the concentrations of the other metals in crops grown on the loamy soil, but not in crops grown on the clayey and the sandy soil. When the Se application dose is varied on the loamy soil, Zn is already affected from an application dose of 0.5 mg Se kg^{-1}. The concentration of Al starts to be also affected from 1 mg Se kg^{-1}, and the concentrations of Fe, Mn and Pb also from 2 mg Se kg^{-1}. The Cu concentration is affected from a dose of 4 mg Se kg^{-1} onwards. The Al concentration clearly decreases with increasing application dose of selenite, whereas changes are less clear upon application of selenate. Zn, Pb and Fe concentrations are always reduced when applying selenite. Upon application of selenate, they are also lower than the control concentrations at the lower application doses (until 2 mg Se kg^{-1}), but they are elevated at the highest application dose (from 4 mg Se kg^{-1}). This may be related to reduced plant growth observed when selenate is used at its highest application dose. Mn concentrations are not affected when applying selenite, but they are reduced when applying selenate. Our findings illustrate that different metals respond to Se application in a different way.

Experiments with other crops and other Se fertilizers, including Se nanoparticles, that also focus on effects on Se mobility in the soil and the effects of ageing, are still ongoing. Results of these experiments will also be presented.

Weathering of ultramafic rocks under tropical conditions in New Caledonia yield lateritic profiles where metals, mainly Ni, are concentrated to economically valuable contents. The vertical distribution of Ni in these lateritic ores was investigated by analysing Ni K-edge EXAFS data along a 64 m depth lateritic weathering profile, to determine the quantitative role of the various minerals on the crystal-chemical behaviour of Ni upon weathering of ultramafic rocks. Three main units were identified from the bottom to the top of the weathering profile, i.e. the bedrock, the saprolite and the laterite. Our results show that Ni is mainly hosted by primary silicate minerals (olivine and serpentine) in the bedrock, while it is mainly incorporated in secondary phyllosilicates and Fe-oxides (goethite) in the saprolite unit, and in goethite within the upper laterite unit. A small part of Ni is also hosted by Mn-oxides at the bottom part of the laterite unit (transition laterite) which is rich in Mn-oxides. Actual modes of association of Ni with all these mineral species yield interesting information about the behaviour of this element during the lateriric differentiation. Ni content and distribution change within the phyllosilicates from the bedrock to the overlying saprolite, suggesting that several generations of these minerals have formed under different weathering conditions. Moreover, the ubiquitous occurrence of Ni-bearing goethite along the studied lateritic regolith emphasizes the major role of this mineral species on Ni speciation at the different weathering stages. This result suggests that Fe-oxides represent the ultimate host for Ni upon tropical weathering of ultramafic rocks in New Caledonia.

Trace metal complexation and dissolution by the triscatecholate siderophore protochelin

Recent evidence has shown that siderophores, biogenic agents generally viewed as iron uptake agents, may play significant roles in the biogeochemical cycling and biological uptake of metals other than iron. For example, the triscatecholate siderophore protochelin, which is produced by the diazotrophic bacteria *Azotobacter vinelandii*, has been implicated in the uptake of non-ferrous metals [1]. To better understand the effect of catechol siderophores on metal cycling and uptake, we examined the solution chemistry of protochelin, its ability to promote the dissolution of metal oxides, and structure and stability of complexes with environmentally relevant trace metals.

Free protochelin was found to be unstable, decomposing in solution on the timescale of hours to days. Additionally, it is sparingly soluble at pH < 7.5. Electrochemical measurements of protochelin and metal-protochelin complexes revealed a ligand half-wave potential of 200 mV, but no electrochemical activity was observed for the metal centers. These results help to explain patterns in the rates and products of protochelin-promoted dissolution of metal hydroxides.

The structure and reactivity of metal-protochelin complexes was probed by spectroscopic, computational, and chemical methods. The Fe(III)Proto^{3-} complex exhibits a shift in coordination mode at circumneutral to acidic pH, as has been observed for structurally related siderophores [2]. The Mn(III)Proto^{3-} complex was found to have a stability constant approximately three orders of magnitude lower than for Fe(III)Proto^{3-}. Cobalt-protochelin complexes undergo redox cycling of Co with concommital siderophore degradation. Structural parameters derived from compuational and spectroscopic methods provide insights into the stability of the metal-protochelin complexes. These results suggest that common metals may affect the biological uptake of metals by protochelin, and that unique properties of the siderophore may affect its dissolution reactivity and the mechanisms of intracellular metal release.

Abstract

The coastline of the Earth is over 400 000 km long and about 40% of the world's population lives within 100 km of the coast. Segmentations of the global coastline and their classification into various coastal settings can be derived from a continental perspective based on an analysis of river basin properties (COSCATS) [1], from an estuarine point of view (typology of estuarine systems) [2] or from an oceanic perspective, constructed around a regionalization of the near-shore and distal continental margins (LME) [3]. Here, we present an overview of recent efforts to characterize the whole aquatic continuum using comprehensive geographical units which retain the most important physical characteristics of the land/river, near-shore, and shelf areas.

Geographic and hydrologic parameters such as the surface area, volume and fresh water residence time are calculated for each coastal unit. Next, a multi-scale typological analysis is used to classify river basins, estuaries and continental shelf seas according to climatic, lithologic, morphologic and hydrodynamic criteria of both land and sea.

We combine the different approaches with global databases (GLORICH, GlobalNEWS, SOCAT) to extend the quantification of lateral carbon and nutrient fluxes and establish regional carbon budgets. Applications relate to coastal sciences at local, regional or global scales (e.g., budget calculations, model parameterisations, scaling of local estimates) such as i) GIS-based modeling of carbon routing showing e.g., that 2/3 of the organic carbon delivered by rivers transit through estuarine filters where further processing occurs while the remaining 1/3 directly reaches continental shelf seas, ii) regionalized estimates of the contribution of estuarine systems (small deltas, tidal systems, lagoons, fjords) and continental shelf seas to atmospheric CO_2 exchanges, iii) first steps towards a regionalization of the coastal CH_4 fluxes to the atmosphere.

[3]Goldcorp Inc., Musselwhite Mine John.Biczok@golcorp.com

The origin of Archean banded-iron formation (BIF) hosted Au deposits are enigmatic and remain highly controversial. Although they are classified as an orogenic Au deposits, the origin of the fluids (magmatic vs. metamorphic) is still in discussion. In an attempt resolve this debate, we present major and minor element compositions of garnet determined by LA-ICP MS and EPMA, from the Musselwhite deposit in the North Caribou greenstone belt, Western Superior Province. The deposit occurs within meta-(chemical) sedimentary rocks, which are enveloped by amphibolite grade mafic to ultramafic rocks. Samples were collected from auriferous garnet -grunerite schist, footwall and hanging wall schist in the mine, as well as auriferous schist from north of Opapimiskan Lake. A sample was also collected from the non-mineralized chemical sedimentary bed that is continuous 24 km from the deposit. Major elements of garnet from mineralized rock show Mn-rich cores (18-25 % Sps component) and Mg (8-15 % Pyp component) and CaO rich rims. The latter is atypical for normal growth zoning in garnet. Mineralized samples show high Eu/Eu* values ranging from 6.34-1.26 in the ore zone in the mine to ~1 to 2.98 from north of Opapimiskan Lake. Low Eu anomalies occur in the non-mineralized sample (Eu/Eu*= 0.706-2.19). The majority of garnet grains show high HREE concentrations with a mean $(Sm/Lu)_{CN}$ value of 1.6 and low LREE (ΣHREE/ΣLREE = 41). Rims of garnet from mineralized samples show large variation in Ni/MgO from ~ 0.14 to 15.5, and Y concentrations from ~ 0.89 to 198 ppm. The high Ni and low MgO are recorded in the core of these grains from the ore zone, whereas their rims show low Ni. Trace element zonation in garnet from the non-mineralized rocks is minor compared to the auriferous samples. The data suggest that garnet growth was contemporaneous with the precipitation of pyrrhotite and chalcopyrite; both sulfides are closely associated with the introduction of Au. Gold-bearing fluid was derived from rocks during metamorphism or extensive alteration of mafic rocks as reflected by variably high Eu/Eu* values and calcic rich rims in the garnet crystals in the mineralized rocks. Results presented here indicate that garnet effectively records the history of hydrothermal activity associated with Au deposits and the data are consistent metamorphic fluid as the principle transporter of Au at Musselwhite.

Linear trend of mid-continent alkaline volcanism, USA: slab-edge focus

GENET I. DUKE[1*], RICHARD W. CARLSON[2], AND CAROL D. FROST[3]

1 Northeastern Illinois University, Earth Science, g-duke@neiu.edu (*presenting author)
2 Carnegie Institution of Washington, Terrestrial Magnetism, rcarlson@dtm.ciw.edu
3 University of Wyoming, Geology and Geophysics, frost@uwyo.edu

Alkaline volcanism in the mid-continent USA includes a linear zone of Cretaceous-Tertiary kimberlite-carbonatite magmatism. Magmatism along the N40°W linear trend from Louisiana to Alberta occurs at 109-85, 67-64, 55-52, and less than 50 Ma. Magmatism along the southern part of the trend occurred at 109-85 and 67-64 Ma, and magmatism in the north occurred during the last three pulses. In Arkansas, initial Sr-Nd-Hf-Pb isotopic compositions indicate that there were at least two distinct melt sources for alkaline rocks. One end member is characterized by low $^{87}Sr/^{86}Sr$ and high $^{143}Nd/^{144}Nd$ and $^{176}Hf/^{177}Hf$, similar to values of oceanic intraplate basalts interpreted as originating by melting of convecting mantle sources. The other end of the isotopic arrays extends to higher $^{87}Sr/^{86}Sr$, but most clearly lower $^{143}Nd/^{144}Nd$ and $^{176}Hf/^{177}Hf$ than seen in most intraplate oceanic basalts. In the north, there are three Sr-Nd isotopic groupings, with latest kimberlite-carbonatite volcanism having the lowest initial $^{87}Sr/^{86}Sr$ and highest initial $^{143}Nd/^{144}Nd$ ratios.

The position of the magmatic track roughly parallel to the western subduction margin of the North American plate, the lack of spatial age progressions of the magmatism that would be consistent with motion of North America over a fixed hot spot, and the presence of Sr-Nd-Hf-Pb isotopic and trace-element compositions that show a temporal evolution from lithospheric to asthenospheric melt-sources, suggest that this linear zone is the surface expression of mantle melting somehow connected to the behavior of the subduction system ~2000 km to the west. We propose that fragmentation of the Farallon and Kula plates, as imaged by tomography beneath North America, opened slab windows parallel to the trench, but well to the east of the convergent margin. These induced sheet-like mantle upwelling along their margins, resulting in small-degree decompression melting that produced highly alkaline magmas.

Tin sorption to magnetite nanoparticles under anoxic conditions

S. DULNEE[1*], D. BANERJEE[1,2], A. ROSSBERG[1,2], AND A.C. SCHEINOST[1,2]

[1]Institute of Resource Ecology, Helmholtz Zentrum Dresden Rossendorf, D-01314, Germany (*correspondance s.dulnee@hzdr.de)
[2]The Rossendorf Beamline at ESRF, F-38043 Grenoble, France

The long-lived fission product ^{126}Sn is of substantial interest in the context of nuclear waste disposal in deep underground repositories. However, the redox state (di- or tetravalent) under the expected anoxic conditions is still a matter of debate. We therefore investigated sorption and oxidation of Sn(II) in the presence of a typical corrosion product, magnetite ($Fe^{II}Fe^{III}_2O_4$), with a mean particle size of 9.4 nm. In order to simulate waste disposal conditions, the experiments were performed under strictly anoxic conditions in a glovebox at <2 ppm O_2. Macroscopic parameters (pH, Eh, [Sn], [Fe]) were monitored along with redox state and local structure of Sn (X-ray absorption spectroscopy) and Fe (XPS) as a function of time, pH, and surface loading.

Magnetite rapidly sorbed Sn(II), reducing Sn concentration within 0.5 h from 10 to 0.0084 µM. Tin was strongly sorbed by magnetite across a wide pH range from 3 to 9. Reduced sorption at pH <3 is in line with electrostatic repulsion between the positively charged surface of the magnetite nanoparticles (IEP ~6.7) and cationic Sn^{2+} or Sn^{4+} complexes. The reduced sorption at pH > 9 is in line with the transition from $Sn(OH)_2^0$ to the anionic $Sn(OH)_3^-$ which occurs at pH 9. Across the pH range 3-9 and reaction periods ≥1 h, EXAFS-derived sixfold oxygen coordination and XANES edge energy positions of ~29207 eV both indicate the presence of Sn(IV) at the magnetite surface. EXAFS shell fitting as well as Monte Carlo simulations showed formation of edge-sharing complexes of Sn(IV) with FeO_6 octahedra (Sn-Fe distance of 3.15 Å), and formation of corner-sharing complexes with FeO_4 tetrahedra (Sn-Fe distances of 3.60 Å). Even after the longest reaction periods of 1 month, we did not observe incorporation of Sn(IV) into the (compatible) magnetite structure. Also, precipitation of SnO_2 was not observed in spite of supersaturation.

In order to elucidate the reaction pathway, we also studied Fe in solution and at the surface (XPS). Starting with the PZC and increasing with $[H^+]$, the magnetite surface released Fe(II) into solution (0.11 g/L at pH 2). After addition of Sn(II), however, [Fe] in solution decreased as a function of Sn loading, in spite of the expected increase of structural Fe(II) due to the coupling to Sn(II) oxidation. This suggests a re-adsorption and possible re-precipitation of Fe(II) at the magnetite surface. Nevertheless, Fe(II) again re-dissolved as a function of time at low pH. With XPS we were not able to detect an adequate increase of the Fe(II)/Fe(III) ratio at the surface, supporting an electron redistribution between bulk and surface Fe centers.

In conclusion, our study demonstrates that Sn is strongly retained by magnetite across a wide pH range, forming stable surfaces complexes and stabilising the magnetite surface against dissolution.

Development of (U-Th)/He geochronology of columbite ores

István Dunkl [1*], Frank Melcher[2], Friedhelm Henjes-Kunst[2] and Hilmar von Eynatten[1]

[1]University of Göttingen, GZG-Sedimentology, Göttingen, Germany, istvan.dunkl@geo.uni-goettingen.de (* presenting author) hilmar.von.eynatten@geo.uni-goettingen.de

[2]Geozentrum Hannover, BGR, Hannover, Germany, frank.melcher@bgr.de, henjes-kunst@bgr.de

Goal

Columbite-tantalite (called also as 'coltan') belongs to the most important source minerals of high-tech elements [1]. Its genesis is mainly connected to granitic pegmatites ranging from the Archean to the Cenozoic. The major- and trace element pattern, and the formation age (typically determined by different techniques of U-Pb geochronology) [2] are used for understanding the development of the deposits, and also as diagnostic tools in provenance studies of ores. We aim to develop a double-dating procedure combining columbite U/Pb geochronology with (U-Th)/He thermochronology.

First He measurements - indications of high closure temperature

In order to avoid effects from zoning of the samples we used air-abraded multi-grain aliquots for dating. Our experiments support that the crystal lattice of columbite is tight, i.e. He is not leaking. The degassing tests were performed in an IR-laser-heated full-metal helium extraction line at the GÖochronology Laboratory. The duration and temperature needed for the complete gas release indicate that the closure temperature of columbite is higher than 250 °C. This temperature is considerably higher than the He closure temperatures of commonly used minerals like apatite (~ 60-70 °C; e.g. [3]), however, considerably lower than the closure temperature of the U-Pb geochronometer in zircon or in other oxides. Consequently, He-thermochronology of columbite can provide constraints to the post-emplacement thermal evolution and erosion history of the deposits. In consequence, the double-dating of columbite is thought to provide useful fingerprints for the provenance studies of ores.

Digestion technique

After degassing it is necessary to perform a complete dissolution of the crystals to measure precisely the U, Th and Sm by ICP-MS. In case of Ta, Nb, Fe and Mn rich solutions the precipitation and the adsorptive loss of U is a common problem. By a series of experiments on synthetic and natural columbite solutions we developed a chloride-based digestion technique that keeps the uranium and thorium quantitatively in low acid concentration solutions.

The first columbite (U-Th)/He ages

A well studied columbite specimen from Madagascar yielded a He age of 450 ± 27 Ma, which is slightly younger than its U-Pb TIMS age of 505.4 ± 1.0 Ma. In other pilot samples from African districts, the lag-times between the U-Pb formation and He cooling ages are considerably longer.

[5] Graduate School of Oceanography, URI, Narragansett, RI, USA, dhondt@gso.uri.edu; spivack@gso.uri.edu.

Determining accurate concentrations of U, Th, and K in marine sediments and rocks is critical for a variety of oceanographic fields such as subseafloor microbiology, paleoceanography, sedimentology and mineralogy, and marine biogeochemistry. Rapid elemental characterization of marine cores will also enhance correlation with downhole geochemical logging. A newly developed natural gamma radiation (NGR) system aboard the Integrated Ocean Drilling Program's (IODP's) *JOIDES Resolution* research vessel provides improved measurement efficiency and lowered background signals to significantly increase the statistical reliability and quality of NGR data [1]. We are developing a combined analytical and modelling technique that converts these high-resolution energy spectra to concentrations with the use of core standards and U/K and Th/K ratios estimated from comparisons to Monte Carlo simulated and experimental spectra.

To further refine the Monte Carlo inversion technique it is critical to calibrate it by comparison to quantitatively measured concentrations of U, Th, and K in the core material. We present results based on the analysis of 38 marine sediment samples from four sites in the South Pacific Gyre recovered during IODP Expedition 329. We analyzed these sediments by ICP-ES and ICP-MS to provide a highly precise and accurate comparative data set. The ICP-ES (for K) and ICP-MS (for U, Th) data were themselves calibrated against international Standard Reference Materials and are both precise and accurate.

Our preliminary results indicate that the NGR technique captured the variability of K concentrations with depth, but systematically underestimated the absolute K concentrations by approximately a factor of two. U and Th NGR concentrations are also seen to deviate from the ICP concentrations, but much of the disparity may be driven by the offset in K concentrations. Since the NGR method calculates U and Th concentrations from U/K and Th/K ratios that are determined from Monte Carlo simulations and experimental data, an improper calibration of K can impact the accuracy of U and Th estimates. Continued improvements of the NGR K concentration calculation are likely to result in more accurate estimates of U and Th concentrations.

Additionally, inconsistencies between the data sets for sediments younger than ~1.5 Myr may arise because the NGR analysis infers U and Th concentrations from the radiation of their daughter products, which can have contrasting chemical behaviour (e.g. adsorptive character) between the different isotopes. We will present our strategies to address these effects, and discuss our efforts to continue development of this evolving new technique.

Microbialite formation in two hypersaline lakes (Bahamas): Insights into organomineralization

CHRISTOPHE DUPRAZ[1*], ALEXANDRE FOWLER[1], CHRISTINA GLUNK[2], OLIVIER BRAISSANT[3], KIMBERLEY L. GALLAGHER[1], NATALIE J. STORK[1] AND PIETER T. VISSCHER[1]

[3]University of Basel, Laboratory of Biomechanics, Switzerland

The precipitation of carbonate minerals within a microbial mat (microbialite) results from complex interactions between the microbial communities and the surrounding geochemical environment. This process is referred to as 'organomineralization', and differs from 'biomineralization' (*e.g.*, shells and bones) by lacking genetic control on the mineral product. Organomineralization can be '*active*', when microbial metabolic reactions are responsible for the precipitation through actively changing the saturation index (*"biologically-induced" mineralization*) or '*passive*', when mineralization takes place within a microbial organic matrix, but is induced by environmental reactions (*e.g.*, through degassing or evaporation; *"biologically-influenced" mineralization*). Microbial metabolism can changed the carbonate mineral saturation by acting as an 'alkalinity engine' (changing the total alkalinity and/or the distribution of carbonate species within the total alkalinity) as well as the calcium availability (through Ca-binding capacity of the organic matrix).

Here two cyanobacteria-dominated microbialites that develop in hypersaline environments (Eleuthera and San Salvador Bahamas) are compared with respect to precipitation mechanism. In both lakes, the microbial metabolic activity, the characteristics and turnover of the extracellular organic matter (EOM), and the physicochemical conditions in the water column and sediments were determined to identify the driving forces in microbialite formation. Geochemical modeling indicated an oversaturation with respect to carbonates (including calcite, aragonite and dolomite) in both systems, but these minerals were never found to precipitate at the mat-water interface. This is attributed to the capacity to bind calcium by the EOM in the water column and the upper layer of the microbial mat, inhibiting crystal formation. Therefore, organomineralization within the microbial mat is the consequence of local oversaturation of the EOM binding capacity and/or EOM degradation.

Both microbialites in this study exhibit tight coupling of element cycling and display a stromatolitic lamination, but differ in some mineral features. Notably, isotopic measurements ($\partial^{13}C$ and $\partial^{18}O$) performed on the top carbonate layer (the microbially most active zone) indicate that the precipitate, although resulting from a complex interaction of metabolisms, indicate two opposite isotopic signatures (autotrophic vs. heterotrophic). However, in both systems the early diagenesis of the mineral product (through burial) suggests an increasing influence of heterotophic processes in the mineral precipitation. In the both systems studied here, the organic matrix (EOM) plays a key role in the shaping of the mineral product.

Iron oxide compositional variations in tills along ice-flow paths: Case studies from Sue-Dianne IOCG, and Thompson Ni-Cu deposits, Canada

CÉLINE DUPUIS[1*], ANNE-AURÉLIE SAPPIN[1], MARGOT POZZA[1], GEORGES BEAUDOIN[1], ISABELLE MCMARTIN[2], AND M. BETH MCCLENAGHAN[2]

[1]Université Laval, Géologie et génie géologique, celine.dupuis.1@ulaval.ca
[2] Geological Survey of Canada, Isabelle.McMartin@NRCan-RNCan.gc.ca

Sue-Dianne IOCG deposit

The composition of iron oxides contained in 8 till samples, 0.25-1 mm in size, and five bedrock samples, were selected along a cross-section from up-ice, proximal to, and down-ice from the Cu-Ag-(Au) Sue-Dianne IOCG deposit, Great Bear Magmatic Zone, Northwest Territories, Canada. Iron oxides in tills show the same, but weaker, compositional variations related to the proximity of the deposit than bedrock samples. At and immediately down-ice of the deposit, hematite is the dominant oxide and shows dominant BIF and IOCG chemical signatures in the Ca+Al+Mn vs. Ti+V discriminant diagram. Up-ice and farther down-ice of the deposit, magnetite and titano-magnetite are the dominant oxides and show dominant Kiruna and IOCG signatures (Fig. 1).

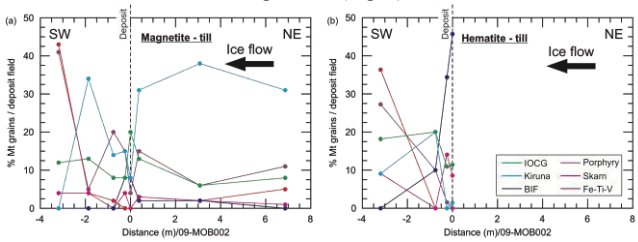

Figure 1: Magnetite and hematite proportion of grains falling in different deposit fields relative to the distance from the Sue-Dianne deposit.

Thompson Ni-Cu deposits

The 0.25-1 mm ferromagnetic fractions of 7 till samples are along a N-S profile along the first direction of ice-flow. In addition, 11 till samples were selected to document a 180 km-long cross-section from the Pikwitonei domain (East) across the Thompson Nickel Belt, Manitoba, Canada, and into the Kisseynew domain (West) along the direction of the last major ice flow movement. The proportions of magnetite having a Ni-Cu deposit signature in the Ni+Cr vs. Si+Mg discriminant diagram increase for at least 2 km to the south of the Pipe Mine along the direction of the first glacial movement, whereas the dispersion of the deposit-derived magnetite to the west is limited during the second glacial movement (Fig. 2)

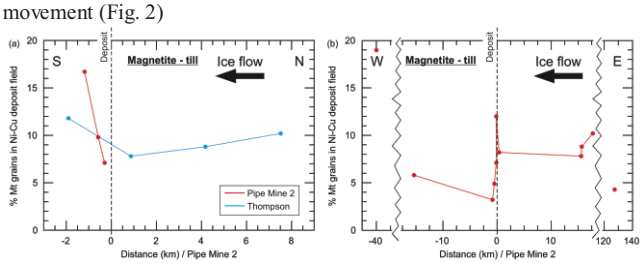

Figure 2: Magnetite proportion of grains falling in the Ni-Cu deposit field relative to the distance from Pipe Mine 2 deposit, Thompson Nickel Belt.

The unconformity-related U-deposits of the Athabasca Basin represent an increasingly important energy resource (18% world's U-reserves) [1] and have been used as natural analogues for the deep geological disposal of radioactive waste products [2]. Since these deposits serve as large-scale natural records of U redox reactions, understanding their formation will contribute to reducing U mobility around contaminated environments. Multiple alteration and uranium mineralization events occurred throughout the basin's history [3] however the role of authigenic, diagenetic and hydrothermal alteration minerals in the reduction of uranium and subsequent precipitation of uraninite is not well understood. Graphite and various other organic compounds have been proposed as possible solid phase reductants [4] but more recent studies suggest the oxidation of Fe in alteration minerals may have played a role in the reduction of U in the Athabasca Basin [5]. In order to better understand the relationship between Fe and U, synchrotron based μXRF and μXAS experiments were conducted on altered and relatively unaltered samples from the McArthur River deposit using the VESPERS beamline at the Canadian Light Source. The distribution of Fe and U as well as other trace elements were determined by collecting μXRF element distribution maps on specific Fe-bearing alteration minerals. XANES and EXAFS spectra were measured on Fe-bearing clay and sulfide minerals, which were selected on the basis of their paragenesis, U concentrations and their proximity to the ore zone. The oxidation states of Fe and U were determined by measuring U LIII and Fe Kα absorption edges and in some cases EXAFS was used to further determine the speciation of U. Results indicate the distribution of U is closely related to that of Fe in proximity to the ore zone but become inversely related with increasing distance away from the ore zone. Variations in the shape of the Fe Kα pre-edge as well as the edge location, measured on similar phases, were attributed to changes in oxidation states. Least altered samples contained abundant reduced Fe and negligible U whereas higher uranium concentrations, and mixed Fe and U oxidation states were observed in altered samples. This study further suggests that Fe-bearing minerals played an important role in the redox processes involved in the formation of the McArthur River U deposit.

Proton and metal adsorption onto oxidized graphene

THOMAS DUSTER[1*], CHONGZHENG NA[1], HAITAO WANG[1], AND JEREMY FEIN[1]

[1]Department of Civil Engineering and Geological Sciences, University of Notre Dame, Notre Dame, IN, USA, tduster@nd.edu (* presenting author)

Oxidized graphene is produced from the chemical or mechanical exfoliation of oxidized graphite, and the resulting particles exhibit distinct physical, electrical, and thermal properties ideal for use in advanced materials, sensors, and transistors. The increasing utility of these materials suggests a strong likelihood for current and future environmental releases, and it will be important to understand the interactions between these particles and other environmental constituents. For example, due to a relatively high surface area to mass ratio and the presence of a variety of proton-active function groups, oxidized graphene may significantly influence the partitioning of metals via adsorption in environments where they exist. However, the surface chemistry and reactivity of oxidized graphene are poorly characterized. In order to construct quantitative surface complexation models of the effects of oxidized graphene adsorption on the distribution of metals in geologic systems, stability constants for the important oxidized graphene surface complexes must be determined. Hence, the objective of this study was to evaluate the capacity of oxidized graphene to adsorb protons and metals via potentiometric titrations and batch adsorption studies, respectively. Target metals included Cd, Pb, Ca, and U, and all adsorption studies were conducted over a wide pH range of approximately 2 to 10 in 0.1 M $NaClO_4$ solutions to buffer ionic strength. The potentiometric titration data indicate that oxidized graphene exhibits proton adsorption over a wide range of pH, and the data constrain the pKa values and site concentrations of the binding sites on the oxidized graphene surface. The batch metal adsorption measurements indicated extensive and strong adsorption of metals by oxidized graphene particles, with increasing adsorption with increasing pH. The pH dependence is consistent with measurements of electrochemical surface properties that indicate a more negative ζ-potential at higher pH values. Using the proton-active site concentrations determined from the potentiometric titrations, the metal adsorption data enable us to determine the thermodynamic stability constants for each of the important surface complexes. Through comparison of these stability constants to those for other environmental surfaces, we consider the propensity of oxidized graphene to influence the distribution of metals in natural and engineered systems.

The international GEOTRACES program has been organized to study the oceanic processes that control the oceanic distribution of trace elements in the ocean. Nd isotopes measurements represent a promising tracer to study past and present ocean circulation. However the processes that control the distribution of this tracer in the ocean are still not perfectly understood. Modeling represents a unique tool to improve our understanding on this trace element in the ocean. We will present some modeling studies where we have explicitly implemented this tracer in the General circulation model NEMO. The modeling studies has allowed us to progress in our understanding of Nd cycle in the ocean and to investigate the fluxes that dominate the Nd Input in the ocean, and to apprehend the relevant processes that control the internal oceanic cycle. We then show some results from past climate, focusing on the closure of the Panama Isthmus and its impact on the climate and the oceanic circulation during the Miocene.

Using Bulk Paleosol Organic Matter to Reconstruct Atmospheric $\delta^{13}C_{CO2}$

S.I. DWORKIN[1], L.C. NORDT[1], S.ATCHLEY[1]

[1]Department of Geology, Baylor University, One Bear Place 97354, Waco, TX 76798 USA

*Correspondance: Steve_Dworkin@Baylor.edu

The carbon isotopic composition of dispersed organic matter in paleosols has the potential to provide two of the input parameters into Cerling's [1] atmospheric pCO_2 paleobarometer equation. These variables are the $\delta^{13}C_{CO2}$ of the atmosphere and the $\delta^{13}C$ of soil respired CO_2. The isotopic composition of marine carbonates has often been used as a proxy for the composition of the atmosphere however, tenuous correlations between marine and terrestrial rocks limits the resolution of resulting atmospheric pCO_2 reconstructions. Additionally, bulk paleosols provide a terrestrial continuum of values for the paleosol barometer as opposed to the sporadic occurrence of coals or charcoal. Therefore, this study investigates the use of dispersed organic matter in paleosols as a record of atmospheric $\delta^{13}CO_2$.

Modern soils have not provided much insight into the likelihood that an atmospheric signal will be preserved in paleosol organic matter. Soil organic matter (SOM) in modern soils typically displays an increase in $\delta^{13}C$ with depth casting doubt on its isotopic reliabily in the rock record. The multitude of conflicting theories that have been proposed to explain modern depth trends in $\delta^{13}C$ of SOM [2] may indicate that the modern is not an appropriate analogue for ancient soils. We therefore turn to the rock record for evidence of a preserved atmospheric signal in bulk paleosol organic matter. Only pre-Miocene paleosols are considered in this study to avoid the confounding presence of C_4 plant material which would add an additonal pool of organic matter with its own distinct atmospheric signal. Additionally, none of the studied paleosols exhibit macroscopic evidence of extreme drought conditions, an environmental stress that significantly alters the atmospheric carbon isotope signal preserved in fossil plants.

The successions of stacked paleosols that we have studied (Late Cretaceous/EarlyTertiary in west Texas and Late Triassic in eastern Arizona) have the following characteristics: 1.) Low organic carbon contents (<0.05 wt. %), 2.) No correlation between organic matter abundance and carbon isotopic composition 3.) Carbon isotopic compositions that are similar to modern C_3 plants, 4.) No consistent relationship beween soil depth and $\delta^{13}C$ of SOM, 5.) Presence of temporal trends in the $\delta^{13}C$ of SOM that can be correlated to $\delta^{13}C$ trends in coeval marine carbonates, and 6.) Carbon isotopic compositions that are similar to terrestrial organic matter of the same age from different geographic locations.

Based on these observations, it appears that dispersed organic matter in bulk paleosol samples has the potential to preserve a carbon isotope ratio that reflects the composition of the ancient atmosphere and may be used for quantitative atmospheric reconstructions.

Constraining tropical climate sensitivity: the need for improved Mg/Ca calibrations

KELSEY A. DYEZ[1]*, A. CHRISTINA RAVELO[2]

[1]Earth and Planetary Sciences Dept., UC Santa Cruz, Santa Cruz, CA, USA, kelseydyez@gmail.com

[2]Ocean Sciences, UC Santa Cruz, Santa Cruz, CA, USA, acr@ucsc.edu

Abstract

One way to estimate how Earth's average surface temperature will increase with rising greenhouse gas concentrations (Earth system climate sensitivity) is to compare contemporaneous temperature and greenhouse gas concentration data from paleoclimate records. Since numerical models indicate that the tropical climate sensitivity is lower and more tightly constrained than global or high-latitude climate sensitivity, measurements of tropical climate sensitivity can be considered as a lower bound for global climate sensitivity estimates. Here we measure Mg/Ca of surface foraminifera *G. ruber* from ODP Site 871 from the past 800 kyr in the western Pacific warm pool to estimate tropical Pacific equilibrium climate sensitivity to a doubling of greenhouse gas concentrations to be ~4ºC. This tropical SST sensitivity to greenhouse gas forcing is ~1-2 Cº higher than that predicted by climate models of past glacial periods or future warming for the tropical Pacific.

Further, this record of past sea-surface temperature (SST) makes use of the relationship between the Mg/Ca ratio of surface foraminifera and mean annual temperature to estimate past SST. Since high-Mg calcite in modern core-top material preferentially dissolves at water depths as shallow as 1.6 km, well above the lysocline, a correction for such dissolution is necessary. Here we present a new type of dissolution correction for Mg/Ca-based paleotemperature estimation based on a regional core-top calibration from the tropical Pacific [data from 1]. We correct the Mg/Ca data for the loss due to dissolution and then apply the corrected value to the accepted Anand equation [2], since dissolution directly affects the Mg/Ca content of the tests. When applied to existing SST records the new correction decreases the observed glacial-interglacial range of SST. Such a depth-based dissolution equation is especially important for estimating the sensitivity of surface temperatures to changes in radiative forcing, such as atmospheric greenhouse gas concentrations. We recommend such a dissolution correction for all Mg/Ca-based temperature records from open ocean, low productivity sites.

[2]The National Geological Survey of Denmark and Greenland, Øster Voldgade 10, 1350 Copenhagen K, Denmark tfk@geus.dk

Essential differences between magmas in subduction zones and magmas in intraplate or MORB type settings have become apparent with an increasing number of ^{238}U-^{230}Th disequilibria data on recent volcanic rocks. Mid-ocean ridge and ocean island magmas are characterized by enrichment of thorium relative to uranium, whereas magmas related to subduction zones have been shown to vary from ^{230}Th-excess to ^{238}U-excess. In fact, radioactive equilibrium of ^{238}U and ^{230}Th (activity ratios = 1) seems to be a typical feature of many arc magmas, particular in continental arcs. We investigate three volcanic centers located in the main Andean arc and into the backarc system in order to constrain the influence induced by fluids in subduction zones.

The new U-series disequilibria analyses from the Andean backarc system support the OIB-character of the Payún Matru volcano, and the more fluid influenced arc-like character of the Infernillo volcano. Results from Maipo show radioactive equilibrium. For all samples the ($^{234}U/^{238}U$) ratios are within 1% of secular equilibrium, supporting evidence for the samples being unaffected by significant alteration.

The Infernillo samples plot beneath the equiline with 5-10% excess of ^{238}U. This feature is characteristic of those arcs deviating from equilibrium and is best ascribed a slab-derived fluid enrichment of the mantle source beneath Infernillo. The excess of ^{238}U also requires that the fluid addition occurred within the last 300 ka. In contrast data from the Payún Matru volcano show 5% excess of ^{230}Th, and plot within the ocean island basalt field as defined by literature data. In the case of OIB, partial melting is the main process fractionating Th/U and thus producing the $^{230}Th/^{238}U$ disequilibria. Analyzed samples are of Holocene age and the relatively low disequilibrium could indicate that melting induced fractionation between U and Th was limited due to shallow melting above the garnet stability field. This is supported by evidence from trace elements (e.g. low Dy/Yb).

Determination of soil organic C species using soft X-ray XANES: normalization & matrix effects

JAMES J. DYNES[1*], TOM REGIER[1], DAVID CHEVRIER[1], ADAM W. GILLESPIE[2], AND DEREK PEAK[3]

[1]Canadian Light Source, Saskatoon, Canada, james.dynes@lightsource.ca (* presenting author) tom.regier@lightsource.ca david.chevrier@lightsource.ca
[2]Agriculture & Agri-Food Canada, Ottawa, Canada adam.gillespie@agr.gc.ca
[3]University of Saskatchewan, Dept. of Soil Science, Saskatoon, Canada derek.peak@usask.ca

Soil organic matter (SOM) storage and turnover are affected by the chemical nature and properties of its constituents, particularly the chemical forms of organic C. Synchrotron-based soft X-ray absorption near edge spectroscopy (XANES), probing the atomic and molecular structures of materials, is being used to provide information on the types of C functional groups (e.g., C=O, C-OH, R-COOH) in SOM [1]. This type of information is required to fully understand the global C cycle.

Normalization of C K-edge TEY and TFY data has always been a challenge due to the C contamination in soft X-ray beamlines, imparting features into the incident x-ray flux (i.e., Io). The mineral fraction of the soil also contributes to the TEY and TFY signal, in ways not fully understood. Hence, there is concerns that artefacts such as erroneous peaks and/or spectral distortions may be introduced into the C K-edge total electron yield (TEY) and total fluorescent yield (TFY) spectra during the normalization of the raw data and/or into the raw data from the matrix itself (e.g., adsorption saturation), particularly at low soil C content. Both of these could result in incorrect conclusions being reached. To date, no fundamental studies have been conducted that address normalization issues and matric effects in known systems as a function of organic C content, organic functionality and in different matrices.

At the SGM beamline, at the Canadian Light Source, we are studying model systems consisting of varying amounts (50 to <1% (w/w)) of an organic compound with different function groups (e.g., citric acid, phthalic acid, glucose, tannic acid) mixed with a soil constituent (e.g., Al hydroxide, kaolinite, montmorillonite, Fe hydroxide). The organic-matrix mixtures are deposited onto various substrates (e.g., Au coated Si wafers) and TEY and TFY spectra are collected under a variety of conditions such as in the presence and absence of a Ti filter and/or reducing radiation dose rates (C is susceptible to radiation damage at high radiation doze rates and/or in the presence of certain elements such as Cu [2]) by conducting fast scans (20sec) versus normal scans (1500sec). Determination of the appropriate Io using different detection methods such a photodiodes and the collection of TEY and TFY of a variety of substrates such as Au coated Si wafers and C-free matrixes are being explored to normalize the data. From this fundamental approach it is expected that a protocol will be developed that reduces the possibly that artefacts are introduced during the normalization process and/or during the collection of the raw data due to matric effects. Also, the study will provide insight into factors that affect the C detection limit of the soft X-ray. Moreover, this project is part of an initiative to make the SGM beamline a center for Soil Science studies.

Surface Complexation Models and their Practical Application

DAVID DZOMBAK[1]

[1]Carnegie Mellon University, Dept of Civil and Environmental Engineering, Pittsburgh, PA 15213, USA. dzombak@cmu.edu

Abstract

While surface complexation theory and models for the description of inorganic ion sorption on mineral surfaces have advanced continuously since the introduction and initial development of these models in the 1970s and 1980s (reviewed in [1]), so too has the practical application of the models. Deployment of surface complexation models to interpret and predict water-mineral partitioning of ions in geochemistry and engineering applications is challenging because of the complexity of these systems, the limitations of the models, the lack of surface complexation databases for all of the minerals of interest, and other factors. The substantial progress in application of surface spectroscopy methods and molecular modeling to increase understanding of the properties of mineral surfaces and the nature of their reactions with ions has been of limited usefulness in constraining surface complexation models [2,3] and has done little to advance their practical application. Of necessity, there is still widespread use of empirical isotherms and distribution coefficients (K_d) to describe and simulate ion sorption processes in field systems. However, surface complexation models have been applied in a variety of contexts to gain insight into the role of sorption reactions in governing the fate and transport of particular ions, and in governing overall system chemistry.

This talk will provide an overview of the development of surface complexation models, and the history of their practical application. Examples from modeling of ion transport in geochemical systems and from contaminant treatment and remediation will be described. The strengths and limitations of the models for practical applications will be examined. Some thoughts about developments needed to advance the practical application of surface complexation models will be offered. The divergence yet complementarity of surface complexation research focused on advancement of basic scientific understanding of mineral-water surface phenomena, and research motivated by practical applications will be discussed.

Primordial Delivery of Potassium to Mercury and Enstatite Chondrites

DENTON S. EBEL[1,2,3*], CONEL M. O'D. ALEXANDER[4], AND RICHARD O. SACK[3]

[1]American Museum of Natural History, New York, NY USA, debel@amnh.org (* presenting author)

[4]Carnegie Institution of Washington, Washington, DC, USA alexander@dtm.ciw.edu

In orbit around Mercury, gamma and x-ray spectrometers on the MESSENGER spacecraft return data indicating terrestrial K/Th [1] and high S/Si ratios [2] in the Mercurian mantle. Sulfur behaves as a refractory element in a vapor of solar composition that is enriched in a dust of anhydrous chondritic interplanetary dust particle (C-IDP) composition [3]. This scenario allows for accretion of Mercury from primordial disk solids in equilibrium with vapor at high temperatures, and suggests a similar origin for the highly reduced enstatite chondrites. Potassium, however, should be strongly depleted in such a scenario. But current equilibrium condensation calculations [3] do not include the refractory phase djerfisherite, ~$K_6(Fe,Ni,Cu)_{25}S_{26}Cl$, an important carrier of K in EH enstatite chondrites [4].

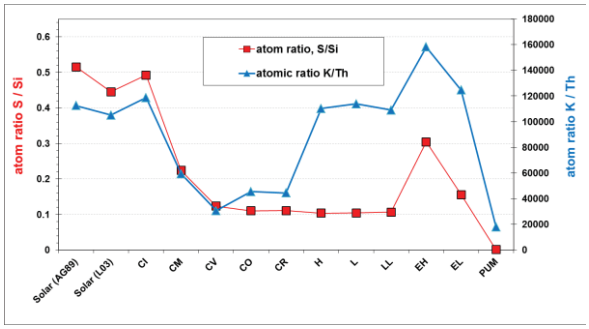

Figure 1: K/Th and S/Si ratios in solar compositions [5,6], carbonaceous chondrites (CI, CM, CV, CO [7] CR [8]), ordinary chondrites (H, L, LL [7]), enstatite chondrites (EH, EL [7]), and primitive upper mantle (PUM [9]).

It was shown by [3] that CaS, FeS and MgS are stable solids above 1100 K in vapor enriched above ~700x (atoms) in C-IDP dust. Little is known of the thermodynamic properties of djerfisherite. To first order, the free energy of djerfisherite may not differ substantially from that of FeS. If so, the abundance of K in both enstatite chondrites and Mercury may be consistent with their accretion from solides formed in equilibrium with highly reduced, C-IDP dust-enriched vapor at high temperature.

Metal fractionation in the water column of a former U open pit mine

FRIDA EDBERG[1*], TERESIA WÄLLSTEDT[2], HANS BORG[1] AND SARA. J. M. HOLMSTRÖM[2]

[1]ITM, Stockholm University, SE-106 91, Stockholm, Sweden
Frida.edberg@itm.su.se (* presenting author)
[2]IGV, Stockholm University, SE-106 91, Stockholm, Sweden

Objectives, background and methods

Lake Tranebärssjön, a former open pit mine in Ranstad in Sweden has an interesting geochemistry; slightly alkaline, groundwater fed, stratified with high sulphate and metal concentrations and with an anoxic hypolimnion. The aim of this study was to investigate the partitioning of metals in the water column by (i) different size fractions: 0.45 µm filters, and ultrafiltration (10 kDa, 3 kDa and 1 kDa) and (ii) compare the analytical results with chemical equilibrium modeling calculations using Visual MINTEQ including Stockholm Humic Model (SHM). The hypothesis was that a more thorough examination of the distribution of metals in the water column would reveal that the size fractions of metals differs strongly between water layers with deviating geochemical conditions. The findings of the study could be relevant for restoration and remediation of mining sites.

Results and conclusions

The chemical analyses showed a stratified lake with an anoxic hypolimnion and high total concentrations of metals including Fe, Ca, Mn and U as well as sulfate and carbonate anions. The extremely high Fe concentration increased with depth and was dominated by particulate and colloidal fractions (>1 kDa) in the epilimnion, whereas in the hypolimnion the dissolved fraction (<1 kDa) held the major part. This was confirmed by analysis of Fe(II) which showed that in the epilimnion Fe(II) constituted less than 1% of the total Fe in contrast to the hypolimnion where Fe(II) made up 95% of the total Fe. For Mn, U, Ca, Co, As and Mo, the dominating fraction in both the epilimnion and the hypolimnion was the dissolved fraction. This is supported by the equilibrium model that suggests soluble inorganic complexes as the dominant species, with the exception of As where the model suggests that the major part is adsorbed to ferrihydrite and U in the hypolimnion for which the model suggests oversaturation with respect to uraninite. For U this partly agrees with the fractionation results as the particulate and colloidal fractions (>1 kDa) where about 30% in the hypolimnion.

Our study shows that the results of the size fractionations agreed well with the models using chemical equilibrium calculations for the water in Lake Tranebärssjön. However there are limitations in the models in the speciation of, e.g. U and of As in waters with high concentrations of Ca and carbonate, which need further investigation. High metal concentrations are still an environmental problem in Lake Tranebärssjön. The fractionation study indicates that a major part of many metals exist in the dissolved form in the anoxic hypolimnion and/or the epilimnion, and can thus be transported to downstream waters during lake turnover.

Highly Swellable Glass Composite Materials For *In Situ* Groundwater Remediation and Organic Vapor Permeable Proppants

PAUL L. EDMISTON[1,2*], DEANNA C. PICKETT[2], JEAN QUENNEVILLE[1]

[1]College of Wooster, Ohio, USA pedmiston@wooster.edu (* presenting author)

[2]ABSMaterials, Wooster, Ohio, USA, d.pickett@absmaterials.com

Abstract

Osorb is an organosilica material that swells in contact with organic compounds, but is impermeable to water. Swelling is substantial leading to absorption of up to 8 times the dry mass of the initial material with concomitant generation of mechanical forces in excess of 500 N/g [1]. The unique properties lead to a wide variety of sub-surface applications. Iron-Osorb® is a solid composite material of swellable organosilica with embedded nanoscale zero-valent iron that was formulated to extract and dechlorinate solvents in groundwater. The unique feature of the highly porous organosilica is strong affinity for chlorinated solvents, such as trichloroethylene (TCE), while being impervious to dissolved solids. The swellable matrix is able to release ethane after dechlorination and return to the initial state. Iron-Osorb was determined to be effective in reducing TCE concentrations in bench-scale experiments. A series of three pilot scale tests for *in situ* remediation of TCE in conjunction was completd in conjunction with the Ohio Environmental Protection Agency at a site in central Ohio [2]. In addition, Osorb has wide ranging uses in the oil and gas industry. The material has been evaluated for use as an proppant additive for selective and enhanced flow rates of hydrocarbons in wet environments, water management, and down-hole tooling.

From tectonic gateways to diatoms: the build-up to Antarctic glaciation

KATHERINE E. EGAN[1*], ROSALIND E.M. RICKABY[1], KATHARINE R. HENDRY[2], ALEX N. HALLIDAY[1]

[1]University of Oxford, Oxford, UK, katherine.egan@exeter.ox.ac.uk (* presenting author)

[2] School of Earth and Ocean Sciences, Cardiff University, Cardiff, UK, (HendryKR@cardiff.ac.uk)

The Eocene-Oligocene boundary witnessed an end to the Earth's greenhouse climate and the abrupt initiation of modern icehouse conditions. Understanding the mechanisms which drove this fundamental shift is essential to a better comprehension of rapid climate response to gradual forcing. It has been suggested that enhanced marine organic carbon export and burial contributed to a drawdown of atmospheric CO_2 which triggered Antarctic Glaciation. We investigate this theory using the novel combination of sponge $\delta^{30}Si$ (a proxy for deep water silicic acid concentration, results from this study and [1]) and diatom $\delta^{30}Si$ (indicating diatom nutrient utilisation) at ODP sites 689 (sponge) and 1090 (diatom) in the Southern Ocean.

Our records, spanning 38-31Ma, document a dramatic increase in Southern Ocean intermediate/deepwater silicic acid concentration between ~35.5Ma and 34.5Ma. A build up of diatom production and global carbon export from 35.5Ma to the Eocene-Oligocene boundary is also implied. We hypothesise that prior to 35.5Ma ocean circulation was sluggish and driven by sinking at high southern latitudes. This drew down surface waters advected from the equatorial regions, bathing the seafloor in a low nutrient (and silicic acid) water mass, in a similar fashion to modern North Atlantic Deepwater. With ongoing subsidence of the Drake Passage and Tasman Gateway, a proto-Antarctic Circumpolar Current became established. From around 35.5Ma, this wind driven current increased the rate of ocean overturning and nutrient re-supply to surface waters, stimulating diatom productivity and increasing global organic carbon export. Thus, the gradual deepening of tectonic gateways prior to the establishment of permanent ice sheets on Antarctica may have driven organic carbon burial and contributed to the CO_2 drawdown that initiated glaciation.

Determining historic extent of seagrass (*Zostera marina*) cover in Virginia's coastal bays

NOAH E. EGGE[1*] AND STEPHEN A. MACKO[1]

[1]Department of Environmental Sciences, Univeristy of Virginia, Charlottesville, Virginia, 22904 USA
noah@virginia.edu (* presenting author)

The environmental degradation of the Chesapeake Bay and its neighboring coastal areas has been linked with explosive population growth and subsequent increases in agriculture and urbanization of the region. In the coastal bays of Virginia, numerous efforts have been made to restore seagrass (*Zostera marina*) meadows. As a result of large-scale, seed-based restorations in South Bay (2001) and Hog Island Bay (2007), *Z. marina* has come to dominate portions of these bays.

In this study geochemical proxies are used to determine the historic extent of seagrass within Virginia's coastal bays. Sedimentary cores were collected from sites with different historical records of seagrass cover, including areas with no seagrass, reseeded seagrass, or naturally occurring seagrass. Carbon and nitrogen isotope analyses were conducted on freeze-dried, acidified samples and used as proxies of the sources of the organic matter; sediments dominated by seagrass contained organic matter more enriched in ^{13}C relative to autochthonous algal and plaktonic marine materials. Peak ^{137}Cs activity and overall inventory were used to infer the relative age of sediments.

Several features are apparent from the preliminary characterization of marine sediments from these locations. The reseeded areas of South Bay and Hog Island Bay have a similar antithetical relationship between TOC (total organic carbon) and $\delta^{13}C$ values in the topmost 15 cm of the sediment core; as the TOC increases the $\delta^{13}C$ values become more depleted, suggesting that in those samples, seagrass provides only a minimal contribution to the preserved organic matter. Additionally there are large sections of the cores, at approximately 20 cm depth within the cores taken from South Bay, that have significantly lower TOC; this could be a result of the period without seagrass cover. The site with a natural seagrass meadow in Hog Island Bay is unlike any of the other sites analyzed: TOC increases from 0.2% at the surface to 1.2% at the bottom of the core, while $\delta^{13}C$ values range from -17.7‰ at the surface to -24.3‰ at depth. This pattern suggests an increased accumulation of ^{13}C depleted organic material in areas with prolonged seagrass cover. Results from this study may be able to be used to infer the spatial extent of the historic seagrass and guide future restoration projects.

Iron Oxidizing Bacteria: Influence of Calcium and Magnesium on Growth Rates

T. EGGERICHS*, S. JEROFKE, T. OTTE, O. OPEL AND W. RUCK

Leuphana University of Lueneburg, Lueneburg, Germany,
(*correspondence: eggerichs@leuphana.de)

Occurring in wells, pipework, and in natural groundwaters, the oxidation of ferrous iron is a partly abiotic-, partly biotic-induced process.

Whilst chemolithoautotrophic bacteria, such as *Gallionella* spp. rely solely on ferrous iron oxidation as energy source, other heterotrophic organisms, *Lepthothrix* spp. for example, can apply their ability to catalyze ferrous iron oxidation. Furthermore, their ability to oxidize iron is nearly all of what is known about these bacteria, save for some findings made by studies concerning their requirements (carbon metabolism [1, 2], Mn oxidation [3], O_2, pH [4]). But knowledge regarding other their nutritional or habitat needs or other requirements is still scant.

The study established that calcium and magnesium concentrations influence *Gallionella* sp. and *Lepthothrix discophora* growth, as concentrations of these two cations vary over a wide range in natural groundwaters and are routinely analyzed. Therefore, the results from the kinetic approach based on laboratory experiments can be compared with Ca and Mg concentrations in waters. A large data base of literature values, combined with own measurements of waters with high ferric iron precipitation rates, where these organisms have been detected, has been used.

Ca and Mg concentrations in culture media were made to undergo variations over a range covering typical natural groundwaters values (Ca: 0.6-150 mgL^{-1}, Mg: 0.12-24 mgL^{-1}). Using optical density and TOC measurements as well as light microscopy, growth rates and maximum cell densities of the model organisms were determined in batch culture. Lowering the two cations corresponding to values in soft natural groundwater reduced both the growth rates and maximum cell densities. Growth occurred even at low nutrient concentrations.

The two organisms used in this study grow more slowly under natural conditions than in artificial culture medium, even at sufficient Ca and Mg concentrations.

Other factors evidently inhibit the growth of the two model organisms more than Ca and Mg do. In very soft groundwaters though, Ca and Mg concentrations, among other factors, may lead to reduced growth rates of *Gallionella* sp. and *Leptothrix discophora*.

Natural solar cells on Earth and Mars

CARRICK M. EGGLESTON[1*], BRUCE A. PARKINSON[2]

[1]Geology and Geophysics, [2]Chemistry, University of Wyoming, Laramie, USA, carrick@uwyo.edu (*presenting author), bparkin1@uwyo.edu

Introduction

There are a range of natural settings in which semiconducting minerals can play a role in driving photochemical reactions that generally involve interfacial electron transfer. Surface, bulk, and defect states of the minerals interact. We present 3 examples of naturally-occurring semiconductor systems that may help drive chemical processes to a degree not previously appreciated.

Example 1: Rock Varnish

There is renewed interest in rock varnishes because they may be biogenic. Some varnishes are rich in iron and manganese oxides, and can produce photovoltages. Hypothetically, sunlit varnishes can oxidize water and other materials, driving a redox cycle that supports the varnish-associated bacteria in a hybrid inorganic-biological system.

Example 2: Perchlorate in Mars polar soil

The Wet Chemical Laboratory on the Mars Phoenix Lander found that perchlorate is remarkably concentrated in the sampled soils, rivaling chloride as the most abundant anion [1]. We have shown that chloride in solutions exposed to TiO_2 (anatase and rutile) surfaces and sunlight can be readily oxidized to perchlorate (20% initial current efficiency, decaying with time). The lowest perchlorate production rates we record, if operating on <0.1% of the Mars surface, are still 2000 times faster than the current atmospheric deposition rates in the Atacama [2].

Example 3: Natural tandem cells for solar hydrogen

The products of sulfide mineral surface oxidation include soluble sulfates and, often, insoluble metal ions. Fe(III) or Mn(IV)-rich oxides and oxyhydroxides often form thin surface layers on sulfides during the incipient oxidation of the sulfides. This constitutes a natural two-semiconductor "tandem cell". Sunlight on the outer oxide layer can produce valence band holes that readily oxidize many species including water; light transmitted by the oxide layer can be absorbed by the underlying narrower bandgap sulfide. Sulfide valence band holes receive electrons from the oxide conduction band, leaving sulfide conduction band electrons available as reductants (e.g., form H_2 from H^+). We show that Fe-based tandem cells can oxidize water and produce H_2 at rates ~10^4 times higher than needed to explain all water loss from Mars, and intriguingly, at about the same rate that iron deposition in Banded Iron Formations has been estimated to occur. We therefore suggest that mineral semiconductor photochemistry could have played a role in widespread redox processes on Earth, as well as on Mars.

Deciphering the processes of crustal reworking during the formation of the Neoproterozoic Lufilian belt, NW Zambia

Introduction

Deciphering the source and *P-T-t* history of high grade metamorphic rocks exposed in the core of polycyclic orogenic blets is not an easy task. In this study, we combine structural analysis, metamorphic petrology and isotopic analyses of monazite and zircon to address these questions on the Lufilian Panafrican belt in Zambia.

Geological setting

The Lufilian belt formed between the Congo and Kalahari cratons during the evolution of the Gondwana supercontinent [2]. The classical interpretation is that this belt is comprised by a Paleo- to Neo-Proterozoic sedimentary cover deposited on an Archean to Paleoproterozoic crystalline basement and that its formation results from tectonic inversion of a continental rift [3]. Alternatively, the identification of a nappe structure with HP mineral relics led other authors to propose that the formation of the Lufilian belt implies closure of an oceanic basin by subduction and development of an orogenic wedge in a way similar to Phanerozoic orogens [4]. It is to note that both models consider that gneisses exposed at the lowest structural level represent a continental basement.

Results

Our field investigation across the Solwezi dome reveals that the transition from the metasedimentary cover to the gneissic basement actually corresponds to a metamorphic gradient reaching partial melting as evidenced by migmatites developed to the expense of metasedimentary protolith. U/Pb dating of zircon grains from the migmatite yields two clusters, one with a weighted mean $^{207}Pb/^{206}Pb$ age of 2032±46 Ma and a second with a weighted mean $^{207}Pb/^{206}Pb$ age of 1342±60 Ma. Zircon grains from paragneisses yield a weighted mean $^{207}Pb/^{206}Pb$ age of 2010±15 Ma. In turn, U-Th-Pb chemical dating of monazite grains from high grade micaschist (P=10±4 kbar, T=630±40°C) give an age of 571±29 Ma.

Discussion

Based on these data, we propose that the migmatite exposed at the lowest structural level of the Lufilian belt were developped to the expense of metasedimentary protolith containing zircon grains attesting for both Paleoproterozoic and Mesoproterozoic sources. This working hypothesis will be tested by new O and Lu-Hf isotpoic analyses on zircon grains coupled with U-Pb geochronology and geothermobarometry in order to reconstruct a P-T-t path for the metasedimentary rocks and for the migmatites. We will discuss their significance in terms of crustal growth and orogenic evolution during the Neoproterozoic.

Se cycling in the critical zone in a seleniferous area in Punjab, India.

E. EICHE[1*], A. NOTHSTEIN[1], T. NEUMANN[1], U. SADANA[2], K. DHILLON[2]

[1]Institute for Mineralogy and Geochemistry, KIT, 76131 Karlsruhe, Germany (*elisabeth.eiche@kit.edu)

[2]Department of Soil Science, PAU, 141004 Ludhiana, India

Elevated selenium concentrations of up to 12 mg/kg occur in top soils from agricultural sites of Jainpur and Barwa in the state of Punjab, North-West India. Selenium concentrations of corresponding groundwaters are higly variable showing maximum concentrations up to 340 µg/L and, therefore, clearly exceeding current guideline values of 40 µg/L [1].

The depth distribution of Se in the soil with highest contents in the top 15 cm (Fig. 1a) suggests that this element is mainly introduced by irrigation with Se rich groundwater. Recent studies indicate that the enrichment of Se in soils and, consequently, in plants has been increasing over the years. This could be explained either by a general increase of Se in the irrigation water and/or by a recent change in agricultural land use practice from wheat-maize to wheat-rice rotation out of which the second is more water intensive.

Considerable percentages of Se in soils seem to be bioavailable as indicated by sequential extraction studies and X-ray absorption measurements. However, the change in agricultural practice probably has an influence on the mobility of Se. Temporary occurence of stagnant and reducing conditions during rice cultivation may lead to immobilization of parts of Se in soils. This assumption is supported by the detection of Se(0) in the top soil. Furthermore, the Fe, As and Mn content in soils below 15 cm is condsiderably higher compared to the top soils (Fig 1b/c) indicating a redox-influenced downward translocation of these elements. Volatilization and/or uptake of Se by plants also seem to be important processes which determine Se cycling in the critical zone as lowest Se concentrations in topsoils occur in the upper 2 cm (Fig. 1a).

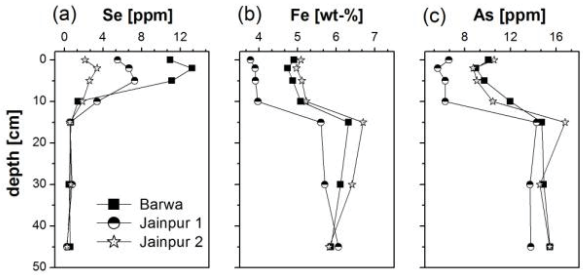

Figure 1: Depth distribution of Se (a), Fe (b) and As (c) in soil profiles from Barwa and Jainpur, Punjab, India.

Origin and evolution of reactive and noble gases dissolved in porewater of low-permeable crystalline rocks

FLORIAN EICHINGER[1,2], H. NIKLAUS WABER[2] AND JOHN A.T. SMELLIE[3]

[1]Hydroisotop GmbH, Schweitenkirchen, Germany, fe@hydroisotop.de

[2]Rock-Water-Interaction, Institute of Geological Sciences, University of Bern, Bern, Switzerland, waber@geo.unibe.ch (* presenting author)

[3]Conterra AB, Stockholm, Sweden, smellie@conterra.se

Reactive and noble gases dissolved in matrix porewater of low permeable crystalline bedrock were successfully extracted and characterized for the fist time based on drillcore samples from the Olkiluoto investigation site (SW Finland).

In crystalline bedrock systems, gases occur dissolved in fracture groundwater, matrix porewater and in fluid inclusions of rock forming minerals such as quartz and feldspars. Fracture groundwater and porewater, the latter being present in the inter- and intragranular connected pore space of the rock matrix, interact with each other predominately via diffusion. In contrast, mineral fluid inclusions represent isolated reservoirs without exchange for most gases under ambient conditions.

Reactive and noble gases dissolved in porewater and their isotope signatures carry valuable information about the evolution of a hydrogeological system. Information about origin and fluxes of dissolved gases is also important within the context of the safety assessment of a nuclear waste repository. For example, owing to their ability to buffer surface-derived dissolved oxygen, the occurrence of small amounts of hydrocarbons in fracture groundwater might be beneficial to safety assessment. In contrast, large amounts of hydrocarbons (mainly CH_4) in fracture groundwaters combined with dissolved sulphate may affect safety assessment adversely.

Changes in the chemical and isotopic composition of gases dissolved in fracture groundwater are transmitted and preserved in the porewater, which forms an archive for hydrogeochemical changes in the past. At Olkiluoto, core samples were collected along a continuos profile from a horizontal borehole that intersects with a major water-conducting fracture zone.. Porewater and present-day fracture groundwater are in transient state with respect to dissolved CH_4 and He concentration as well as the hydrocarbon mass ratio. Concen-trations of CH_4 and He are higher in the porewater and approach those of the fracture groundwater towards the water-conducting zone. For the encountered fracture system this indicates that the circulation of present-day low CH_4 and low He fracture groundwater has been to short to achieve equilibrium between the two reservoirs and CH_4 as well as He is now transferred along chemical gradients from the porewater into the fracture groundwater. Hydrocarbon mass ratios and $\delta^{13}C$-CH_4 values suggest the preservation of a small component of bacterially formed hydro-carbons in some parts of the pore water profile, whereas in fracture groundwater and porewater furthest away from the water-conducting zone only evidences for thermogenic formed hydrocarbons could be detected.

Preservation of lipid biomarkers of Fe(III)-reducers and anoxygenic phototrophic Fe(II)-oxidizers during exposure to high pressure and temperature (P/T)

MERLE EICKHOFF[1*], DANIEL BIRGEL[2], JÖRN PECKMANN[2], AND ANDREAS KAPPLER[1]

[1]University of Tuebingen, Center for Applied Geosciences, Geomicrobiology Group, Tuebingen, Germany merle.eickhoff@uni-tuebingen.de (* presenting author); andreas.kappler@uni-tuebingen.de

[2]University of Vienna, Department of Geodynamics and Sedimentology, Vienna, Austria daniel.birgel@univie.ac.at; joern.peckmann@univie.ac.at

Background

The rock record is analyzed to search for traces of ancient life on Earth. The fractionation of carbon, sulfur and iron stable isotopes, sedimentary structures, microfossils, as well as molecular fossils (lipid biomarkers), are important indicators for past life. Molecular fossils are persistent compounds that often derive from membrane lipids, recording biological activity in ancient rocks. They provide information on past environmental conditions as well as dominant microbial metabolisms and have been found in sediments as old as 1.6 Ga [1] and 2.5 Ga [2].

So far, molecular fossils have not been detected in Archean Banded Iron Formations (BIFs). The formation of these sediments is still controversial. Most likely, the earliest BIFs were deposited in the absence of significant amounts of oxygen [3,4]. Anoxygenic phototrophic Fe(II)-oxidizing bacteria were suggested being the most plausible mechanism for the deposition of the Fe(III) minerals under anoxic conditions [5]. Moreover, Fe(III)-reducing bacteria might have been involved in iron mineral transformation after deposition, as suggested by Fe and C isotope analyses [6].

Hence, Fe(II)-oxidizing and Fe(III)-reducing bacterial strains were chosen for a systematic biomarker study focusing on the fate of molecules during exposure to high pressure and temperature (P/T).

Current Research and Outlook

We present a new approach investigating the preservation of organic biomolecules of anoxygenic phototrophic Fe(II)-oxidizing and anaerobic Fe(III)-reducing bacterial cells during exposure to diagenetic conditions (P/T) in inert gold capsules. Analysis of fatty acids, alcohols and hydrocarbons was done before and after P/T exposure, with a focus on fatty acids and cyclic terpenoids. We determined how these lipid compounds are affected at increasing temperatures in the absence and presence of iron minerals. In particular, the close association of the iron minerals with the cells appears to have an influence on the stability and preservation of biomarkers. Moreover, in the future we are planning to extend this method to identify carotenoid pigments in the phototrophic Fe(II)-oxidizers and study their preservation.

In summary, the approach of simulating diagenetic and late-stage alteration will help identify stable and source-specific molecular fossils, and elucidate the likelihood of finding diagnostic biomarkers (and thereby evidence) for Fe-cycling bacteria in BIFs and other Fe-rich sediments.

The MAT-253 Ultra — a novel high-resolution, multi-collector gas source mass spectrometer

JOHN EILER[1*], MATTHIEU CLOG[1], MICHAEL DEERBERG[2], PAUL MAGYAR[1], ALISON PIASECKI[1], HANS-JUERGEN SCHLUETER[2], JOHANNES SCHWIETERS[2], ALEX SESSIONS[1], DANIEL STOLPER[1], NITHYA THIAGARAJAN[1]

[1]California Institute of Technology, Pasadena CA, USA, eiler@gps.caltech.edu (* presenting author)

[2]Thermo Fisher Scientific, Bremen, Germany, johannes.schwieters@thermofisher.com

We present the design, performance and representative applications of the MAT 253 Ultra – the first prototype of a new class of high-resolution gas source isotope ratio mass spectrometers.

The MAT-253 Ultra is a forward geometry double focusing sector mass spectrometer with a Nier-type gas source. Samples are introduced through capilary bleeds from any of 4 automated flexible bellows and/or a carrier-gas port. Ions enter the analyzer through an adjustable entrance slit (5 to 250 μm). The analyzer has a 23 cm radius magnet and is similar in scale and design to the Neptune Plus MC-ICPMS. The detector array consists of 1 fixed position and 7 moveable positions on 6 trolleys. An RPQ lens is positioned before the central detector position. Each detector position contains both an SEM and faraday cup detector; each faraday can be registered through any of 10 amplifiers varying in gain from 10^7 to 10^{12}.

Ion beams from m/z 1 to ~300 can be collected, with a ~15 % mass range for simultaneous collection. Useful ion yield is ~1 ion per 1200 molecules for CO_2 under standard analytical conditions and using a 250 μm entrance slit. The dynamic range in simultaneously measurable ion currents is ~10^{14}. Backgrounds are negligible in the central detector position when the RPQ is in use, permiting quantitative analysis of low intensity ion beams even with high source pressures. Mass resolving power (M/ΔM, 5%/95% definition) has been measured up to 26,000 and is routinely as good as ~22-24,000 — sufficient to separate most isobaric interferences among isotopologues of H-C-N-O-S molecular species; in particular, it permits separation of ^{13}C from D isotopologues and both from H adducts in alkanes and related organics. Analyzer system stability is routinely < 2ppm/hour, permitting precise analysis of small features on complex peaks. External precision for isotope ratio measurements of relatively intense ion beams are routinely 10's of ppm, relative; measurements of weaker ion beam using SEM detectors reach counting statistics limits down to external precisions of ~0.1 ‰.

The MAT 253 Ultra enables many previously impossible isotopic analyses of gases and volatile organics and their fragment and adduct ions. Demonstrated examples include: $\delta^{13}C$, δD and $^{13}CH_3D$ of methane; $\delta^{13}C$ of propane and many of its fragments (enabling position-specific ^{13}C determination); direct analysis of $\delta^{17}O$ $\delta^{18}O$, $\delta^{15}N$ and ^{15}N-^{18}O 'clumping' in N_2O and its NO fragment; $^{18}O^{17}O$ and $^{18}O_2$ in O_2; and clumped isotope analysis of CO_2 free of contaminant isobaric interferences.

Abstract

The Wadi Watir Delta in Sinai, Egypt consists of an alluvial and sandy clay aquifer underlain by impermeable Precambrian basement. The scarcity of rainfall during the last decade and high pumping rates has increased salinity and degraded water quality in the main water-supply wells along the mountain front and along the coast. This degradation has required a reduction in groundwater production.

The main factors controlling groundwater salinity in the delta are water-rock interaction, seawater intrusion, and mixing with deep saline water. Water chemistry and stable isotopes in groundwater including $^{87}Sr/^{86}Sr$, $\delta^{37}Cl$ and $\delta^{81}Br$, were utilized to evaluate the groundwater geochemical evolution, sources of groundwater mixing, and the amount of seawater intrusion along the coast. Also, $^{87}Sr/^{86}Sr$, $\delta^{37}Cl$ and $\delta^{81}Br$ of various aquifer rocks were determined to assist in understanding the groundwater flow system.

Inverse geochemical modeling was used to identify possible geochemical processes that account for the chemical and isotopic changes in groundwater. Possible models are presented that quantify the amount of water-rock interactions, mixing and evaporation.

The isotopic results were utilized to develop a three-dimensional, variable-density, flow and transport model using the SEAWAT modeling environment. The models were calibrated using groundwater level changes and salinity variation. The models estimate average annual groundwater recharge and simulate annual groundwater pumping, upwelling of saline water from beneath the well field, and seawater intrusion along the coast for different pumping scenarios.

Abstract

For many engineering applications, such as sealing tunnels, shafts and boreholes, it is necessary to limit fluid flow through fractures. The particle size of conventional cementitious grouts limits the size of fractures into which they can penetrate. To address this issue increasingly microfine and ultrafine cement grouts are becoming commercially available. Despite this the radius of penetration remains dependent on the grout viscosity alongside injection pressure, pumping rate, grout setting time and grout cohesion: lower viscosity aqueous solutions potentially have a greater radius of penetration. In addition cementitious grouts typically undergo volumetric shrinkage during setting. In many applications this change in volume may not be of particular importance but in others where a very low hydraulic conductivity is a critical design criterion, such as borehole sealing for carbon storage reservoirs and tunnel sealing for nuclear waste repositories, this reduction in volume may be significant.

This study investigates the use of microbially induced carbonate precipitation (MCP) as a technique for grouting fine aperture rock fractures. Two types of laboratory experiment have been conducted: sealing fractures at the 10cm-1m scale between transparent polycarbonate plates; and sealing artificial fractures within granite cores. We investigate both the hydraulic and mechanical properties of the MCP grout. We show that the grout has the potential to seal fractures with apertures less than 100 microns, that it can 'biologically re-heal' when damaged and that the shear strength can be greater than traditional cementitious grouts.

Multiple Sulfur Isotope Effects During Sulfite and Bisulfite Oxidation in Aqueous Solution

DANIEL L. ELDRIDGE[1*], SANG-TAE KIM[2], AND J. FARQUHAR[1]

[1]Dept. of Geology and ESSIC, University of Maryland, College Park, MD 20742 USA (*correspondence: eldridge@umd.edu)

[2]School of Geography and Earth Sciences, McMaster University, Hamilton Ontario, Canada, L8S 4K1.

The multiple sulfur isotope fractionations accompanying the oxidation of sulfite (SO_3^{2-}) and bisulfite (HSO_3^-) to sulfate via oxygen (O_2) have been investigated, revealing both normal (-) and inverse (+) fractionations depending on pH. These compounds are important reaction intermediates in the oxidation of biogenic and volcanogenic hydrogen sulfide (e.g., [1]) and can be used by a variety of prokaryotes for dissimilatory metabolism, including the processes of oxidation, reduction, and disproportionation (e.g., [2]). Reactions involving these compounds are also relevant to the sulfur cycle in a variety of environments, including hydrothermal hot springs (e.g., Yellowstone NP), the chemocline in euxinic water bodies, marine sediments, and the atmosphere (forming acid rain).

Buffered sulfite and bisulfite solutions were prepared in batch reaction vessels from sulfur dioxide (99.9+%, Sigma Aldrich) at a pH of 12.5 (corresponding to ~99.9% SO_3^{2-}) and 4.6 (corresponding to ~99.5% HSO_3^-) using a custom built glass vacuum line. Oxidation of sulfite/bisulfite was initiated after placing vessels in a temperature controlled water bath (stability of 0.01 ˚C) and introducing ultrapure oxygen (Airgas), enough to oxidize a fraction of the bisulfite/sulfite in solution. Residual sulfite/bisulfite was separated from product sulfate via acidification and cryogenic trapping of evolved SO_2, and both product and residual reactant were processed for isotopic analysis using standard techniques.

Table 1 shows the preliminary results of sulfite and bisulfite oxidation experiments conducted at 5.00±0.01˚C. At relatively low pH where bisulfite is dominant, product sulfate is isotopically *light* relative to reactant bisulfite by about 5.32 ‰ based on $^{34}S/^{32}S$. In contrast, at high pH where sulfite is dominant, product sulfate is isotopically *heavy* by about 4.48 ‰ relative to reactant sulfite. Variations in the $\Delta^{33}S$ and $\Delta^{36}S$ values approach the limits of detection, although small positive shifts in $\Delta^{33}S$ may accompany these reactions. The change in the direction of the fractionation based on speciation appears to be a new observation. It is clear that the isotope effects associated with these reactions are more complex than previously recognized.

pH	$10^3\ln(^{34}\alpha)$ (‰)	$\Delta^{33}S$ (‰)	$\Delta^{36}S$ (‰)
4.6 (2 exp.)	-5.32±0.10	0.018 ± 0.010	-0.1 ± 0.2
12.5 (4 exp.)	4.48±0.29	0.011 ± 0.040	-0.1 ± 0.1

Table 1: Fractionations ($^{34}\alpha=^{34}R_{product}/^{34}R_{reactant}$) determined for bisulfite (pH=4.6) and sulfite (pH=12.5) oxidation experiments at 5.00±0.01˚C. Uncertainties are 2σ standard deviations of repeat experiments (duplicate or quadruplicate).

Microbial-mineral-metal interactions in suspended aquatic floc

ELLIOTT, A.V.[1*]; PLACH, J.M.[1]; DROPPO, I.G.[2,1]; AND WARREN, L.A.[1]

[1]McMaster University, Hamilton, Canada, elliotav@mcmaster.ca (* presenting author)

[2]National Water Research Institute, Environment Canada, Burlington, Canada

Characterization of suspended floc trace element (TE) abundance and partitioning for Ag, As, Cu, Ni and Co across 6 variably impacted aquatic ecosystems identify floc to be a key trace element sequestration phase, concentrating TEs ~55x above that of surfical bed sediments. Further, floc TE geochemical partitoning patterns were highly conserved across systems, with amorphous Fe oxyhydroxides (FeOOH) consistently the most important sorbent phase for TE retention, regardless of physico-chemical conditions or elements involved. In contrast, surfical (0-0.5cm) bed sediment TE partitioning was more classically reflective of both system geochemical parameters and element-specific reactivity, indicating differing controls on TE sequestration by suspended versus bed sediment system compartments. Results indicate that floc TE uptake is biologically linked to floc microbial components. Imaging analysis of floc architecture reveals bacterial extracellular polymeric substances (EPS) as the major constituent of floc organics and physical bridging mechanism between floc-associated organic and inorganic constituents. Moreover, floc organic concentrations (live cells, EPS) directly predict floc-FeOOH concentrations. Thus while floc-FeOOH are the dominant TE sequestration phase, floc-associated organic and microbial constituents provide the critical foundation underpinning enhanced floc TE uptake through their structure role in the nucleation, precipitation and/or trapping of TE-reactive FeOOH; ultimately creating a distinctly different solid than surfical sediments in close proximity with differing controls on trace element uptake.

Kinetics of Rb isotope equilibration in Savannah River Site soils

J. M. WAMPLER[1], W. CRAWFORD ELLIOTT[1]*, EIRIK J. KROGSTAD[2], BERND KAHN[3], LAURA ZAUNBRECHER[1], AND DANIEL I. KAPLAN[4]

[1]Georgia State University, Atlanta, GA, USA, claylab@gsu.edu (* presenting author)
[2]Pacific Northwest National Laboratory, Richland, WA, USA Eirik.Krogstad@pnnl.gov
[3]Georgia Institute of Technology, Atlanta, GA USA, Bernd.Kahn@gtri.gatech.edu
[4]Savannah River National Laboratory, Aiken, SC, USA daniel.kaplan@srnl.gov

Most of the Rb and nearly all of the Cs in near-surface soils of the Savannah River Site (SRS) appear to be fixed in interlayer wedge zones within hydroxy-interlayered vermiculite (HIV) particles [1]. To further investigate this idea, we studied the equilibration of added, highly enriched ^{85}Rb with natural soil Rb under mildly acidic and mildly basic conditions. Consistent results from four soil samples in acidic suspension show equilibration of the added ^{85}Rb with from 4% to 6% of the soil Rb in one day, followed by continued slow equilibration until after two months about twice as much of the soil Rb had equilibrated with the added ^{85}Rb. Equilibration was faster and continued to greater extent when soil was suspended in $NaHCO_3$ solution, on average by a factor of about 2 in rate and extent. We attribute the faster and more extensive equilibration in basic suspensions to slight expansion of the vermiculite interlayers, and of the adjoining interlayer wedges, as hydrated Na ions replaced the natural exchangeable acidity and as hydroxy-Al polymers were neutralized.

Data obtained earlier by Goto *et al.* [2] show that equilibration of natural soil Cs with ^{137}Cs proceeds more rapidly and is more extensive than what we observed for Rb. Up to 20% of the soil Cs equilibrated with the added ^{137}Cs under mildly acidic conditions, and up to about 50% under mildly basic conditions, in just four days. We interpret the more rapid and more extensive equilibration of Cs than Rb with an added isotope to indicate that Rb is more deeply entrenched in interlayer wedges of HIV than is Cs, because Rb ions are smaller than Cs ions. This interpretation is in accord with results of another experiment in which we found that added Mg, whose hydrated ions keep vermiculite interlayers expanded, strongly enhances the rate of acid extraction of Cs from SRS soils but has little effect on the rate of extraction of Rb.

Interaction of Volatile Organic Compounds with Magnetite Nanoparticles: Fundamentals and Implications for Air Remediation

NERMIN ELTOUNY[1*], PARISA A. ARIYA[1]

McGill University, Chemistry, Montreal, Canada, nermin.eltouny@mail.mcgill.ca[1*]
McGill University, Chemistry and Atmospheric and Oceanic Sciences, Montreal, Canada parisa.ariya@mcgill.ca [1]

Introduction

Nanoparticles have become one of the most researched topics in the recent years as they are of interest to many fields. We are interested in the fundamental processes between organic vapours and iron oxide nanoparticle for their application in the remediation of polluted air.

Experimental Methods

We show the efficiency of iron oxide nanoparticles for the removal of organic vapours (BTEX) from air. We use various techniques including GC-FID, GC-MS, XRD, XPS and UV-VIS absorption spectroscopy to understand the interaction between gaseous organic molecules and iron oxide nanoparticles.

Results and Conclusion

We will discuss the role of the iron oxide nanoparticle heterogeneity in the interaction with aromatics vapours and the effect of organic vapours on the oxidation state of the iron oxide [1].

Determining the fundamental processes can yield information on the properties that dictate how iron oxide nanoparticles behave in the presence of organic vapours, which allows for improved designs of adsorption media as well better understanding of potential reactions in the environment.

Gas clathrate hydrate thermodynamics and kinetics: limits on near-surface volatile fluxes for cold terrestrial planetary systems through deep time.

MEGAN ELWOOD MADDEN[1*], MARGARET ROOT[1], SETH GAINEY[2] AND JOHN LEEMAN[1]

[1]University of Oklahoma, School of Geology and Geophysics, melwood@ou.edu (*presenting author),
[2]University of Nevada,Las Vegas, Department of Geosciences

Gas clathrate hydrates (a gas molecule such as CO_2, CH_4, H_2S, etc. trapped within a cage of water molecules) are thermodynamically stable at low-moderate temperatures and moderate-high pressures, conditions found near the surface of many terrestrial planetary bodies in our solar system, including Earth, Mars, Europa, Titan, Enceladus, and other icy moons. While gas hydrates are often thought of as ephemeral phases in Earth's ocean and permafrost sediments, they can serve as reservoirs for water, carbon, and other volatile phases over millions to billions of years. Hydrate stability zones (HSZ- the depth at which gas hydrates are thermodynamically stable given the P-T conditions) can extend to significant depths [1]. In addition, gas hydrate formation and dissociation rates below the freezing point of water are transport limited, relying on solid-state diffusion of gas to or from the ice-hydrate interface [2]. Slow gas diffusion rates through ice and hydrate at low temperatures result in geologically long-lived metastable gas hydrate reservoirs in the near subsurface.

Geologic models of gas hydrates in planetary systems must thefore consider both thermodynamic and kinetic constraints on clathrate reservoirs to better understand long-term volatile fluxes in the near subsurface. Gas diffusion as well as hydrate formation and dissociation rates are needed to effectively model these complex systems. Using gas hydrate formation and dissociation rates measured in our laboratory, we have developed a coupled thermodynamic and kinetic model of obliquity-driven changes in HSZs on Mars. This model suggests that gas hydrates may provide a significant reservoir for carbon and water within the crust over 10s of km depth. In addition, these hydrate reservoirs may remain thermodynamically stable over geologic timescales, and even when preturbed, may persist as metastable bodies for thousands to millions of years, resulting in significant long-term volatile fluxes. Similar geologic models of gas hydrate reservoirs on Europa, Titan, and Enceladus are underway.

Control of aqueous Mn(II) on Mn(III, IV)-oxide mineralogy and structure

EVERT J. ELZINGA[1*]

[1]Rutgers University, Newark, New Jersey, USA, elzinga@andromeda.rutgers.edu (* presenting author)

Mn oxides are among the most reactive mineral phases found in the environment, exerting strong control on the aqueous and solid phase chemistry of soils and sediments through adsorption and redox reactions. Natural Mn oxides are believed to be of predominantly biological origin, representing either primary products of biological Mn(II) oxidation, or secondary products resulting from alteration of primary bio-oxides [1]. Oxidation of Mn(II) by bacteria and fungi has been shown to produce poorly crystalline and highly reactive hexagonal birnessite-type Mn-oxide products [2-5], which readily engage in (abiotic) secondary redox and sorption reactions that may impact their structure and reactivity.

Recent work [3,6] has shown that aqueous Mn(II) may act as a reductant of hexagonal birnessite (which typifies the phyllomanganates that dominate in natural aquatic environments), causing reductive transformation of birnessite (nominally Mn(IV)O2) into the feitknechtite and manganite polymorphs of Mn(III)OOH through interfacial electron transfer from adsorbed Mn(II) to structural Mn(IV) atoms and arrangement of product Mn(III) into Mn(III)OOH, summarized by the comproportionation reaction $Mn(II) + Mn(IV)O_2 + 2\,H_2O \rightarrow 2Mn(III)OOH + 2H^+$. The transformation reaction is time-dependent, involving formation of feitknechtite as the initial metastable transformation product which is catalytically converted into the more stable manganite polymorph during ongoing reaction with Mn(II) [6]. An important finding from this work is that thermodynamic predictions of occurring reactions and transformation have limited merit in these systems due to uncertainty in thermodynamic data of the Mn oxides involved (due to size and composition effects), which necessitates experimental work to assess the occurrence and importance of specific transformation pathways.

The work presented here focuses on the impacts of pH and Mn(II) concentration on occurring transformation reactions, reporting notable changes in system reactivity as a function of these variables. The results point to a potentially major role of aqueous Mn(II) as a control on the mineralogy and structure of environmental Mn-oxides, and as a moderator of the reductive arm of Mn-oxide redox cycling.

Iron isotope signatures in magnetite formed by marine invertebrates

SIMON EMMANUEL[1], JAKOB VINTHER[2], JAN A. SCHUESSLER[3]*, FRIEDHELM VON BLANCKENBURG[3], ALAN MATTHEWS[1]

[1] Institute of Earth Sciences, The Hebrew University of Jerusalem
[2] Jackson School of Earth Sciences, University of Texas at Austin
[3] German Research Centre for Geosciences GFZ, Section 3.4, Earth Surface Geochemistry, Potsdam, Germany, jan.schuessler@gfz-potsdam.de (* presenting author)

Marine organisms can be powerful recorders of past environmental conditions. Fe isotopic signatures in marine organisms might be used to infer paleoenvironmental conditions and/or biological processes. Chitons - a type of marine mollusk - are a remarkable group of marine invertebrates that accumulate significant amounts of Fe. They produce radula (teeth) that are coated in biomineralized magnetite, enabling them to graze on algae living on the surface of rocks [1]. As a result, their Fe isotopic signatures might be expected to provide an efficient tracer of ambient oceanic conditions and biogeochemical cycling.

Here, we examine Fe isotopes in modern marine chitons collected from different locations in the Atlantic and Pacific oceans to assess the range of isotopic values that might be encountered, and whether or not the isotopic signatures reflect seawater values. Furthermore, by comparing two species that have very different feeding habits but collected from the same location, we attempt to isolate the possible impact of diet on isotopic signatures.

The Fe isotopic analyses were performed on a total sample set of 17 individual chitons using a *Neptune* MC-ICP-MS at GFZ Potsdam. δ^{56}Fe values (relative to IRMM-014) cover a range from -1.89 to +0.12 (±0.03‰ external reproducibility in δ^{56}Fe). All analysed teeth show negative δ^{56}Fe values, some even more negative than reported for oceanic Fe(II). Strikingly, two different species from Port Orchard (Washington, USA) have distinct isotopic signatures. The teeth of the species feeding on red algae (*Tonicella lineata*) show a tight range in δ^{56}Fe of -0.58±0.12(1σ), while *Mopalia muscosa*, which feeds primarily on green algae, cover a range in δ^{56}Fe from -1.89 to -0.92.

The results suggest that although chitons do not record the ambient seawater Fe isotope signature, they could provide a potential tracer of Fe biogeochemical cycling. The distinct Fe isotope signatures of the two species from the same locality might be a result of the different ways in which magnetite is biomineralized (presumably Fe is being taken up as Fe(II) in the organisms); alternatively, the chitons may simply be inheriting the signatures from the different algal food sources.

Mineral reactions in a porous world: calcite dissolution experiments revisited

SIMON EMMANUEL[1*] AND YAEL LEVENSON[1]

[1]The Hebrew University of Jerusalem, Jerusalem, Israel, simonem@cc.huji.ac.il (* presenting author)

The dissolution of calcite influences processes as diverse as the evolution of karst landscapes and the response of carbonate-hosted oil reservoirs to enhanced recovery techniques. Although much research has focused on determining the reaction kinetics of calcite dissolution from individual crystals, it is often assumed that the empirical rate laws derived in such studies can be used in a straightforward manner to describe calcite dissolution in porous and fractured rocks. In this study we challenge this assumption by using atomic force microscopy (AFM) to study the dissolution of natural porous carbonate substrates. We demonstrate how AFM can be used to estimate in situ reaction rates and identify dissolution mechanisms during reactive transport in porous media. Critically, in advective systems we observe a high degree of spatial heterogeneity that can be directly related to the porous structure. The precise mechanism behind pore-scale heterogeneous reaction rates is discussed, and we present a 3D numerical model that accurately reproduces the observed dissolution patterns on a porous surface. We also discuss the implications for current continuum descriptions of reactive transport, and how they might be modified to incorporate pore-scale heterogeneity.

Experimental study of S-MIF by SO_2 photolysis under CO atmosphere

YOSHIAKI ENDO[1]*, SEBASTIAN DANIELACHE[1], YUICHIRO UENO[1]

[1]Department of Earth & Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan. endo.y.ac@m.titech.ac.jp

Sulfur mass independent fractionation (S-MIF) of Archean sediment is regarded as a proxy of the atmosphere at that time. S-MIF is produced by photolysis of SO_2 in oxygen-free environment. However, the elementary reaction and the mechanisms of fractionation in the atmosphere are not fully understood. We present here a newly developed experimental setup to reveal the atmospheric photochemistry observed in the geological record. The photochemical system consists of a D_2 light-source, two gas chambers attached to a monochrometer and a UV detector designed to operate with no interference of atmospheric air. Here we present the first round of experiments of SO_2 photolysis conducted under SO_2 at low partial pressure (<5 Pa) and high amount of CO. The purpose of this experiment is to test a different experimental conditions from previously reported results where the environment of high pressure SO_2 is oxidative and optically thick, which may be significantly different from Archean atmosphere. Thus, our experiment condition hinders these problems. Additionally, this setting allow us to test the hypothesis that reducing atmosphere with a large amount of CO produces an stable amount of OCS [1]. In order to cut-off the large emission band of the deuterium lamp at 168 nm the chamber previous to the photochemical chamber was filled with CO_2. Analysis of reactions products confirms the production of OCS under CO atmosphere. The product OCS shows clear MIF signature. We calculated fractionation factors of SO_2 photolysis (185-220 nm) and also the chemistry associated with SO_2 photoexcitation (250-320 nm) as an additional source of MIF. We discuss a source of MIF involving not only SO_2 photodissiaction but also the chemistry associated to the photoexited SO_2* species in relation to the MIF signal meaured on the geological record.

Barite precipitation in submarine hydrothermal vents: Insights from Sr-isotope ratios

MARGARET S. ENGELBERT[1*], JOHN W. JAMIESON[2], BRIAN L. COUSENS[1], NICOLE M-B. WILLIAMSON[1] AND MARK D. HANNINGTON[2]

[1]Carleton University, Ottawa, Canada, (*mengelbe@connect.carleton.ca)

[2]University of Ottawa, Ottawa, Canada

At submarine hydrothermal vents, barite precipitates within vent chimney walls as hot hydrothermal fluid comes into contact and mixes with cold seawater. The formation of barite is dependent upon temperature and the availability of Ba^{2+} and SO_4^{2-}, from the hydrothermal fluid and local seawater, respectively. Fluid temperatures and ion availability are both intimately linked to the source fluids with respect to their amounts and degree of mixing. Thus, barite precipitation records the physical and chemical conditions of fluid mixing within the porous chimney walls. Here, we use $^{87}Sr/^{86}Sr$ values recorded in barite from hydrothermal vents along the intermediate-rate spreading Endeavour Segment of the Juan de Fuca Ridge, along with detailed petrography and electron microprobe analysis, in order to investigate the conditions of barite precipitation and fluid interactions within chimney walls.

The $^{87}Sr/^{86}Sr$ ratio in seawater differs from the $^{87}Sr/^{86}Sr$ ratio in hydrothermal fluid, making it possible to use the $^{87}Sr/^{86}Sr$ ratio in barite as a measure of the relative amount of local mixing between seawater and the hydrothermal fluids. The $^{87}Sr/^{86}Sr$ isotope ratios in a suite of 16 hydrothermal barite samples from the Endeavour Segment have been measured. The results demonstrate a broad scale of mixing, with the percent hydrothermal fluid component ranging from 25% to 90%. This variation in relative mixing suggests that barite can form under a variety of conditions. Petrographic examination of barite crystals show that barite in chimney walls can precipitate as a variety of different crystal habits, from dendritic to acicular and blocky. Variations in the relative amount of mixing are linked to barite crystal morphologies, providing further insights into the controls of ion availability on barite precipitation.

Electron microprobe analysis of barite crystals from the Endeavour vents reveals well-defined zones, characterized by varying Sr-concentrations within individual crystals. Two possible mechanisms for the formation of these zones are: 1) The relative contributions of seawater and hydrothermal fluid changes during the formation of the barite crystals; 2) The concentration of strontium in the seawater-fluid mixture changes as the crystals form. LA-MC-ICP-MS is used to determine the $^{87}Sr/^{86}Sr$ ratios of individual zones within the crystals, in order to evaluate the relative importance of these two processes.

The relationships between fluid mixing, barite crystal morphology, Sr content and $^{87}Sr/^{86}Sr$ ratios provide insights into the degree of conductive cooling relative to fluid mixing and into temporal variations in fluid chemistry as a control on mineral precipitation within vent chimney walls at Endeavour.

The Eh and pH of Fracking

DR. TERRY ENGELDER

[1]Department of Geoscience, The Pennsylvania State University (USA),

The extraction of natural gas from shale is now routine using massive slickwater hydraulic fractures. Along with its obvious economic advantages, this extraction technique comes with a number of well publicized risks, foremost of which is the migration of methane in the subsurface. Subsurface migration is a consequence of drilling into exhumed gas fields such as the Appalachian Basin where the areal extent of the Marcellus makes this gas reservoir one of the world's largest. During thermal maturation of the Marcellus between 300 Ma and 265 Ma gas was distributed throughout the Catskill Delta complex by natural hydraulic fractures (NHF). Migration of reducing fluids within redbeds of the delta complex accompanied NHF. Reduction halos allow the mapping of these pathways. While NHF was gas-driven as indicated by a cyclic plume pattern on fracture surfaces, high permeability NHF allowed the modern distribution of gas in these exhumed gas fields.

Peat land records of atmospheric mercury deposition in the French Pyrenees

ENRICO, MAXIME [1,2,3*], HEIMBÜRGER, LARS-ERIC[1], LE ROUX, GAEL[2,3], SONKE, JEROEN E.[1]

[1]CNRS; Geosciences Environment Toulouse, 31400, Toulouse, France, maxime.enrico@get.obs-mip.fr (* presenting author)
[2] Université de Toulouse; INP, UPS; EcoLab (Laboratoire Ecologie Fonctionnelle et Environnement); ENSAT, Avenue de l'Agrobiopole, 31326 Castanet Tolosan, France, gael.leroux@ensat.fr
[3] CNRS; EcoLab; 31326 Castanet Tolosan, France

Abstract

Mercury (Hg) has a long residence time in the atmosphere, which suggests that Hg recorded in peat lands derives partly from long-range transport. However, Hg accumulation rates (Hg AR) reconstructed from peat cores in European bogs do not show exactly the same spatiotemporal evolution. The question remains to which extent local point sources, climate and site specific processes might influence Hg AR.

We present here results of three peat lands in the French Pyrenees: 1) Pinet (42°51'N, 1°58'E), 2) Orri de Théo (OT: 42°45'N, 1°24'E), and 3) Estibere (42°50'N, 0°10'E). The three sites cover a 150 km East-West transect along the French Pyrenees. The peat cores were cut at 1cm resolution according to the protocol of Le Roux *et al.* [1], Hg AR were determined for the last 2,000 years in OT and Estibere, and for the last 10,000 years for Pinet. A multi-coring protocol was used to investigate local-spatial variability of Hg AR. Pre-anthropogenic Hg AR obtained at Pinet show natural variations during the Holocene (between 0.2 and 13µg.m^{-2}.y^{-1} with an average of 1.5µg.m^{-2}.y^{-1}), which could be related to climate change. Since the beginning of the Anthropocene, Hg AR increased by a factor 25 and are similar within and between the three peat lands.

In the upper part of the peat cores, three peaks are well-defined and recorded similarly at OT and Pinet, corresponding to the periods 1950-1955 (Hg AR at around 25µg.m^{-2}.y^{-1} at OT and 42µg.m^{-2}.y^{-1} at Pinet), the 1970's (38µg.m^{-2}.y^{-1} at OT and 52µg.m^{-2}.y^{-1} at Pinet) and 1994-95 (55µg.m^{-2}.y^{-1} at OT and 62µg.m^{-2}.y^{-1} at Pinet). The similar evolution of Hg AR in these two peat lands, which are spread out over 50km, suggest that they do not reflect Hg deposition from different local sources but more likely common regional or global source(s).

In addition to these similarities, we also observe some differences in Hg AR, reflecting local emission sources. For example, high Hg AR (around 12µg.m^{-2}.y^{-1}) are found around 1500AD at OT, probably the result of local Fe-Pb-Ag mining activities and related to coal burning, and a peak (100µg.m^{-2}.y^{-1}) is found at Pinet in 2001.

Calcification mechanisms explain why proxies in foraminifera and corals are good recorders of their environment

JONATHAN EREZ *

The Institute of Earth Sciences, The Hebrew University, Jerusalem, Israel . erez@vms.huji.ac.il

Current thinking on biologically controlled calcification involves active and passive transport of calcium from the environment across cell membranes to form cellular storge [1]. The formation of the mineral phase may be intracellular (e.g. coccolithophores) or extracellular, within a delimited space. Calcium is transported from the cellular stores as an free ion or in vesicles, under tight cellular control to the delimited space. The carbonate supply is usually ignored or assumed simple: CO_2 may diffuse freely from the environment, or respiratory CO_2 may provide an internal source for DIC. Given the complete cellular control on the ions supply, it is surprising that trace elements and isotopes are incorporated into marine biogenic carbonates with meaningful relations to the seawater. Furtheremore, despite some deviations from thermodynamic equilibrium, geochemists and paleoceanographers have utilized various proxies in biogenic carbonates (mainly foraminifera, corals, sponges and mollusks) very successfully to reconstruct past oceanic conditions. The current biological thinking (described above) is incorrect. The ions (Ca, Mg, Sr, Ba, DIC, B, Li, and others) and their isotopes are supplied to the delimited calcification space by **direct trasport of ambient seawater** (slightly modified). This has been demonstrated unequivocally in foraminifera [2,3], and more recently has been shown for corals [4]. The pathway of seawater transport to the site of biomineralization is by vacuolization in foramoinifera, and apparently by paracellular leakage in corals. In other marine invertebrates seawater is present at the biomineralization delimited space, but it remains to be shown how this is achieved. Seawater is rich in Ca (~10.5 mM, as opposed to 0.1 µM in live cells), however the DIC concentration (~ 2mM), is much lower.. High Mg concentration (~ 55 mM) inhibits calcite precipitation and hence high supersaturation is needed in order to precipitate the $CaCO_3$ shells. The most common mechanism to increase saturation is elevation of pH at the calcification site. This pH elevation helps to supply DIC both from seawater and from respiration as observed in corals and foraminifera.. The composition of various isotopic and elemental proxies in both groups (e.g. O, C, B, Li, Mg, Sr and others) are best explained using this novel calcification mechanism. Direct seawater transport (DST) explains the usefulnes of paleoceanographic proxies in biogenic carbonates.

Coupled Ge/Si and Ge isotope ratios as new geochemical tracers of seafloor hydrothermal systems: A case study at Loihi Seamount

ESCOUBE R. [1,2,3*], ROUXEL O.J.[2,3*], DONARD O.F.X.[4]

[4] LCABIE, CNRS UMR 525, Hélioparc, 64053 Pau, France

Germanium isotope and Ge/Si ratio systematics were investigated in low temperature hydrothermal vents from Loihi Seamount (Hawaii, USA) and results were compared to high-temperature vents from East Pacific Rise at 9-10°N. Loihi offers the opportunity to understand a low temperature basalt leach system with surface deposits mainely composed of iron oxyhydroxides. The results show that both Ge/Si and $\delta^{74/70}$Ge in hydrothermal fluids are fractionated relative to the host basaltic rock with Ge/Si ~ 30 and 5.7 µmol/mol and δ^{74}Ge ~ 1.9 and 1.55‰ for Loihi and EPR (Bio9) respectively vs. Ge/Si ~ 2.2 µmol/mol; δ^{74}Ge ~ 0.56‰ for basalt[1]. The relative enrichment in Ge vs. Si together with Ge isotope fractionation can be explained by quartz precipitation in the reaction zone at depth. Using Ge mass balance between hydrothermal fluids and fresh basalts, we calculated a $\Delta^{74}Ge_{quartz\text{-}fluid}$ of about -5.0‰. Although the fractionation of Ge isotopes in quartz is presently unknown, such apparent large Ge isotope fractionation at elevated temperature suggests concomitant loss of Ge and Si during fluid upflow resulting in Rayleigh-type effect and/or a fractionation during the basalt dissolution. The study of microbial mats at Loihi Seamount, composed essentially of Fe-oxyhydroxide with minor phases of amorphous silica and volcanic materials, also suggest that Ge isotopes are fractionated upon precipitation at the seafloor during seawater - hydrothermal fluids mixing. We obtained a maximum Ge isotope fractionation between Fe-oxyhydroxide (ferrihydrite) and dissolved Ge in the fluid of about -2.74‰. Isotopic variations observed in the different mats have being interpreted as reflecting the percentage of Ge sequestration in microbial mats; the lower values corresponding with the highest Ge trapping. This result is consistent with recent experimental estimation[2]. This study shows that combining Ge/Si and δ^{74}Ge systematics provide a useful tool to trace hydrothermal Ge and Si sources in marine environments and to understand formation processes of seafloor hydrothermal deposits. Preliminary mass balance of germanium isotope in seawater reveals that the missing Ge sink may correspond to Ge sequestration into Fe-oxyhydroxides within marine sediments.

Do melt inclusions record the pre-eruptive volatile content of magmas?

ROSARIO ESPOSITO[1]*, JAMES SCHIFFBAUER[2], JERRY HUNTER[2] AND ROBERT J. BODNAR[1]

[1]Virginia Polytechnic Institute & State University, Department of Geosciences, Blacksburg, VA 24061 USA rosario@vt.edu (*presenting author)

[2]Nanoscale Characterization and Fabrication Labs, Virginia Tech, Blacksburg, VA 24061 USA

In the last several decades the number of publications describing the use of melt inclusions (MI) to determine the pre-eruptive volatile contents of magmas has significantly increased. However, in most MI studies, the volatile contents of the MI vary widely within phenocrysts from the same volcanic sample. It is common for MI hosted in the same phenocryst to show significant variations in volatile concentrations, especially for CO_2. In fluid inclusion (FI) studies, workers have developed a protocol to test that the inclusions in a sample record the original trapping conditions by studying groups of FI trapped at the same time (Fluid Inclusion Assemblage, FIA), and which obey Roedder's (Sorby's) Rules. Specifically, (i) the FI must have trapped a single homogeneous phase, (ii) the volume of the FI must remain constant after trapping, and (iii) nothing can be added or lost from the FI after trapping. While this approach has worked successfully in FI staudies and should be successful in MI studies, there are two main reasons why MI studies rarely apply this methodology. The first is related to the lower probability, relative to fluid inclusions (FI), of finding Melt Inclusion Assemblages (MIA) in a phenocryst. The second is related to the necessity of exposing MI at the crystal surface in order to obtain chemical analyses, and this is particularly true for volatile analyses. In this study, the MIA approach has been used to assess if MI provide reliable information of pre-eruptive volatile contents. Groups of MI within well-defined MIAs hosted in phenocrysts from White Island (New Zealand) and from Solchiaro (Italy) were analyzed by Secondary Ion Mass Spectrometry (SIMS). We have studied 39 MIA and 144 MI were analyzed for CO_2, H_2O, F, S, and Cl.

In most MIA, H_2O, F, and Cl abundances are consistent, indicating that MI in these MIA represent the pre-eruptive abundance of these three volatile species. CO_2 and S abundances were consistent in some MIA, but especially CO_2 showed a wide variation in others. The wide range in CO_2 content could reflect the presence of a CO_2-rich boundary layer at the MI/host interface controlled by post-entrapment crystallization of the MI, and may also be a function of the MI morphology. Thus, MI may appear to be highly heterogeneous in volatiles such as CO_2 and S that are the less soluble in melts of this composition. The wide range in S is restricted to MIA hosted in Fe-bearing phenocrysts, suggesting that the variability may be due to post-entrapment processes. Although working with MIAs is time consuming and tedious, we recommend the MIA approach to study pre-eruptive volatile contents in order to recognize MI whose volatile abundances do not accurately reflect pre-eruptive volatile concentrations in the magma.

Bulk and Micro Mineralogical Characterization of As in Uranium Mine Tailings

JOSEPH ESSILFIE – DUGHAN[1]*, M. JIM HENDRY [2], JEFF WARNER[3], AND TOM KOTZER[4]

[1]University of Saskatchewan, Geological Sciences, Saskatoon, Canada, joe377@mail.usask.ca (* presenting author)

[2]University of Saskatchewan, Geological Sciences, Saskatoon, Canada, jim.hendry@usask.ca

[3]Canadian Light Source Inc., Saskatoon, Canada, Jeff.Warner@lightsource.ca

[4] Cameco Corporation, Saskatoon, Canada, Tom_Kotzer@cameco.com

Introduction

In northern Saskatchewan, Canada, high-grade uranium ores and the resulting processed tailings can contain high levels of arsenic (As). The potential mobilization of As from the tailings management facilities (TMFs) to contaminate regional groundwater systems is an environmental concern in the uranium mining industry.

Knowledge regarding the speciation of As in natural systems is critical for determining its long-term environmental fate. Specifically, characterization of As-bearing mineral phases and complexes within the processed U tailings is required to evaluate their potential transformation, solubility, and long-term stability within the tailings mass. Synchrotron-based bulk X-ray absorption spectroscopy (XAS) was used to study the redox and molecular speciation of As in tailings samples obtained from the Deilmann TMF at Key Lake, Saskatchewan. Electron microprobe analysis (EMPA) and synchrotron-based micro-focussing X-ray fluorescence mapping and absorption spectroscopy (μXRF; μXAS) were employed to study the spatial distribution and speciation of As at the micron scale.

Results and Conclusion

Comparisons of K-edge XAS spectra of tailings samples and reference compounds indicate As in the tailings samples primarily exists in the +5 oxidation state; this reflects the generation of the tailings in a highly oxic mill process, their deposition in an oxidized environment, and complexation within stable oxic phases. Extended X-ray absorption fine structure (EXAFS) analysis of As K-edge spectra indicates that As^{+5} (arsenate) present in the tailings samples is adsorbed to ferrihydrite though an inner-sphere bidentate linkage. Backscattered electron (BSE) images of the tailings from the electron microprobe show the presence of nodule-like features with bright rims. Data from elemental mapping indicate the nodules are largely composed of Ca and S (i.e., gypsum), with the surrounding rims mainly consisting of As and Fe. μXRF elemental mapping confirms the EPMA results. μXAS data collected at various points on the rims surrounding the gypsum nodules suggest that Fe is present as ferrihydrite with adsorbed As.

These findings will facilitate the accurate characterization and quantification of the potential for long-term migration of As from TMF porewaters to adjacent groundwater systems.

[3]Mount Holyoke College, South Hadley, USA, mdyar@mtholyoke.edu
[4]Wellesley College, Wellesley, USA, dbraband@wellesley.edu

Introduction

Due to their ubiquity in the environment, high surface area, and affinity for both inorganic and organic molecules, iron oxides and hydroxides (FeOx) play an important role in mediating contaminant mobility. Coprecipitation and adsorption of ions influence the reactivity and long-term stability of FeOx minerals by altering their crystal structure, grain size and morphology, and extent of particle aggregation. Al, Si, phosphate, and organic matter, for example, may coprecipitate at stoichiometric ratios up to 50%. TThese ions, along with heavy metals and other less common elements, may produce changes in reactivity and structure even at significantly lower concentrations. While numerous lab-based studies have parameterized the influence of individual variables, the difficulty inherent in characterizing naturally-precipitated FeOx minerals in a complicated matrix has limited the extrapolation of results to field systems.

Methods

We analyze natural samples collected from the Pb-, Zn-, and Cd-contaminated Tar Creek Superfund Site through a combination of sequential chemical extractions targeting iron phases and Mössbauer spectroscopy to monitor how heavy metal speciation varies during reactive transport and whether FeOx structural parameters obtained via Mössbauer correlate with sample bulk chemistry. We also show results of small angle X-ray scattering (SAXS) on synthetic ferrihydrite samples to investigate how ion coprecipitation and sorption affect aggregate morphology.

Results

Si and organic matter content covary most significantly with Mössbauer parameters, although extraction of P and Al by the sequential extraction steps targeting more crystalline FeOx phases suggests that they may also be an important determinant. Of the ions tested, phosphate produced the largest effect on aggregate structure, increasing mean particle radius and aggregate fractal dimension. This combination of techniques ultimately provides insight into how the matrix may alter iron reactivity and thus control contaminant speciation.

Probing the interactions between glutamic acid and diopside

Abstract

The manner in which organic molecules adsorb onto the mineral/water interface may hold implications for the origin of life. Chiral amino acids may have selectively adsorbed onto the chiral growth faces of silicate minerals by three or more non-colinear points of attachment, which may have led to the evolution of homochirality. Diopside is a common clinopyroxene mineral with the chiral growth faces (110) and (1-10), which are also the principal cleavage planes prominent in powdered samples. We demonstrated with batch adsorption experiments that up to 30% of L-glutamic acid (initially 20 μM) adsorbs onto crushed natural diopside at pH=10. We investigated the enantioselective potential of diopside by probing the interactions between glutamic acid and the chiral growth faces (110) and (1-10) with vibrational sum frequency generation (SFG) spectroscopy. Prior to our experiment, we prepared two 0.63 mm thick (1-10) diopside sections of approximately 500 mm^2, which were cleaned with a plasma cleaner. One diopside section was submerged in 100 μM L-glutamic acid for 2h and dried under nitrogen, whereas the other section served as a blank. The SFG spectra we collected for the diopside section with L-glutamic acid significantly differed from those of the blank. As a preliminary analysis, we assigned asymmetric and symmetric stretching modes for the β-methylene group and a symmetric stretching mode for the γ-methylene group of L-glutamic acid. We obtained SFG spectra of adsorbed L-glutamic acid under two experimental mutually perpendicular polarization combinations. In principle, spectra such as these can establish the configuration of the adsorbed molecule. A comparison of the ratio of SFG signal intensity for the methylene vibrational modes between the two polarization combinations will determine the dipole orientation of the methylene stretches relative to the diopside surface. This technique may be useful for establishing an enantioselective trend in glutamic acid adsorption.

Structural controls on fluid evolution in the Devonian Marcellus shale during deformation of the central Appalachians

MARK A. EVANS*

Central Connecticut State University, New Britain, CT 06050 USA
(Correspondence: evansmaa@ccsu.edu)

Fluid inclusion microthermometry of temporally controlled vein minerals is used to evaluate the fluid conditions of the Middle Devonian Marcellus shale during the Alleghenian orogeny. Samples from folded rocks in the Pennsylvania salient and in less deformed rocks of the Plateau province indicate that fluid pressure – temperature — composition (PTX) does not remain static during orogenesis, but varies significantly both in time and between structural settings.

Regionally, the earliest trapped fluids are in dolomite, calcite, and/or barite and consist of degraded liquid hydrocarbons, liquid hydrocarbons and condensate-type fluids. These fluids are interpreted to have been trapped during peak oil generation and migration, probably during basin filling and before folding. Fluid trapping occurred at temperatures of 60° - 118°C and at depths of less than 3.8 km.

Within the Valley & Ridge province, however, samples from folded rocks additionally contain later quartz and calcite with multiple fluid trapping events reflecting a dynamic vein opening history related to changes in fluid connectivity associated with syn-folding fracturing that allows for increased fluid mobility. The fluid trapping events are characterized by diferent fluid salinities (ranging from 10 to 25 wt. % equiv.) and CH_4:CO_2 ratios. This increased connectivity is occurring during 1) burial associated with overthrusting and/or syntectonic depositional loading and/or 2) syn-folding uplift and erosion. Importantly, the PTX history of sites in synclines is different from sites on anticlines, and reflects the different structural history of each location. The influx of fluids is indicated by the concurrent dissolution of vein calcite and precipitation of quartz, and that brine inclusions in the quartz consistently increase in T_h from early to late quartz. Interestingly, this late quartz is suprisingly methane-rich, and contains abundant, large CH_4±CO_2 inclusions, while aqueous inclusions are exceedingly rare.

Along the boundary between the subhorizontal rocks of the Plateau province and the folded rocks of the Valley and Ridge, the PTX conditions determined for the Marcellus veins indicate a significant variation along strike. To the northeast, the lack of quartz and the presence of only liquid hydrocarbon and CH_4±HHC inclusions in calcite and barite suggests little fluid mobility. On the other hand, to the southwest, late quartz contains more mature CH_4±CO_2 inclusions and the presence of corroded early calcite suggests a fluid influx. The sites containing the later quartz are adjacent to an area of the Plateau with increased thermal maturation based on vitrinite relectance, suggesting that 'warm' fluids passing through the Marcellus may be responsible for the increased maturation.

Yellowstone hot spring microbial communites fed with hydrogen and bicarbonate as a metabolically active analogue for early Earth environments

HALLGERD EYDAL[1,2*], LISE ØVREÅS[2], JOHN R SPEAR[1]

Obsidian Pool in Yellowstone National Park

Microbial ecosystems independent of sunlight and supported by hydrogenotrophic primary production have been shown in subsurface environments such as basaltic rock aquifers and volcanic rock [1,2]. The presence and activity of such ecosystems in Obsidian Pool sediments in Yellowstone National Park (YNP) was the focus of this study, as microorganisms in these environments include groups branching deeply in the phylogenetic tree of life.

Obsidian Pool is known to have diverse microbial communities of hydrogen-oxidizing bacteria and archaea [3, 4] and the water in the pool contains 46 nM H_2. The H_2 to support miro-organisms can be generated from magmatic gases [5]. Using molecular techniques, hydrogen oxidizing aerobic bacteria have been shown to be the most abundant microorganisms present at Obsidian Pool. By contrast, the sediment in Obsidian Pool is anoxic and hydrogen utilizing methanogens have been shown elsewhere in YNP [6].

Experimental

To study active hydrogenotrophic methanogens anaerobic *in situ* incubation microcosms fed with H_2 and $NaHCO_3$ were set up. Changes in H_2 and CH_4 concentrations were followed using gas chromatography. Additionally, copy number changes of a metabolic gene for methanogenesis (methyl coenzyme M reductase α-subunit; mcrA) was studied using quantitative PCR. The microbial community structure was studied with 16S rRNA gene sequence diversity via 454 pyrosequencing.

Results and conclusion

When the diversity of the 16S rRNA gene was followed using 454 pyrosequencing, Obsidian Pool was found to be dominated by Aquificales. Quantitative PCR of archaeal 16S rRNA and mcrA genes, consumption of H_2 and production of CH_4, as well as relative abundances of 16S rRNA sequences confirmed active populations of the hydrogenotrophic *Methanothermobacter* with a generation time of 6.4 h. Hydrogenotrophic organisms in turn sustained growth of heterotrophic organisms such as Thermotogales and Nitrospira. Our study supports the exsistence of a hydrogen driven subsurface ecosystems which in the 16S rRNA gene phylogeny have deeply branching microorganisms, potentially similar to the early life on Earth. This highly active and accessable early Earth analogue, will allow studies of microbial interaction in a natural environment.

Melt movement by dilation-assisted compaction, Damara Belt, Namibia

CARLY FABER[1*], JOHANN F.A. DIENER[1], ALEX F.M. KISTERS[2]

[1]Department of Geological Sciences, University of Cape Town, South Africa, carlyfaber1@gmail.com (* presenting author), johann.diener@uct.ac.za

[2]Department of Earth Sciences, University of Stellenbosch, South Africa, akisters@sun.ac.za

Melt migration through the crust is the main mechanism that facilitates upward movement of heat and mass and the chemical differentiation of the continental crust. Crustal-scale melt movement is divided into three phases; segregation from the source, migration and ascent, and emplacement[1]. Whereas the processes of segregation and emplacement are relatively well understood, melt ascent mechanisms are more speculative.

We document an example of long-lived syn-deformational melt migration through an 80m-thick upper-amphibolite facies, subsolidus metasedimentary sequence in the southern Central Zone of the Damara Belt, Namibia. The package is shallowly-dipping and structurally bound by migmatitic gneisses at the top and bottom. The metasediments have not experienced extensive anatexis, and preserved leucosome represents migration and emplacement from the underlying migmatitic gneisses (melt source) into the metasediments.

The position and orientation of the leucogranites is structurally and lithologically controlled, and defines a composite 3D network of intersecting sheets and stringers on the metre to decametre-scale. Structures that comprise the networks include fabric-concordant sheets, sheets and dykes within conjugate shear zone planes, and leucogranite-bearing boudin necks, tensile fractures and leucogranite-cemented breccias. The deformation along the conjugate shears indicates that melt migration occurred during tectonic compaction of the sequence. The presence of at least five compositionally and texturally distinct leucogranite phases of different volume shows that structures within the network were repeatedly utilized by separate melt batches over a protracted period of time.

Low-volume melts achieved ascent through stepwise pervasive migration, controlled by the rate at which structures were able to dilate and create permeability during progressive deformation. High-volume melts ascended rapidly and in a single pulse along 10-25m diameter pipes that crosscut the entire supracrustal sequence. These pipes contain leucogranite-cemented breccias consisting of 5-10m angular and rotated wall-rock fragments. This suggests rapid opening of the fractures followed by implosion of the country rocks.

The different leucogranite phases indicate a repeated and long-lived utilization of networked structures formed during regional deformation. However, low melt volumes exploited these networks passively as the rate of tectonic dilation was sufficient to accommodate the low melt volumes. In contrast, high melt volumes contributed additional permeability to the network through fracturing and brecciation, driven by melt embrittlement and overpressure as melt supply exceeded the rate of tectonic dilation.

How do oceanic biotic components influence the production mechanism of organic aerosol in Marine Boundary Layer (MBL)?

M.C. FACCHINI[1]*, C. O'DOWD [2]

R. DANOVARO[3]

[1] Institute of Atmospheric Sciences and Climate, National Research Council ,Italy(*correspondence:mc.facchini@isac.cnr.it)

[2] Department of Experimental Physics & Environmental Change Institute, National University of Ireland Galway, Galway, Ireland

[3] Department of Life and Environmental Sciences Polytechnic University of Marche, Ancona, Italy

Studies performed during the past years strongly suggest that biogenic organic compounds play an important role in submicron marine aerosol chemical composition over biologically productive, high latitude, marine regions, in both hemispheres and new biogenic oceanic sources of primary and secondary origin of OA were revealed. We discuss on the global importance of biogenic OA marine sources and their high spatial and temporal variability and the complex interaction with gaseous biogenic precursors and oceanic biotic components (Phytoplankton, viruses and bacteria). Submicron marine organic aerosol are a complex mixture of biogenic materials transferred from the ocean surface by the sea spray or by oxidative gas to particle conversion of volatile organics emitted by decomposition processes of oceanic dissolved organic carbon. The role of marine biota on the evolution of plankton bloom and on the partitioning of oceanic organic carbon in POC and DOC or gaseous species and on transfer mechanisms into MBL will be discussed.

Opening-mode fracturing and cementation during hydrocarbon generation in mudrocks: an example from the Barnett Shale, West Texas

ANDRÁS FALL[1*], JULIA F. W. GALE[1], PETER EICHHUBL[1], WALAA A. ALI[1], STEPHEN E. LAUBACH[1], ROBERT J. BODNAR[2]

[1]Bureau of Economic Geology, Jackson School of Geosciences, The University of Texas at Austin, Austin, TX, USA, (* presenting author: andras.fall@beg.utexas.edu)

[2]Department of Geosciences, Virginia Tech, Blacksburg, VA, USA

Natural fractures in mudrocks are common and develop due to different mechanisms operating at different times during the burial history. Knowledge on the mechanisms and timing of fracture opening and cementation is desirable because natural fractures can contribute to permeability if open, and can interact with hydraulic fracture treatments of shale hydrocarbon reservoirs whether open or sealed.

Analysis of fracture-filling cements in three fracture sets in core from the Barnett Shale in the Delaware Basin, West Texas is combined with a burial history model and data from fluid inclusion microthermometry and Raman spectroscopy to determine fracture timing, and to obtain insights into the mechanism of fracture formation. An early fracture set that was folded during shale compaction is mostly sealed with dolomite cement, but retains small pores lined with barite. A second set includes horizontal (bedding-parallel), low angle, and irregular subvertical fractures that are sealed with fibrous barite. The barite contains coexisting primary, liquid-rich hydrocarbon (oil) and aqueous fluid inclusions trapped at temperature and pressure (P-T) conditions of ~110°C, and ~55 MPa, respectively. We interpret the primary inclusions as forming during rapid burial when compaction disequilibrium combined with cracking of type II kerogen to oil caused an overpressure, thus providing a mechanism for fracturing. In addition, this set of fractures contains secondary, vapor-rich hydrocarbon (methane dominated) inclusions with condensate rims, trapped along planes that cross-cut the barite fibers. We interpret these secondary inclusions as having formed during secondary gas generation from oil (bitumen). A third set of fractures, which are partly open, contains quartz cement bridges with crack-seal structure indicative of quartz cementation during episodic fracture opening. Quartz cementation continued after opening had ceased, overgrowing the crack-seal structure. Methane saturated aqueous inclusions in the quartz bridges formed at P-T conditions of ~110°C and 35-45 MPa in the crack-seal quartz, and ~128°C and ~35 MPa in quartz overgrowths. Correlation with a burial history model suggests this set opened concurrently with, or soon after, the fractures with fibrous barite, but prior to secondary gas generation. The heterogeneous distribution of inclusions may reflect heterogeneous trapping of the two-phase hydrocarbon/aqueous fluid system in the reservoir. All three fracture events may have formed during the burial phase, although elements of the third set may have developed during the first uplift event associated with Laramide deformation.

Evaluating the provenance study methodology of using detrital zircon U-Pb ages in the Changjiang drainage basin

DAIDU FAN*, YANGYANG WANG

Tongji University, State Key Lab of Marine Geology, ddfan@tongji.edu.cn

High-resolution provenance study has been highly expected since the availability of single-grain dating methods, especially after the wide application of LA-ICPMS on the microanalyses of zircon grains. Large volumes of zircon dating data have been published in the last two decades in China. Data of crystalline zircon U-Pb ages and εHf(t) values have been extensively collected in the Changjiang drainage basin from over 100 journal papers, which were majorly published in the last decade. They were systematically analyzed, together with statistics on the outcropped area of igneous rocks, to explore the possibility to fingerprint provenance in such a wide and complex drainage basin.

Some major findings are summarized. (1) Some vast tectonic provinces, like the Yangtze Block extending from the upper reach to the lower reach, should be subdivided into several parts for the high spatial resolution of provenance study. (2) Only a few groups of zircon ages, including <50 Ma, 250~270 Ma and >3000 Ma, can be used directly to fingerprint their source from the Changdu Block, the northern and the western subdivisions of the Yangtze Block, respectively. (3) Some zircon ages are indicative of their specified sources based on the different peak ages of single individual tectonic events in the varied tectonic blocks (subdivisions). (4) The effectiveness of provenance distinguishing can be significantly improved by application of the scatter plotting of zircon U-Pb ages and εHf(t) values, while some groups of zircon ages are still unable to assign to any certain source. (5) The intrusion of the recycled zircons cannot be excluded, and sometimes they make a significant contribution to the fluvial zircons, like those from the widely distributed Triassic turbidites in the Songpan-Garze Massif. (6) The frequency based on counting the available dated zircon grains in each tectonic units are not necessarily the abundance of different aged zircons, usually quite different from the area statistics of the outcropped igneous rocks of the corresponding ages, so the high-resolution provenance study should take both into consideration.

Evaluating pore fluid Mg isotopic and elemental constraints on seawater Mg chemistry in the Cenozoic

MATTHEW S. FANTLE[1,*] AND FANG-ZHEN TENG[2]

[1] Department of Geosciences, Penn State University, University Park, PA, USA, mfantle@psu.edu (* presenting author)
[2] Department of Geosciences, University of Arkansas, Fayetteville, AR, USA, fteng@uark.edu

Interpreting Cenozoic climate and environment accurately using marine geochemical proxies requires high fidelity proxies that are resistant to diagenetic alteration over tens of millions of years. For mineral-based proxies that do not passively sample seawater, such as Mg/Ca and stable isotopic proxies, it is also necessary to place limits on the chemistry of seawater (i.e, the solution from which the minerals precipitate). The latter is predominantly true for Cenozoic proxies over time scales longer than elemental residence times (τ) in the ocean (τ_{Mg}~10 Ma; τ_{Ca}~1 Ma).

This study utilizes depositional reactive transport models of carbonate diagenesis to simulate measured pore fluid and solid Mg isotopic and elemental data from ODP Site 807A (ave. $CaCO_3$ ~92 wt%). The ultimate goal of the iterative modeling approach taken is to (1) evaluate the extent to which pore fluid chemistry can be used to elucidate the Mg chemistry of the Cenozoic ocean and (2) estimate the degree to which diagenesis alters the Mg isotope and Mg/Ca proxies. Previously published recrystallization rates, based on Ca and Sr isotopic and elemental data, constrain the models [1-2].

The Mg isotopic composition ($\delta^{26}Mg_{DSM3}$) of 807A pore fluids varies systematically from -0.79 to -0.25‰ between the shallowest (13.4 mbsf) and deepest (738 mbsf) fluids. There is notable structure in pore fluid $\delta^{26}Mg$ as a function of depth that is not well explained by diffusion, either of an initial seawater signal or between boundaries that reflect modern seawater (upper) and basement basaltic Mg (lower). Accordingly, reaction must be considered.

In the current study, endmember model scenarios are used to evaluate the applicability (and uncertainty) of pore fluid chemical data for constraining past seawater chemistry. The modeling assumes that carbonate recrystallization is the dominant reaction controlling the alteration of Mg pore fluid chemistry in the sedimentary column. The first endmember scenario generates seawater Mg concentration and $\delta^{26}Mg$ curves for a range of partition coefficients (K_{Mg}) assuming a constant value for the diagenetic fractionation factor. A second set of simulations assumes seawater Mg concentrations consistent with evaporite fluid inclusion data and constrains K_{Mg} and the Mg isotopic evolution of the ocean accordingly.

The model results are subsequently used to assess the potential for diagenetic alteration of bulk carbonate. Given low Mg concentrations, reactions rates on the order of <2%/Ma, and an assumed equilibrium fractionation factor and partition coefficient that are different at depth than in the surface ocean, there is considerable leverage to change both the Mg isotopic composition and Mg/Ca of bulk carbonates over tens of millions of years.

Mineral-scale $^{87}Sr/^{86}Sr$ heterogeneities in the Elba Island intrusive complex: a consequence of prograde disequilibrium melting of the source

FEDERICO FARINA[1]*, ANDREA DINI[2], SERGIO ROCCHI[3] AND GARY STEVENS[1]

Session- Evolution and differentiation of the continental crust: A celebration of the contributions by Michael Brown

Large $^{87}Sr/^{86}Sr$ variations are preserved at the mineral-scale within igneous units forming the late Miocene Elba Island intrusive complex (Italy), namely the San Martino granite porphyry laccolith (7.4 Ma), the Monte Capanne granite pluton and the Cotoncello felsic dyke (6.9 Ma). Decimetric K-feldspar megacrysts from the three units record a similar large core to rim decrease of $^{87}Sr/^{86}Sr_i$ ratios (from ≈ 0.719 to 0.715) while biotites included within feldspar cores, interpreted as an early crystallized magmatic phase formed from an early magma batch, have diverse initial Sr isotope ratios. Biotite inclusions from the pluton and the dyke have extremely high $^{87}Sr/^{86}Sr_i$ (≈0.733), while those in the porphyry record the lowest ratio in the intrusive system (≈0.712). It is noteworthy that reliable initial Sr isotope ratios for biotites included in the megacrysts have been determined as a consequence of the exceptional young emplacement age of the Elba Island intrusive complex.

The record of isotopic variations preserved at the mineral-scale in the different megacryst-bearing units of the Elba Island intrusive complex, reflects episodic recharge and mixing between crustally-derived magma batches having contrasting $^{87}Sr/^{86}Sr$ signatures. Intrusion of basaltic magmas in the crust causes high heating rates (>100 °C/Ma), preventing complete equilibration within rock-forming phases in the protolith prior to anatexis, as well as between the residuum and the melt during anatexis and magma segregation. Therefore, phases with $^{87}Rb/^{86}Sr$ ratios that are high (i.e. biotite), intermediate (i.e. muscovite) and low (i.e. hornblende and plagioclase) develop contrasting $^{87}Sr/^{86}Sr$ through time. Consequently, a range of isotopically distinct magma batches arise from disequilibrium melting of individual sources that are able to undergo melting through different reactions.

The increase in $^{87}Sr/^{86}Sr_i$ recorded by the San Martino system reflects mixing between magmas produced by the progression from muscovite- to biotite fluid absent melting within a metapelitic source. At higher temperatures, the progression from biotite to hornblende-dominated fluid absent melting within a layered, compositionally intermediate source generates the decrease in Sr isotope ratios recorded by the pluton-dyke magmatic system.

Shells of articulate brachiopods composed of low-Mg calcite provide valuable archives of temporal changes in trace element and isotope composition of past ocean water [1, 2]. However, in order to faithfully reconstruct the paleo-seawater signatures from geochemical data encoded in fossil brachiopods, one must have a full understanding of trace element incorporation, and the accompanying isotope fractionation during shell formation, in modern brachiopod species. Here we present high-resolution ontogenetic profiles of trace element distribution (i.e. Mg/Ca ratios) and Mg isotope variation ($\delta^{26/24}$Mg) in species of modern articulate brachiopods, *Terebratalia transversa* and *Terebratella sanguinea*, collected from the northeast (San Juan Island, Friday Harbor) and the southwest Pacific Ocean (New Zealand, Doubtful Sound), respectively. Results from LA-ICP-MS (Agilent 7500ce) and wet chemistry (Thermo X-Series II) elemental analysis indicate that Mg/Ca ratios (mmol/mol) in the secondary-layer composed of low-Mg calcite range between 5 and 10, whereas a thin primary layer composed of high-Mg calcite yielded significantly higher Mg/Ca ranging from 25 up to 50. Results of the isotope analysis, done on MC-ICP-MS (Thermo Neptune), show that for low-Mg calcite of modern brachiopods there is no significant species-dependent fractionation of stable Mg isotopes, as $\delta^{26/24}$Mg (DSM3) signatures of secondary shell layers of *T. transversa* and *T. sanguinea* yielded identical values of -2.225 ±0.055 and -2.241 ±0.187 per mil, respectively. Moreover, these values are also identical with those from modern *Terebratulina retusa* with published $\delta^{26/24}$Mg signatures of -2.075 ±0.097 [3] and -2.290 ±0.060 [4]. Hence, our preliminary data seem to support an existence of a common taxon-specific control of Mg isotope fractionation during biocalcification of low-Mg calcite of brachiopod shells from ambient seawater. In addition, we found no resolvable temperature-dependent Mg isotope fractionation for samples representing habitat temperatures ranging from 8.8 to 13.7 °C. However, a single sample with an estimated 8 to 15% contribution of Mg from primary high-Mg calcite layer (calculated based on Mg/Ca mass-balance) yielded significantly lower $\delta^{26/24}$Mg of -2.819 ±0.099, suggesting that an extra caution has to be exercised during sampling of brachiopod shell material for $\delta^{26/24}$Mg analysis. We plan to present new Mg/Ca and $\delta^{26/24}$Mg data from several other modern brachiopod species, and discuss their implications for paleo-seawater $\delta^{26/24}$Mg reconstructions.

Boron isotopes in deep-sea bamboo corals

JESSE R. FARMER[1]*, BÄRBEL HÖNISCH[1], LAURA ROBINSON[2], TESSA HILL[3] AND MICHÉLE LAVIGNE[3]

[1]Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, USA, jfarmer@ldeo.columbia.edu (* presenting author)

Background

Deep-sea corals represent an intriguing archive for application of the boron isotope-pH proxy because of their potential for subdecadal-scale reconstructions [1] during present and past carbon system perturbations [2]. However, previous studies of boron isotopes in aragonitic deep-sea scleractinian corals showed evidence for systematic skeletal variations in δ^{11}B that could not be attributed to environmental factors [3]. In contrast to scleractinians, deep-sea gorgonian bamboo corals secrete high-magnesium calcite and may not be expected to exhibit similar δ^{11}B heterogeneity, but the boron isotopic composition of bamboo corals has not been investigated in detail. Here we present an evaluation of δ^{11}B variability from the genus *Keratoisis*, a cosmopolitan deep-sea calcitic bamboo coral.

Results

Initial results from four modern *Keratoisis* specimens collected between 500 and 2500m depth in the North Atlantic and North Pacific Oceans show that coral surface δ^{11}B positively correlates with ambient seawater pH and is consistent with borate incorporation from seawater. Samples taken at 1mm spacing across the width of individual corals shows that intra-sample δ^{11}B does not exceed 2-3 per mil. An increase in δ^{11}B toward the central growth axis of our North Pacific *Keratoisis* specimen is associated with lighter carbon and oxygen isotopes [4]. Two North Atlantic corals show increased δ^{11}B toward the surface of the outer growth surface, a result that is in contrast to the expected increased contribution of anthropogenic carbon in the deep sea. We seek to constrain the observed boron isotopic variability and coral growth rates using trace metal (B/Ca, U/Ca, Sr/Ca, Mg/Ca), stable isotope (δ^{18}O, δ^{13}C), and radiocarbon analyses within our *Keratoisis* corals.

Hotspots with double volcanic chains provide a unique opportunity to map the distribution of isotopic heterogeneities in the deep mantle. Recently, Weis et al., [1] proposed that the isotopic enrichment of the southern (Loa-trend) Hawaiian volcanoes is due to sampling of deep material coming from the edge of the 'large low-shear-velocity province'. By studying several Pacific hotspots with double volcanic chains (i.e., Hawaii, Samoa, Marquesas) Huang et al., [2] showed that the southern chain is always isotopically enriched with respect to the northern one. Such a large scale, systematic geochemical zonation may be caused by the progressive involvement of a more enriched (DUPAL) component toward the southern latitudes.

Here we take a geodynamics perspective and model a north-south increase in the radiogenic lead isotope ratio ($^{208}Pb^*/^{206}Pb^*$) across the thermal boundary layer (TBL) source region of plumes. Our numerical simulations show that the resulting conduit structure has a novel `lobate' zonation. By mapping $^{208}Pb^*/^{206}Pb^*$ distribution within the melting zone of the Hawaiian plume we predict that Loa-trend volcanoes should have higher $^{208}Pb^*/^{206}Pb^*$ than Kea-trend ones. Moreover, the calculated $^{208}Pb^*/^{206}Pb^*$ time evolution is distinct, namely, in a Loa-trend volcano, shield-stage lavas are expected to have higher $^{208}Pb^*/^{206}Pb^*$ than pre- and post-shield lavas. In contrast, in a Kea-trend volcano, $^{208}Pb^*/^{206}Pb^*$ should progressively decrease from pre- to post-shield stages. Our simulations show that any large-scale north-south $^{208}Pb^*/^{206}Pb^*$ increase in the TBL causes bilateral zonation of plumes sheared in the direction of the Pacific plate motion.

Effect of redox oscillations on iron and manganese behavior in a bank filtration setting

CLAIRE FARNSWORTH[1,2*]

[1]California Institute of Technology, Pasadena, CA, USA, claire.farnsworth@gmail.com (* presenting author)

[2]EAWAG, Swiss Federal Institute of Aquatic Science and Technology, Duebendorf, Switzerland

In bank filtration, groundwater is extracted from a well adjacent to a river or lake, thereby inducing infiltration from the surface water body into the shallow groundwater. The infiltrate is exposed to variable redox conditions along the flow path, from oxic surface water to reducing shallow sediments, followed by the re-introduction of oxygen in the vicinty of the production well as it cycles on and off. The natural processes along the infiltration flow path lead to nutrient, organic carbon, and pathogen removal, thereby improving the quality of the water recovered. However, manganese (Mn) and iron (Fe) can be released into bank filtrate along its flow path to the production well to an extent that necessitates drinking water treatment after extraction, as observed at various well fields in Canada, Germany, and the Netherlands.

The behavior of Mn and Fe were investigated at a lake bank filtration site (Lake Tegel, Berlin, Germany) subject to water table fluctuations and seasonal organic carbon loads, resulting in transient redox oscillations in the shallow groundwater. Field data will be compared with the potential of Mn and Fe for release in the reducing shallow sediments and for sequestration in the aquifer adjacent to the production well. The conditions under which transient redox oscillations in shallow groundwater can drive the release and sequestration processes in alluvial sediments will be presented.

Preservation of fossil bones of small mammals from El Harhoura 2 cave (Morocco, Pleistocene – Holocene)

YANNICKE DAUPHIN[1], AND BASTIEN FARRE[2*]

[1]UMR IDES, Université Paris Sud, France, yannicke.dauphin@u-psud.fr

[2]GEGENA2 Université de Reims, Champagne Ardennes, Bastien.farre@univ-reims.fr (* presenting author)

Introduction. Studying the Hominid installation in Maghreb is an outstanding question due to the fact that early *Homo sapiens sapiens* originated from Africa and some of the earliest remains has been found in North Africa. Numerous archaeological sites have revealed large mammals. However, only few Pleistocene sites from Atlantic Morocco have yielded microvertebrates. Did the 6th extinction start as modern humans settled? Biodiversity is based on the abundance of taxa. However, fossilisation induces substantial preservational bias in the fossil record. Thus, we study the preservation of fossil bones to estimate the impact of fossilisation on past biodiversity (ANR MOHMIE project [1]).

Results and Conclusion

Eleven layers have been identified in the Late Pleistocene - Middle Holocene series [2]. Sands represent more than 80% of the sediment. From SEM observations [2], rodent bones are well preserved, showing the main histological features (Fig.). Secondary deposits are rare. Nevertheless, FTIR analyses have evidenced differences between modern and fossil samples. The primary mineralogy (apatite) is preserved. All fossils show a decrease in CO_3/PO_4 ratio, but no regular trend from the top to the bottom of the excavation. Crystallinity is variable. All bones are strongly depleted in organic matrices, but again no regular trend has been detected through the stratigraphic levels.

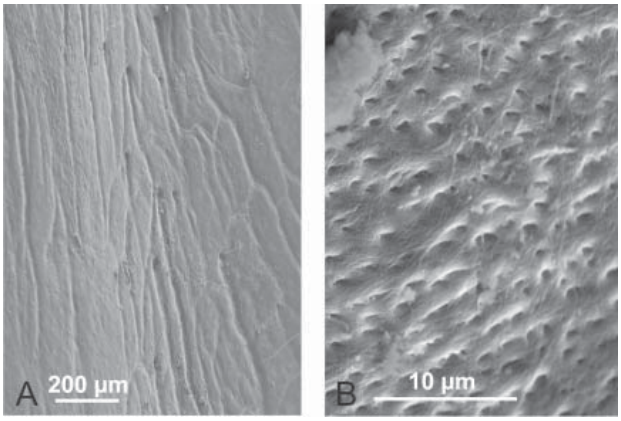

Figure: External surface (A) and fracture (B) of a femur of *Meriones*

Preliminary extractions yield very few quantities of soluble and insoluble organic components, and insoluble extracts contain residual minerals. There is no correlation between the external aspect and the preservation of histology and composition. Additional data are needed to answer the question about biases and changes in biodiversity in this site.

The Buffering Nature of Iron Slag in Ironville, Adirondacks, NY, USA—a Preliminary Study

DORI J. FARTHING[1*]

[1]The State University of New York at Geneseo, Geneseo, NY, USA, farthing@geneseo.edu (* presenting author)

For years, acid rain has been an issue for the Adirondack region of the United States. Extremely low pH values have impacted the hydrosphere and the health of many local ecosystems (e.g., [1, 2]). This preliminary study indicates that, in Ironville, NY, the presence of iron slag might buffer these extreme conditions.

Iron smelting in Ironville, NY took place from 1828 through 1886. Today, all that remains of the operations are the foundations of worker buildings, part of the furnace and a ~362 square meter slag pile. The pile is a loosely consolidated mixture of slag and other debris including bricks and modern tree roots. The slag is highly glassy, variegated in color, and often has a vesicular and ropey appearance. Iron prills are common and are often in an oxidized state. Some samples also contain visible areas of crystalline material. SiO_2, FeO, and CaO predominate the major element chemistry for Ironville slag. Slag is not confined to the pile and can be found littering the ground adjacent to the pile, around the smelter remains, and also in Putnam Creek which borders the pile.

More than 50 soil samples from the slag pile and its vicinity were collected and analyzed on site using a Hellige-Truog Soil pH test kit. GPS data was collected in coordination with each soil sample so that a detailed map could be generated. The soils of the area are typically a fine sandy loam and the analyzed samples came from predominantly the O and A horizons (the upper 13 cm of soil). A pit was dug into the slag pile and soil-like material from the pit was also analyzed for pH. Soils from the pile and adjacent to it have an average pH of 8.0. Even close to the furnace, pH values continue to be mildly basic in nature. Moving beyond the pile, the basic pH persists and even 0.8 km downstream from the pile, pH's of 8 were still found. However, when soil samples were tested approximately 13 Km away, the soil pH dropped down to a value of 2.

Partitioning and mobility of trace elements in brine impacted fly ash residues

O.O. FATOBA[1*], L.F. PETRIK[1], R.O. AKINYEYE[1] AND W.M. GITARI[2]

[1]Environmnetal and Nano sciences Resaerch Group, Chemistry Department, University of the Western Cape, Private Bag X17, Bellville, 7535, South Africa. (*Correspondence: ofatoba@uwc.ac.za)

[2]Department of Ecology and Resourses Management, University of Venda, Thohoyandou, Limpopo, South Africa

Fly ash and brine are waste materials generated from the combustion of coal and wastewater treatment respectively. Apart from the major elements, these waste materials contain trace elements such as As, Zn, Cu, Pb, Mo and Cr. The need to safely dispose fly ash and brine, in order to avoid contaminating the surrounding soils and groundwater, has led to the co-disposal of fly ash and brine by some power utilities in South Africa. Chemical speciation reveals the availability and mobility of metals in solid materials in order to understand their chemical behaviour and fate [1]. To evaluate the availability and mobility of metals from solid materials such as fly ash, some extraction tests such as sequential chemical extraction have often been applied. This study aims at determining the partitioning of the trace elements and their mobility in the brine impacted fly ash residue. The brine impacted fly ash residue was exposed to sequential chemical extractions [2]. The filtrates from each of the sequential extraction steps were analysed for trace elements using ICP-MS. The results of the tests showed that trace elements were partitioned into different physicochemical forms in the residue. Apart from the bulk of the Co, Cu, Ni, Pb and Zn that are contained in the residual fraction, high concentrations of these elements in the carbonate fraction showed their existence as co-precipitates with carbonate minerals which are not easily mobile under natural environmental conditions except when the pH is very low.

Geochemical investigations of fjord surface sediments as basis for Holocence climate change studies in the Trondheimsfjord area

JOHAN C. FAUST[1*], JOCHEN KNIES[1], JACQUES GIRAUDEAU[2] AND GESA MILZER[2]

[1]Geological Survey of Norway, Trondheim, Norway, Johan.Faust@ngu.no (* presenting author), Jochen.Knies@ngu.no

[2]EPOC, University of Bordeaux - CNRS, Talence, France, j.giraudeau@epoc.u-bordeaux1.fr, g.milzer@epoc.u-bordeaux1.fr

High sedimentation rates in fjords provide excellent possibilities for high resolution sedimentary and geochemical records over the Holocene. To increase the understanding of these records the aim of this study is to investigate (a) recent factors controlling the inorganic/organic geochemistry of surface sediments, (b) to identify geochemical proxies for terrestrial input/river discharge and (C) compare these findings with Holocence records from three sediment cores.

In April 2011 sixty evenly distributed surface sediment samples were collected around the entire Trondheimsfjord, one of the largest fjords in Norway. All samples were analysed with regard to elemental composition, total organic carbon (TOC) and total nitrogen content (N), organic and inorganic carbon and nitrogen stable isotopes ($\delta^{13}C$, $\delta^{15}N$), bulk mineral composition and grain size distribution.

The TOC:N ratio of all samples varies between 8 and 16. However, excluding 7 samples collected in river deltas the ratio decreases to 8-10 corresponding to a high correlation between TOC and N (r^2=0.95) indicating a marine source. The fraction of $CaCO_3$ decreases gradually from 24% at the entrance to 1.4% at the inner fjord. The ratios of Fe/Al, Zr/Al and Sr/Ca show the opposite pattern. They are highest at river deltas and at the inner part of the fjord. Anthropogenic influences are identified by elevated heavy metal concentrations around Trondheim and heavy industries near the city of Orkdal in the south. The highest amount of total nitrogen (0.21%) and TOC (1.87%) are found at the fjord entrance in the Stjørnfjord. We assume that the TOC and N values are high in the Stjørnfjord due to a local upwelling. The Atlantic water entering the fjord is topographically steered towards the surface and induces an area of high primary production.

Our findings show that three main factors control the elemental distribution in Trondheimsfjord surface sediments: the inflow of ocean waters, the inflow of river waters and anthropogenic contributions. Therefore, we propose that Trondheimsfjord sediments provide an excellent geochemical record reflecting the intensity of river discharge and the impact of the North Atlantic Current on local climate and environmental changes since the last deglaciation. The application of these findings to Holocence sequences will provide insights into climate vulnerability of the Trondheimsfjord region.

Using surface complexation modeling to quantify bioavailability of metals to bacteria

JEREMY B. FEIN

University of Notre Dame, Civil Engineering and Geological Sciences, Notre Dame, IN 46556 USA; fein@nd.edu

Determining the controls on metal bioavailability is crucial in order to understand the geomicrobiology of geologic systems with high metal concentrations, such as acid mine systems or contaminated soils, and in order to optimize bioremediation strategies aimed at remediating those types of systems. In addition, the controls on the rates of several environmentally significant metabolic processes, such as mercury methylation or bacterial reduction/oxidation of metals, are poorly understood. The key to improved models of all of these geomicrobiological processes is the ability to quantitatively model bacterial metal bioavailability. Metal adsorption onto bacterial cell walls represents the first interaction of a metal with the cell, and for this reason we hypothesize that accessibility of the metal to the cell is directly related to, and can be predicted by, cell wall metal speciation.

In the research that will be discussed, we test the hypothesis that bacterial surface speciation and concentration of heavy metals controls the bioavailability of those metals. Previous models of metal bioavailability (e.g., the Biotic Ligand Model) characterize metal binding onto a wide range of organisms using a generic, unspecified metal-binding biotic ligand that does not account for the many complexities of metal adsorption reactions onto biological surfaces. These models often fail because of these overlooked complexities in adsorption reactions. Over the past 15 years, we have learned much about the mechanisms involved in metal binding onto bacterial cell walls, and have developed quantitative surface complexation models based primarily on x-ray absorption spectroscopy and bulk adsorption measurements.

In this presentation, I will review my group's work to improve surface complexation models of bacterial metal binding, and to use those models to quantify the controls on the bioavailability of aqueous metals to bacteria. We have shown that bacterial chemotactic response and the enzymatic reduction of U(VI) are two examples of adsorption-controlled processes. The extent and rate of both of these processes can be directly related to the concentration of metal adsorbed onto the bacterial cell wall. Therefore, improving the sophistication and accuracy of surface complexation models of metal adsorption onto bacteria will lead to improved quantitative models of bacterial processes in realistic complex systems.

"Normal" Southern Volcanic Zone basalts behind the arc at 34˚15′-34˚45′ S

MAUREEN FEINEMAN[1*], TIMOTHY MURRAY[1], DANA DREW[2], PATRICIA SRUOGA[3]

[1]Pennsylvania State University, University Park, PA, USA, mdf12@psu.edu (* presenting author)
[2]University of Oregon, Eugene, OR, USA
[3]CONICET/SEGEMAR, Buenos Aires, Argentina

The section of the Southern Volcanic Zone (SVZ) between ~33˚S and 34.5˚S is distinguished from the more southerly SVZ by its distinct geochemical signature – namely, $^{87}Sr/^{86}Sr$ > ~0.7045, Sr/Y > 35, La/Yb > 12, and major element characteristics typical of the High-K andesite series. Also charactieristic of the northernmost segment of the SVZ is a lack of basaltic lavas on the volcanic front (basaltic andesites are common). The distintive geochemical characteristics of the Northern SVZ magmas suggest a unique source, either in a lower crustal hot zone [1] / MASH zone [2], where mantle melts are hybridized by extensive partial melts of deep lower crust, or by incorporation of eroded crustal materials into the mantle source itself [3,4]. The lack of primitive basaltic materials in the NSVZ makes it difficult to directly assess the nature of the subarc mantle in this region. We have sampled seven olivine basalt lava flows, tephra rings, maars, and cinder cones from just behind the volcanic front (~50 km from the arc axis) between 34˚15′ and 34˚45′ S. Although these basalts do not necessarily represent the mantle source beneath the arc front, they do provide some constraints on the mantle composition at this latitude. The Sr isotopic composition of these primitive basalts is $^{87}Sr/^{86}Sr = 0.7040 \pm 0.0004$ (2σ), which is statistically different from the basaltic andesites and andesites located on the arc front at the same latitude, which have $^{87}Sr/^{86}Sr = 0.7050 \pm 0.0004$ (2σ). Neodymium isotopes show the same trend, with less overall varibility.

The basalts from behind the arc at 34˚15′ to 34˚45′ S have isotopic compositions essentially identical to those found in arc front lavas from the SVZ south of 35˚. It is certainly possible to imagine scenarios in which the mantle directly behind the arc could be compositionally decoupled from the mantle directly beneath the arc. Nonetheless, the existence of typical SVZ mantle in the atypical NSVZ region suggests that mantle source contamination by eroded crustal materials is not a pervasive feature at these latitudes. The strong contrast in source composition over 50 km E-W can be compared to the relative homogeneity of the NSVZ (radiogenic Sr) signature over ~150 km N-S at the arc front. Alternatively, the arc front lavas in the SVZ may be sourced in a hybridized lower crustal hot zone, while the behind-arc samples are sourced from the mantle itself with little crustal interaction. The lack of crustal interaction is consistent with thinner crust behind the arc, as well as the occurrence of these monogenetic basaltic features along lineations, suggesting that the low-volume melts have exploited planes of weakness in the overlying crust.

The Cu Conundrum: Cu Budget During Partial Melting of Earth's Upper Mantle

STEVE A. FELLOWS[1*] AND DANTE CANIL[2]

[1]University of Victoria, Victoria, Canada, sfellows@uvic.ca (* presenting author)
[2]University of Victoria, Victoria, Canada, dcanil@uvic.ca

Abstract

Primitive basaltic glasses from mid-ocean ridges (MORB), ocean islands (OIB) and arcs contain three to five times the Cu as the currently accepted primitive upper mantle (PUM) value, suggesting a bulk partition coefficient $D_{Cu}^{mantle/melt}$ of ~0.20. Sulfide, with a $D_{Cu}^{sulfide/melt}$ of > 250 is presumed to be ubiquitous in the mantle, but its presence during melting is not commensurate with the Cu abundances in most basalts. To address this conundrum we determined D_{Cu} in olivine and orthopyroxene at 1250–1525 °C and 1.0 GPa in a hydrous basalt and KLB1 peridotite, at fO_2 near to melting conditions of the upper mantle. The measured $D_{Cu}^{ol/liq}$ of 0.06-0.21 and $D_{Cu}^{opx/liq}$ 0.15-0.82 do not vary with melt fraction, nor significantly with fO_2, and can be combined with estimates for D_{Cu} for clinopyroxene into melting models to examine the Cu contents of mantle-derived melts. The Cu abundances for MORB, OIB, and arc glasses are all explicable by the melting (up to 15%) of the silicate-only portion of the mantle in which Cu behaves as a mildly incompatible element $D_{Cu}^{mantle/melt}$ of ~0.26. For Cu to be enriched in basaltic melts in the presence of sulfide, the melt/sulfide ratio, or the oxidation state of the mantle during melting, must be significantly high to diminish the potential of sulfide to sequester any Cu.

Conclusion

Our results suggest the role of sulfide during mantle melting may be insignificant in regards to controlling the concentration of moderately chalcophile elements like Cu, and confirm that the previously estimated Cu content for PUM of 20 ppm is correct.

The dynamic nature of iron oxyhydroxides on modes of ion retention

SCOTT FENDORF[1*]

[1]Stanford University, Stanford, CA, USA, fendorf@stanford.edu (* presenting author)

Introduction

Iron oxyhdyroxides exert a dominant control on the fate and transport of numerous elements ranging from arsenic to phosphate to uranium. Owing, in part, to the redox active metal center, iron oxyhydroxides are dynamic solids within soils and sediments. As a consequence, iron retention is not strictly an adsorption phenomena but rather commonly also entails uptake into the mineral structure.

Conclusions

The iron oxide ferrihydrite is particularly prone to Fe(II) induced transformation to thermodynamically more stable phases such as goethite. Upon formation of the secondary phases, elements such as arsenic and uranium can be incorporated into the surface structure or adsorbed on the mineral surface; in the case of uranium, we also see reduction and secondary precipitation of UO_2 as a common retention mechanisms. However, competing ions such as phosphate as well and structural dopants (e.g., Al) modify the transformation pathway of ferrihydrite and may therefore limit formation of secondary phases that can host arsenic and uranium. The mode of retention is, however, often not singula, with multiple mechanisms in operation. Further, geochemical gradients, and in particular redox gradients resulting from variations in oxygen egress, lead to progressive changes in retention mechanisms. As an example, uranium retention often occurs via adsorption at high oxygen concentrations and progresses through a coprecipitated phase to a heterogeneously nucleated uranannite phase with successfully lower oxygen partial pressures. Here, variation in retention mechanisms and their spatial distribution within soil/sediment assemblages are illustrated.

The impact of on mineral surfaces metal-contaminant redox cycles

SCOTT FENDORF[1]*, AND PETER S. NICO[2]

[1]Stanford University, Stanford, CA, USA, fendorf@stanford.edu (* presenting author)
[2]Lawrence Berkeley National Laboratory, Berkeley, CA, USA, psnico@lbl.gov

Introduction

Redox reactions have a controlling influence on the cycling of numerous elements within surface and subsurface environments. Mineral surfaces are particularly critical conduits for redox reactions that both invoke and catalyze electron transfer processes, and which do so at rates that often rival (or even exceed) biologically mediate reactions. Here we examine the role metal (hydr)oxides play in the oxidation-reduction of elements ranging from arsenic to nitrogen to uranium within surface and near-surface environments.

Results and Conclusions

Of the various oxidizers in soils and sediments, Mn(III/IV) oxides are classically the strongest oxidant present; they serve as facial oxidants of most redox active metals and metalloids. While we generally do not consider solid-solid electron transfer processes, the rapid rates of oxidation imposed by Mn oxides for species such as Cr(III) allow even sparingly soluble solids (e.g., chromite) to undergo oxidation through a solubility minimum. In contrast to Mn, Fe can serve as a potent reductant as Fe(II) or an oxidant as Fe(III). For metals with close redox couples to Fe(III)-Fe(II), such as U(VI)-U(IV), the specific form of the Fe(III) mineral along with reaction conditions determine whether Fe serves as a reductant or oxidant. In other cases, such as with Cr(VI), Fe(II)-bearing solids and surfaces serve as dominant reductants. Collectively, metal (hydr)oxides have a critical impact on the redox state of a wide-range of elements within soils and sediments.

A reevaluation of early Cambrian ocean redox conditions through the iron geochemical studies of the lower Hetang black shales in South China

LIAN-JUN FENG[1*], CHAO LI[2], JING HUANG[1], HUA-JIN CHANG[3], CHAO-FENG LI[1], QI-RUI ZHANG[1], XUE-LEI CHU[1]

changhuajin@163.com

The widespread organic-rich shales during the early Cambrian in South China were always regarded to be deposited in persistent euxinic conditions suggested by the enrichment of redox-sensitive trace elements and narrow distribution of small-size pyrite framboids [e.g. 1].

In this study, iron speciation and ratios, widely applied redox proxies, clearly reveal that the black shales of the lower Hetang Formation were predominantly deposited under anoxic and ferrous iron-rich (ferruginous) water columns with some intermittent intervals of euxinia in contrast the previous interpretation of persistent euxinia. These observations suggest that the anoxic and ferruginous conditions during early Cambrian may have been more prevalent than generally recognized.

Mercury contamiation to the environment and health impacts by small and large scale Hg mining activties in China

XINBIN FENG[1,*], GUANGLE QIU[1], PING LI[1], HUA ZHANG[1], THORJORN LARSSEN [2]

[1]State Key Laboratory of Environmental Geochemistry, Institute of Geochemsitry, Chinese Academy of Scineces, Guiyang 550002, China, fengxinbin@vip.skleg.cn

[2]Norweigian Water Research Institute, Oslo, Norway, thorjorn.larssen@niva.no

China currently is one of the largest mercury (Hg) consumers and Hg producers worldwide. From the perspective of the global plate tectonics, Guizhou province is situated in the center of the circum-Pacific mercuriferous belt [1]. Therefore, Guizhou was one of the world's important Hg production centers. So far, at least 12 large and super-large Hg mines have been discovered in the province. Currently all large scale Hg mining activites in Guizhou were completely stopped, but small scale Hg mining activites are still on-going. The Xunyang Hg mine situated in Shaanxi Province is presently the largest active Hg mining district in China[2]. We have conducted detailed studies to investigate Hg contamiantion to the envirnment and health impacts to local inhibitants at both large scale Hg mining and small scale (artisanal) Hg mining areas.

Our study revealed a significant contamination of Hg in soil, sediment, water, and rice in both Hg mining areas in Guizhou and the Xunyang Hg mining district. The highest concentrations of Hg in riparian soil, sediment, water and rice were found at the areas in the vicinity of the Hg retorting and mining sites. Moreover, GEM concentrations in ambient air exhibits a local spatial pattern indicating Hg^0 emission during the process of cinnabar ores retorting. Elevated concentrations of MeHg in rice also were found. The sources of MeHg in rice mainly derived from the soil MeHg, which is likely related to the deposition of GEM [3]. High concentrations of THg in surface water and stream sediment are mainly constrained by the calcines introduced during the retorting activity, which represents the major source of Hg contamination to the local ecosystems in the region. The mining waste piles in the study region must be appropriately disposed of and the mine runoff from those calcine piles should be properly treated and not be used as irrigating water to the paddy field. Our study showed that artisanal Hg miners exposed to high levels of Hg vapor and urine Hg concnetrations in Hg miners were two to three magnitudes higher than the control groups. Our data showed a serious adverse effect on renal system for the smelting workers. The workers were exposed to mercury vapor through inhalation, and the exposure route of Me-Hg was through intake of rice. Meanwhile, rice consumption is the primary MeHg exposure route for the local population in Hg mining areas.

Zircons in the T-Zone, Thor Lake rare element deposit: implications for deposit genesis

YONGGANG FENG[1*], AND IAIN SAMSON[2]

[1]University of Windsor, Department of Earth and Environmetal Sciences, fengl@uwindsor.ca*

[2]University of Windsor, Department of Earth and Environmetal Sciences, ims@uwindsor.ca

The Thor Lake Y-REE-Nb-Ta-Zr-Be deposit, NWT, Canada, one of the largest known rare-element deposits hosted by alkaline-peralkaline igneous complexes, comprises two main mineralized zones: the Nechalacho deposit and the T-Zone. The T-Zone is hosted by granite and syenite, and is a pegmatite that has a significant hydrothermal overprint. It is zoned, comprising, from rim to core, a Wall Zone, Lower Intermediate Zone (LIZ), Upper Intermediate Zone (UIZ), and Quartz Core Zone.

We have investigated the morphology, internal textures and chemistry of hydrothermal zircon from the UIZ and magmatic zircon from the host granite and syenite, combining LA-ICP-MS analysis with petrography, CL imaging, SEM-EDS and EMPA. Based on the morphology and associated mineral assemblages, zircon can be broadly classified into three types. Type 1 is fine grained (< 50 μm), euhedral, well-zoned, hydrothermal zircon and mainly occurs in pseudomorphs that have a prismatic to rhombic habit. Type 1 zircon can be subdivided into two subtypes: 1a, which is hosted by massive quartz, and 1b, which is associated with fluorite and sulfides. Type 2 zircon is anhedral, unzoned, and fine-grained, and is associated with rutile, quartz, magnetite, and hematite in the LIZ. Type 3 is magmatic zircon from the host igneous rocks, that is coarser grained and (50 ~ 300 μm) and also exhibits oscillatory growth zoning.

Type 1 zircon was affected by Ca metasomatism that altered the zircon and precipitated REE-bearing minerals, such as xenotime. Ti and REE concentrations in Type 1 and 3 zircons were obtained by LA-ICP-MS (Type 3 zircon was also analyzed by EPMA). The Ti in the unaltered magmatic zircon yields apparent Ti-in-zircon temperatures of ~ 614 to 860°C. In contrast, hydrothermal zircon has unreasonably high Ti concentrations and therefore calculated temperatures. This type of zircon contains high concentrations of REE and other HFSE, such that the coupled substitutions involving Ti may be affected to such an extent to invalidate the established geothermometric calibrations. Alternatively, the assumptions regarding Ti activity are invalid under hydrothermal conditions [1]. Both magmatic and hydrothermal zircon are generally HREE-enriched and exhibit negative Eu anomalies, however, the former is distinguished by a pronounced positive Ce anomaly. In addition, significant tetrad effects observed in the REE patterns of Type 1a zircon, but not Type 1b zircon, suggest that the nature of coprecipitated minerals play an important role in controlling zircon REE chemistry.

Structure of the calcite (104)-Water interface: direct comparison of x-ray reflectivity data with computational results

PAUL FENTER[1*], SANG SOO LEE[1], NEIL C. STURCHIO[2], AND SEBASTIEN N. KERISIT[3]

[1]Argonne National Laboratory, Chemical Sciences & Engineering, Argonne, IL, USA. fenter@anl.gov
[2]University of Illinois at Chicago, Earth and Environmental Sciences, Chicago, IL, USA.
[3]Pacific Northwest National Laboratory, Chemical & Materials Sciences Division, Richland WA, USA.

Understanding the calcite-water interface structure is important because of its abundance in natural systems, relatively high reactivity (e.g., rates of growth and dissolution), and ability to incorporate trace impurities. Previous studies have probed the structure of the calcite-water interface by X-ray reflectivity (XR) [1] and computational approaches [2]. These different approaches have led to a qualitatively similar picture of the molecular-scale structure at this interface, including displacements of the surface lattice and organization of the fluid water adjacent to the surface, but without a full quantitative agreement in the derived structures. It is unclear if these differences are significant (i.e., if there is a conflict between the XR measurement and the simulation) or whether the apparent discrepancy between the XR data and the simulation reflect a deficiency in the model used to described the XR data (e.g., due to a potential non-uniqueness of the model).

Substanial improvements in XR reflectivity data quality due to advances in detectors over the past ~10 years suggest that a reassessment of this system may be warranted. New XR measurements of the calcite-water interface were made at the Advanced Photon Source following previously described procedures [1] and care was taken to avoid X-ray-induced perturbations to the interfacial structure. The XR results show clear modulations of the specular reflectivity signal, which are associated with the presence of a small but significant oscillatory relaxation profile of the calcite surface layers, which has not been previously observed. Also observed is an organized interfacial water layer, similar to previous results.

A further test of these new results is to compare these XR data *directly* to computational results without any intevening model-dependent assumptions using a recent conceptual advance [3]. Comparison with a molecular-dynamics simulation shows that the simulated structure provides a qualitative description of the XR data, but with a poorer quality of agreement than that obtained using the model-dependent fitting approach.

High Os in late Devonian, shale hosted epigenetic pyrite

The Devonian - Mississippian Earn Group in the Selwyn Basin contains a number of sediment-hosted barite sequences which outcrop in the Mackenzie Mountains, NWT and Yukon. The Hess occurrence (middle Devonian) contains epigenetic pyrite with textures suggesting that it was formed post-lithification, but predating barium mineral formation.

Re-Os isotopic composition of Hess pyrite give values of 16.51 to 93.8 for $^{187}Re/^{188}Os$, and 0.8253 to 1.6001 for $^{187}Os/^{188}Os$ respectively. Most calculated initial $^{187}Os/^{188}Os$ ratios (at 390 Ma) range from 0.6 to 0.9, substantially higher than that of the $^{187}Os/^{188}Os$ value for seawater at the Frasnian-Fammenian boundary (0.42) [1].

Oxidation of organic matter as a source of Os

We suggest, therefore, the fluid that precipitated pyrite had acquired substantial radiogenic Os before pyrite formation. It is likely that organic matter in the underlying lower Earn Group shales was the source for the high Os and low Re values in the fluid. Oxidizing fluids migrating through the stratigraphy would be necessary in order to degrade the organic matter in the host shale and solubilize Os.

If we assume the Os is derived from the host shales, then modeling the data suggests that it would take 25 to 75 Myr to generate the high initial $^{187}Os/^{188}Os$ ratios observed. This supports an epigenetic source for the pyrite and suggests that the Re-Os isotopic system is a powerful tool in understanding the evolution of black shales and shale-hosted mineralization.

[3]Arcadis, Villeurbanne, France

[4]Comurhex Malvési, Narbonne, France

The COMURHEX Malvési industrial site is the first step in the treatment of uranium mining concentrate. Since 1959, the process waste, resulting from the conversion of yellowcake into uranium tetrafluoride (UF_4) has been managed in settling ponds. These ponds have been constructed on mine tailings and waste resulting from the flotation process of a former sulphur mine.

The settling waste, i.e. the resulting sludge, contains a variety of chemicals (nitrates, carbonates, fluorides and sulphates) and radioactive elements (the alpha activity in the solid phase is attributable to uranium (34%) and thorium-230 (64%)).

Previous studies of the source term suggest that the mine tailings act as an efficient buffer that minimises migration to the underlying ground. However, the actual mechanisms by which this control is active are not well understood.

This contribution focuses on the mobility of uranium in the waste based on the results of static experiments (batch studies) of leaching of solid samples. We aim to examine the desorption mechanisms that may account for release of contaminants from the waste and compare the results to field conditions.

In situ GISAXS studies of carbonate mineral nucleation on mineral surfaces

ALEJANDRO FERNANDEZ-MARTINEZ[1,*], YANDI HU[2], YOUNG-SHIN JUN[2], GLENN A. WAYCHUNAS[1]

[1]Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, USA, AFernandez-Martinez@lbl.gov (* presenting author)

[2]Department of Energy, Environmental and Chemical Engineering, Washington University, St. Louis, MO, USA

The precipitation of carbonate minerals –mineral trapping– is considered the safest CO_2 sequestration mechanisms. However, the high pressure and temperatures and the high salinity of the fluids present in many geological reservoirs play important roles in modifying the properties of the mineral faces exposed to the solution, adding more uncertainties to the factors controlling nucleation in these environments. The goal of the present study is to determine the thermodynamic factors controlling heterogeneous nucleation of carbonate minerals on mineral surfaces representative of both reservoir and cap rocks. The quartz (100) and a mica (001) faces have been selected as representative of a sandstone reservoir and as a mineral face characteristic of cap-rocks, respectively.

A technique based on Grazing-Incidence Small-Angle X-ray Scattering, previously developed in our group [1], has been used to follow mineral nucleation of the carbonate minerals on quartz (100) and K-muscovite (001). By measuring nucleation rates at different saturation indexes, effective interfacial energies (α') can be determined. Effective interfacial energies result as the combination of different interfacial energies involved in the process: α_{ls} (liquid-substrate), α_{lc} (liquid-crystal) and α_{sc} (substrate-crystal). Literature values for α_{ls} and α_{lc} allow determining α_{sc}, a quantity very difficult to measure using other techniques.

The first experiments have been performed nucleating $CaCO_3$ on quartz (100) at ambient pressure and room temperature. The results show that heterogeneous nucleation of calcium carbonate is favored on quartz (100), even though the obtained substrate-crystal interfacial energies are higher than the typical values for liquid-crystal interfaces (*e.g.*, ~100 mJ/m^2 for calcite-water interfaces). This fact highlights the interplay existing between the different interfacial energies at play, and the 'competition' between water and the nucleated crystals for the substrate. From a thermodynamic point of view, and as a general rule of thumb, high substrate hydrophobicity and low surface mismatch are found to favor heterogeneous nucleation. In addition, a crystal growth mechanism based on aggregation of nuclei has been identified to be the dominant mechanism at the circum-neutral pH solution values used in this study.

Other mineral substrates currently under study include the edge-faces of phlogopite, a mica mineral, and olivine. These *in situ* and *ex situ* observations yield important quantitative parameters readily usable in reactive transport models of nucleation at the reservoir scale.

[4] Fac. Ciencias, Univ. Republica, Montevideo, Uruguay

[5] Universidad Nacional de Salta, Salta, Argentina

Introduction. Mercury tends to concentrate in sediments deposited right after major glacial events [1] as a result from leaching of volcanogenic Hg from land surface and accumulation along argillaceous sediments. Wherever geological background of Hg is negligible, its concentration in sediments may be useful for investigation of climatic changes.

Volcanism is assumed to be responsible for CO_2 build up in the atmosphere during Snownall Earth event with subsequent greenhouse effect, ice melting and cap carbonate deposition [2]. Intense volcanism witnessed the Cretaceous-Paleogene transition [3] and was, perhaps, responsible for dramatic climatic change.

Results. We have used Hg as a proxy of volcanism intensity and CO_2 buildup during snowball events in Neoproterozoic cap carbonates in NE Brazil. Localities where carbonates are in sharp – but not erosional – contact with basal diamictites (earliest stages of aftermath of glacial events) and show $\delta^{13}C$ values ~ −5‰ were analyzed. Hg contents are usually over 10 times higher than background values (<1 ngg^{-1}), occasionally reaching values > 200 ng g^{-1}. Hg contents in cap carbonates of the Sergipano Belt and Ubajara Basin are similar to those in carbonates deposited coevally to volcanic activity elsewhere. This study supports mantle-origin for the CO_2 in cap carbonates, transferred to the atmosphere by volcanism.

Across the the K-T transition (KTB) in the Yacoraite Formation, Argentina, Hg contents reach ~ 20 ngg^{-1}. In three drill cores in carbonate rocks across the KTB in the Paraiba Basin, northeastern Brazil, Hg increases (4 ngg^{-1}) in the early Danian right above the KTB. Hg spikes predating immediately the KTB suggest volcanism before this transition. At Stevns Klint, Denmark, Hg contents reach almost 300 ngg^{-1} within a 5 cm-clay layer (Fish Clay) that registers the KTB, and where a $^{87}Sr/^{86}Sr$ positive excursion and negative excursions of $^{206}Pb/^{204}Pb$ (T=65 Ma) and $^{187}Os/^{188}Os$ (T=65Ma) have been observed [4].

Hg content and Al_2O_3 show stratigraphically co-variation in all of the studied sections of Neoproterozoic cap carbonates or across the KTB, suggesting that Hg is probably adsorbed onto clays.

Conclusions. This study supports Hg stratigraphy as possible tracer of dramatic climatic changes as those in Neoproterozoic snowball Earth events and in the KTB.

Hydrothermal hydrocarbon gases: geothermometry and origins

JENS FIEBIG[1]*, FRANCO TASSI[2], WALTER D'ALESSANDRO[3], ORLANDO VASELLI[2] AND ALAN B. WOODLAND[1]

[1]Goethe University Frankfurt, Earth Sciences, Jens.Fiebig@em.uni-frankfurt.de (* presenting author)

[2]University of Florence, Earth Sciences, Franco.Tassi@unifi.it

[3]INGV Palermo, w.dalessandro@pa.ingv.it

Upon their ascent through the crust, volcanic gases often interact with externally and internally derived fluids. For reasons of energy exploitation and surveillance of volcanic activity it is of great interest to determine hydrothermal temperatures at depth. Methane discharging from these systems has been ascribed a hydrothermal origin, with the magnitude of carbon isotope fractionation between CH_4 and CO_2 reflecting the formation temperature of CH_4 [1]. For most volcanic-hydrothermal discharges, however, apparent carbon isotopic temperatures cannot be confirmed by common gas concentration geothermometers involving redox pairs such as H_2/H_2O and CO/CO_2. In these cases, the geological significance of the carbon isotope geothermometer remains open.

We have addressed the genetic relationship between H_2, H_2O, CO, CO_2, n-alkanes and n-alkenes in volcanic-hydrothermal gases emitted from Nisyros (Greece), Vesuvio, Campi Flegrei and Pantelleria (all Italy). Our results imply that the isotopic CH_4-CO_2 geothermometer records temperatures of CO_2-water interaction at depth. In any case, apparent carbon isotopic temperatures are confirmed by measured propene/propane concentration ratios. Apparent temperatures are close to the critical conditions of pure and saline waters, i.e. ~360°C at Nisyros, 420-460°C at Vesuvio, ~450°C at Campi Flegrei and ~540°C at Pantelleria. For temperatures >400°C, apparent carbon isotopic temperatures are additionally confirmed by ethene/ethane ratios. At least in some systems, CH_4-CO_2 and propene-propane equilibration takes place in different water phases, implying that boiling in high-enthalpy hydrothermal systems may occur isothermally. Among the redox pairs investigated, CO/CO_2 is most prone to secondary vapor phase reequilibration reactions occurring after hydrothermal interaction at depth. Redox conditions during these reactions are homogeneously buffered by H_2/H_2O ratios of the vapor.

Methane most likely derives from an abiogenic source (Sabatier-type reduction of CO_2). In contrast to CO_2, the C_{2+}-n-alkanes are not in equilibrium with CH_4. They derive either from the thermogenic decomposition of organic matter or from abiogenic methane polymerization.

Extreme magmatic differentiation at Dabbahu Volcano, Afar, Ethiopia

L. FIELD[1], J. BLUNDY[1*], A. CALVERT[2], G. YIRGU[3],

[1]School of Earth Sciences, University of Bristol, UK
jon.blundy@bris.ac.uk
[2]USGS, Menlo Park, USA
[3]Department of Earth Sciences, Addis Ababa University, Ethiopia

Dabbahu is a composite volcano at the north end of the Manda-Hararo segment of the Afar Rift, Ethiopia, which has experienced multiple dyking events since 2005. Dabbahu has erupted magmas ranging in composition from mildly alkaline basalt through trachyandesite to peralkaline rhyolites (comendites and pantellerites). Effusive eruptions predominate. On the basis of a new geological map, 93 new whole rock major and trace element data, mineral analyses from 65 samples, and 9 new ^{40}Ar / ^{39}Ar dates we show that Dabbahu has been active for a little over 70,000 yrs. Samples are aphyric or phenocryst-poor with olivine + clinopyroxene + feldpsar present in all rock types; minor Fe-Ti oxides and aenigmatite occur in some more evolved rocks. Continuous variations in whole rock chemistry, mineral compositions, e.g. Fo_{88-0} olivine, and calculated eruption temperatures support earlier findings [1] that the magma types are related through protracted (~90%) fractional crystallisation from a basaltic parent. Field evidence indicates that magmas were not erupted in fractionation sequence. Some magma mixing between cogenetic magmas is observed in intermediate rocks, but was not a primary cause of chemical varaitaion in the suite as a whole.

Geochemical modelling indicates recently erupted transitional basalts from the Manda-Hararo rift constitute plausible parents. MELTS modelling of differentiation provides an optimal match to rock and mineral chemistries with crystallisation at 100-300 MPa pressure and fO_2 ~1 log unit below FMQ buffer to suppress saturation with orthopyroxene, which is not observed in any samples. Melt inclusions from pantelleritic obsidians and pumices contains up to 6 wt% H_2O and ≤500 ppm CO_2, consistent with ~0.5 wt% H_2O in the parent basalt. Volatile saturation pressures are in the range 30-250 MPa, although solubilities in pantelleritic liquids are not well constrained experimentally. The CO_2-H_2O systematics are consistent with cooling-driven crystallisation of small magma batches over a range of depths, probably in a complex of stacked sills.

We propose that differentiation from basalt to rhyolite occurs in sills (or dykes) at relatively shallow depths (5-10 km) beneath the volcano, although some prior differentiation of mantle-derived basalts is likely to have occurred at greater depths. The sub-volcanic plumbing system must be configured in such a way that cogenetic magmas of different composition can be stored separately prior to eruption, rather than in a single large sub-volcanic reservoir. It is likely that the volcanic load facilitated focussing of magmas through a single summit fissure or vent.

Introduction. A better understanding of the ecology and physiology of the methane-producing communities associated with coal-beds may promote new techniques that can improve coal-bed methane (CBM) production and enhance the sustainability of the wells. We have conducted initial phylogenetic diversity studies using inoculated coal and *in situ* samples from methane-producing wells in the Powder River Basin (PRB) (southeastern Montana and northeastern Wyoming). Advances in subsurface sampling and molecular techniques have provided a route to capture active microbial consortia from coal beds, but methods need to be refined in order to deal with the unique attributes of coal. We used coal-filled Diffusive Microbial Samplers (DMS) that were lowered into three wells in the PRB along a hydrogeochemical gradient and microbial communities were allowed to develop *in situ*.

Results and Conclusion. Coal slurry associated with the DMS had 100-fold more microbial cells as determined via epifluorescent direct counts. Coal slurry was immediately removed from the DMS in the field and fixed for FISH analysis. *Archaea* and *Bacteria* were detected and bacteria appeared to outnumber archaea within the *in situ* sample. Microorganisms appeared to be concentrated in the proximity of coal particles, and aggregates around coal particles contained both *Bacteria* and *Archaea*. Incubated materials from the DMS were used to inoculate enrichment cultures for the assessment of methane-production under different conditions, and archaeal diversity was low based upon both SSU rRNA and *mcr*A gene sequences. Sequences indicative of both hydrogentrophic and acetoclastic methanogens were detected. In addition, a coal-only enrichment contained higher bacterial diversity than an acetate-amended enrichment, and sequences indicative of presumptive fermenters and acetogens were observed. Nucleic acids were extracted from *in situ* material (DMS-coal and well-water), and 454 pyrosequencing libraries were used to characterize community composition and structure of *in situ* materials. Multivariate statistical methods were used to relate community composition and structure to hydrogeochemical parameters. The low sulfate well had low bacterial diversity compared to a well with intermediate sulfate levels while the archaeal diversity was higher in the low sulfate well compared to wells with higher sulfate levels. The described study aims to identify the relationships between populations of bacteria and archaea associated with CBM with the intent of identifying strategies for enhancement of *in situ* CBM production in terms of microbial structure-function relationships.

Coralline algae as pH-recorders on seasonal to centennial timescales

J. FIETZKE[1*], F. RAGAZZOLA[1,2], J. HALFAR[3], H. DIETZE[1], L.F. FOSTER[2], T.H. HANSTEEN[1], A. EISENHAUER[1]

Both ocean warming and acidification caused by the antropogenic emission of carbon dioxide (CO_2)are the major challenges to marine ecosystems. In particular marine calcifiers are expecteded to be affected in their ability to produce skeletal hard parts when facing an environment with continuously decreasing calcium carbonate ($CaCO_3$) saturation state.

To evaluate the performance and possible strategies of acclimatisation/adaptation of marine calcifying organisms the reconstruction of ambient seawater pH is essential. This reconstruction is in particular important for the last decades and centuries as it allows for a comparsion of natural and antropogenic pH variability.

Boron stable isotopes ($\delta^{11}B$) revealed from carbonates have been used as a proxy for seawater pH for many years. Using a recently published LA-MC-ICP-MS method [1] we analysed the spatial distribution of boron isotopes in a specimen of *Clathomorphum nereostratum* a long-lived crustose coralline alga that exhibits annual growth increments. Crustose coralline algae have recently been introduced as climate (SST) recorders in high-latitude shallow-water habitats.[2] The particular specimen used in this study was collected alieve off the coast of Attu island (Aleutian Islands) in summer 2004.[2] With an annual growth of 400-500µm the 6cm long profile covers more than the entire 20th century.

Here we present the first high-resolution 2D-images of boron isotopes providing a precision and accuracy close to analytical bulk techniques for a spatial resolution of 100µm. The combination of electron microprobe elemental mappings and LA-MC-ICP-MS isotopic images now allows for a detailed reconstruction of two seawater key parameters: SST from Mg/Ca and pH from $\delta^{11}B$, respectively.

Our data show that long-term pH-decrease is recorded in the skeleton of our sample specimen. Between 1900 and the 1990's boron isotopes indicate a drop of ~0.08(1) pH units which is in accord with the value expected from atmospheric CO_2 time-series data.

A seasonal cycle of pH-variability (up to 0.1 pH units) is recorded too with highest values during late spring/early summer. His is most likely a result of the CO_2 consumption during the spring microalgal bloom. The latter is in agreement with instrumental data from a nearby location. During the spring bloom in May a rapid pH increase of up to 0.15 units was measured.[3]

Smectites are phyllosilicates with high cation exchange capacity (CEC) in the interlayers. For these and other features, smectites have been used in various parts of the world as secondary barriers for possible leak of liquids that contain radioactive elements in definitive deposits of nuclear waste disposal [1]. In such case, radioactive cation could be captured by smectite through cationic exchanges. However, very little is known about the stability of smectite under high pressures and high temperatures (HPHT). Preliminary studies developed by our group in dioctahedral calcium smectites showed that the smectite structure is stable, remaining dioctahedric after processing up to 7.7 GPa and at room temperature [2]. This work replaced the calcium of the smectite for La^{+3}, an analogous of the actinide nuclear waste elements, with the difference that those elements are harmless [3]. We submitted this smectite doped with La to different range of pressure (2.5GPa and 7.7GPa) and temperature (400°C, 500ºC, 650°C and 700ºC), using a hydraulic presses with toroidal board, and we obtained a new La-rich muscovite-like structure. Moreover analyses of x-ray diffraction with Rietveld refinement, fourier transform infrared (FTIR) and transmission electron microscopy (TEM) were performed. Image of smectite doped with La from TEM shows layers of smectite with heavier elements due to the contrast of the image (Fig. 1) and also the effect of lattice fringe. Further images will be achieved in the coming days.

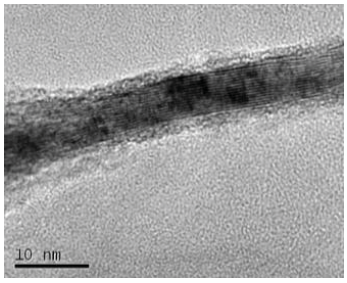

Figure 1: Image of smectite doped with La using TEM

Does reservoir rock integrity change during geological CO_2 storage in a saline aquifer?

SEBASTIAN FISCHER [1,2,*], AXEL LIEBSCHER[1], MARCO DE LUCIA[1], AND THE KETZIN-TEAM

[1]GFZ German Research Centre for Geosciences, Potsdam, Germany, fischer@gfz-potsdam.de ([*]presenting author)
[2]Berlin Institute of Technology, School VI, Department of Applied Geosciences, Chair of Mineralogy-Petrology, Berlin, Germany

At Ketzin in the federal state of Brandenburg, Germany, CO_2 is injected into a saline aquifer of the Upper Triassic Stuttgart Formation, since June 2008. Ketzin is the first European onshore pilot site for the geological storage of CO_2. To evaluate CO_2-fluid-rock interactions, two sets of long-term CO_2-exposure experiments were carried out. One set on reservoir rock (described here), the other on cap rock (data in process). Core samples of Ketzin reservoir sandstone were exposed to pure CO_2 and synthetic reservoir brine at simulated in-situ P-T conditions of 5 MPa and 40 °C. Mineralogical and geochemical analyses were performed on rock and fluid samples taken after 15, 21, 24, and 40 months, respectively. Over time, XRD data with Rietveld refinement show decreasing proportions of analcime, chlorite, hematite and illite, and increasing proportions of quartz. On freshly broken rock fragments, CO_2-treated samples display corrosion textures on plagioclase, K-feldspar and anhydrite surfaces. EMPA data exhibit a change in plagioclase composition from intermediate to Na-rich and albite endmember compositions. Compared to the synthetic reservoir brine, Na^+, Mg^{2+} and Cl^- concentrations increased slightly, while K^+, Ca^{2+} and SO_4^{2-} concentrations increased significantly. Reactive geochemical modeling using PHREEQC-2 code was performed to reproduce experimental observations.

The mineralogical and geochemical measurements imply preferred dissolution of Ca^{2+} out of plagioclase next to dissolution of K-feldspar and anhydrite. Petrophysical data show tendentially increasing porosities and permeabilities [1] also suggesting mineral dissolution during the experiments. Due to the heterogeneous character of the Stuttgart Formation, which formed in a fluvial environment [2], it is often difficult to distinguish between natural, lithostratigraphic variability and CO_2-related changes. Assuming thermodynamic equilibrium, preliminary reactive geochemical modeling of the observed CO_2-fluid-rock interactions shows that the measured evolution of fluid composition is consistent with precipitation of albite and dissolution of anhydrite and illite, respectively. Based on experimental data, the integrity of the Ketzin reservoir is not significantly affected by CO_2.

Ru isotope anomalies in meteorites

MARIO FISCHER-GÖDDE[1]*, CHRISTOPH BURKHARDT[2] AND THORSTEN KLEINE[1]

[1]Institut für Planetologie, Westfälische Wilhelms-Universität Münster, Wilhelm-Klemm-Str. 10, 48149 Münster, Germany, m.fischer-goedde@uni-muenster.de (*presenting author)
[2]Institut of Geochemistry and Petrology, ETH Zürich, Clausiusstrasse 25, 8092 Zürich, Switzerland

Nucleosynthetic isotope anomalies in bulk meteorites have been documented for some siderophile elements (e.g., Ni, Ru, Mo) [1-4] but seem to be absent for others (e.g. Os) [5]. The contrasting isotope systematics of these chemically similar elements may place important constraints on the extent and efficiency of mixing processes as well as pathways of material transport within the early solar nebula. So far, only a limited number of samples have been investigated for Ru and nucleosynthetic anomalies have been mainly reported for magmatic iron meteorites [3]. These Ru isotope anomalies correlate with those in Mo exactly as predicted from s-process nucleosynthesis, supporting evidence for a heterogeneous distribution of s-process carrier phases [1,4]. To further investigate the extent of Ru isotope anomalies in meteorites and to evaluate the significance of the cosmic Mo-Ru correlation we developed new analytical techniques for precise Ru isotope measurements by multicollector inductively coupled mass spectrometry (MC-ICPMS). We present new Ru isotope data for IVB iron meteorites, the ungrouped iron Chinga, and the CB chondrite Gujba. Ruthenium isotope compositions were measured using the ThermoScientific Neptune Plus at the University of Münster and are reported in ε^iRu-deviation from terrestrial Ru. For mass bias correction relative to $^{99}Ru/^{101}Ru$ all samples show a well resolved negative anomaly in $\varepsilon^{100}Ru$, consistent with previous data for IVB irons [3]. There are also hints for positive anomalies in $\varepsilon^{96}Ru$ and $\varepsilon^{98}Ru$ and negative anomlies in $\varepsilon^{102}Ru$ but these are not yet clearly resolved. When normalized to $^{99}Ru/^{100}Ru$ all samples show resolvable deficits in $\varepsilon^{96}Ru$ and large enrichments in $\varepsilon^{101}Ru$, $\varepsilon^{102}Ru$ and $\varepsilon^{104}Ru$. Small deficits in $\varepsilon^{98}Ru$ seem to be present as well but are currently not well resolved. The observed Ru isotope patterns are in excellent agreement with anomalies predicted for a deficit in s-process isotopes according to the stellar model of nucleosynthesis [6], consistent with previuosly reported data [3]. The CB chondrite Gujba plots on the Mo-Ru correlation line for a s-process deficit, indicating that the cosmic Mo-Ru correlation also extends to relatively young carbonaceous chondrites. However, more high-precision Ru isotope data for chondrites are needed to further evaluate the correlated behaviour of Mo and Ru anomalies in case of carbonaceous chondrites. A companion study on the same IVB irons did not find evidence for nucleosynthetic Pt isotope anomalies [7], indicating that in contrast to Ru and Mo, the solar nebula was well mixed with regard to Pt (and Os [5]) isotopes. The contrasting isotope systematics of Os, Ru and Pt may thus be related to thermal processes within the nebula, rather than reflecting a primordial heterogeneity in the distribution of presolar dust.

A Sr isotope survey of a marine terrace chronosequence: equilibrium interrupted.

JOHN A. FITZPATRICK*[1], MARJORIE SCHULZ[1], DAN BAIN[2], THOMAS D. BULLEN[1], AND ART WHITE[1].

[1]United States Geological Survey, Menlo Park, CA jfitzpat@usgs.gov (* presenting author)
[2]University of Pittsburg, Pittsburg, PA

A well studied marine terrace chronosequence north of Santa Cruz, CA affords an ideal natural laboratory for the investigation of established cation pool equilibrium dynamics. The soils mantling the 5 terraces have developed in sediments derived locally from the Miocene Santa Margarita sandstone, the Purisima formation, and Salinian granites. Each of the terraces were extensively instrumented and sampled. Soils, vegetation, surface and soil pore waters, and precipitation have been sampled at various intervals. Sr isotopes ($^{87}Sr/^{86}Sr$) and cation chemistry have been utilized to investigate sources, cycling and behaviour of Sr and other base cations within each terrace soil horizon. Measured values of $^{87}Sr/^{86}Sr$ in the samples range from 0.706 in deep soil water and soil exchange extracts to 0.710 in surface waters and soil digests. Analysis of precipitation samples average 0.7095. Previous work has demonstrated establishment of similar Sr isotope trends with depth at terraces 1,2,3 and 5. $^{87}Sr/^{86}Sr$ ranges from 0.709 at the top of the profile toward 0.706 at 6 meter depth. Decreasing $^{87}Sr/^{86}Sr$ values with depth imply a precipitation influence at the top of the profile and an increasing mineral weathering signal at depth. Also evident in the depth profiles at these sites is apparent isotopic ($^{87}Sr/^{86}Sr$) equilibrium between ammonium-acetate exchangeable Sr and soil water Sr at equivalent depths. Sr isotope measurements at terrace 4, however, have demonstrated neither trend nor equilibrium. The contrast between behaviour at terrace 4 and the remaining terraces is the subject of this study. $^{87}Sr/^{86}Sr$ measurements of soil pore water at terrace 4 show an essentially fixed value (avg. 0.7088) from the top of the profile to >6 meter depth. Preliminary work on ammonium-acetate exchangeable Sr have yielded $^{87}Sr/^{86}Sr$ values averaging 0.7095. Comparatively, bulk water and soil chemistry are not unusual at terrace 4. Evidence for anthropogenic activity at the terrace 4 sampling site was not obvious at time of site selection. Absence of an A horizon at the site and nearby charcoal bearing mounds suggest small scale charcoal manufacture. Stripping of the Sr exchange pool may have been accomplished by pyroligneous acids interacting with terrace 4 minerals and the subsequent reset to precipitation like values (0.7091).

Dissolved iron in the Southeast Pacific Ocean: OMZ to the gyre

JESSICA N. FITZSIMMONS[1,2*], JONG-MI LEE[1,2], RICHARD A. KAYSER[2], AND EDWARD A. BOYLE[2]

[1]MIT/WHOI Joint Program in Chemical Oceanography, Cambridge MA, USA, jessfitz@mit.edu (* presenting author)
[2]Massachusetts Institute of Technology, Cambridge MA, USA, eaboyle@mit.edu

Dissolved iron (dFe, <0.4µm) samples were collected in the Southeast Pacific Ocean during the C-MORE Big RAPA cruise aboard the *R/V Melville* in December 2010, which sailed from Arica, Chile, to Easter Island. Full depth profiles are presented from three stations: one near the Chilean coast in the oxygen minimum zone (OMZ), one in the subtropical gyre, and one halfway between these two points. Four additional profiles to 1000m are also presented, two between each of the full depth stations, in order to provide higher geographic resolution of surface dFe dynamics.

This dataset provides a unique opportunity to examine dissolved Fe cycling in a transect with a wide biogeochemical range. Conncentrations of dFe were in excess of 3nmol/kg in the OMZ where oxygen concentrations fell below 3µM. In contrast, in the oligotrophic gyre where atmospheric deposition of Fe is very low, dFe is over an order of magnitude lower, near 0.1nmol/kg at the surface and throughout the upper ocean. In this transect are also recorded the first deep ocean dFe concentrations ever measured in the southeast Pacific Ocean.

This dFe distribution provides insight into the major sources of dFe to this understudied region, Fe:nutrient relationships, and the scavenging behavior of dFe from the OMZ into the gyre. This transect will also be of particular interest to participants in the upcoming US Pacific GEOTRACES cruise, which will occupy a similar biogeochemical regime along a nearby transect.

Thermodynamic stability of U60 nanoclusters based on solubility measurements

SHANNON L. FLYNN*, JENNIFER E. S. SZYMANOWSKI, PETER C. BURNS, AND JEREMY B. FEIN

Dept. Civil Eng. and Geological Sci., University of Notre Dame, Notre Dame, IN 46556, USA (Correspondence: *sflynn4@nd.edu)

U60 nanoclusters are uranyl peroxide based spherical phases that are approximately 2 nm in diameter, with a stoichiometry of $K_{18}Li_{42}[(UO_2)(O_2)OH]_{60}$. Although U60 nanoclusters remain intact in alkaline solutions for at least a year, their thermodynamic stability has not been determined. Of particular interest is whether the nanoclusters behave thermodynamically as a solid phase or as an aqueous species. In this study, we measured the dissolution of U60 nanoclusters under several pH conditions in order to determine their thermodynamic stability. We used the experimental results, in conjunction with aqueous speciation modelling, to calculate an ion activity product (IAP) for each condition studied using two approaches: 1) assuming unit activity for the U60 'solid', and 2) treating the U60 as an 'aqueous' ion.

U60 crystals were made in a mother solution of uranyl nitrate, potassium chloride, hydrogen peroxide and lithium hydroxide. Crystals were harvested by vacuum filtration and then disaggregated in nanopure water, creating a suspension of U60 nanoclusters of known concentration. Batch U60 dissolution experiments were conducted in Teflon reaction vessels at pH 7.5, 8.0 and 8.5, with approximate nanocluster concentrations of 1.4, 2.8 and 6.0 g/L. Samples were extracted periodically for 14 days. Each sample aliquot was divided into two portions: an unfiltered portion for total K, Li and U analysis, and a portion that was filtered through a 10 k Da molecular weight sieve to determine the aqueous concentrations of K, Li and U in each sample. All metal concentrations were determined using ICP-OES. The presence of U60 nanoclusters was verified using electrospray mass spectroscopy at the beginning and end of each dissolution experiment and no other phases were created during the course of the experiments.

Aqueous concentrations achieved steady-state values within 24 hours in each experiment. IAP values, calculated from the experimental measurements assuming unit activity for the U60 nanoclusters and accounting for the aqueous speciation of K, Li, and U, were found not to vary significantly with pH, but to vary as a function of nanocluster concentration, with the calculated IAP value increasing with increasing nanocluster concentration. The variation in the calculated IAP as a function of nanocluster concentration suggests that the assumption of unit activity for the nanocluster is invalid. Models with non-unit activity for the nanocluster yield significantly less variation in the calculated IAP values as a function of nanocluster concentration. Our results suggest that the U60 nanoclusters behave more like aqueous species than a solid phase, and our calculated stability constant for the U60 nanoclusters can be used to estimate the solubility of the nanoclusters under a range of aqueous conditions. Our results underscore the importance of characterizing the charging behavior of these nanoclusters in order to better constrain their activity coefficients and hence their solubility behavior.

Resilience of bacterial communities in a pristine aquifer despite changes in the availability of sulfate

THEODORE M. FLYNN[1,2*], ROBERT A. SANFORD[1], JORGE W. SANTO DOMINGO[3], NICHOLAS J. ASHBOLT[3], AUDREY D. LEVINE[3], AND CRAIG M. BETHKE[1]

[1]University of Illinois at Urbana-Champaign, Department of Geology Urbana, IL, USA

[2]Argonne National Laboratory, Bioscience Division, Argonne, IL, USA, tflynn@anl.gov (* presenting author)

[3]U.S. Environmental Protection Agency, Office of Research and Development, Cincinnati, OH, USA

We test how bacterial communities in a pristine aquifer respond to geochemical changes by incubating initially-sterile sediment traps in groundwater with a relatively high (1.5 mM) or low (0.04 mM) concentration of sulfate for one year, then transferring each trap to the opposite well. We sequenced 16S rRNA genes and created terminal restriction fragment length polymorphism (T-RFLP) profiles of the bacterial community from these switched traps, then used multivariate statistics to compare them with control traps which had remained in the same well for the duration of the experiment. These analyses showed that despite the 12 month incubation in a well with a 40-fold difference in the availability of sulfate, the bacterial communities attached to the switched traps retained a characteristic structure more similar to the well in which each trap was initially incubated than to the control community where they were subsequently placed. Although the relative abundance of many populations on the switched traps remained unchanged by this change in the availability of sulfate, the relative abundance of certain phyla associated with sulfate reduction (*Desulfobacter* and *Desulfobulbus*) was found to increase or decrease along with the corresponding change in the availability of sulfate. Other functional groups whose abundance has also been linked to the amount of sulfate in groundwater, however, such as the iron reducers *Geobacter* and *Desulfuromonas*, appeared unaffected by the switch between high and low sulfate wells. These results indicate that many bacterial populations present in an aquifer community do not simply represent the taxa are most favored by current geochemical conditions. Rather, the biogeographical and geological history of the area play a significant role in determining the composition of the bacterial community. Predicting its response to external perturbations, whether naturally-occurring or anthropogenic, would therefore require a more holistic understanding of the environment being studied than can be provided by a survey of bacterial populations alone.

Fe-isotopes of arc basalts indicate a variably oxidised mantle source?

JOHN FODEN[1*], PAOLO SOSSI [2,1], AND GALEN HALVERSON [3,1]
[1]University of Adelaide, Geology and Geophysics,
john.foden@adelaide.edu.au (*presenting author)
[2]Research School of Earth Sciences, ANU,
paolo.sossi@anu.edu.au
[3]McGill University, Earth and Planetary Sciences,
galen.halverson@mcgill.ca

New Fe-isotope data on (> 60) primitive basalt samples from the global network of arcs is used to investigate if Fe isotopic compositions reflect differing oxidation and water content of arc sources due to tectonic factors (rate of subduction, age of subducting plate) [1]. Subduction magmas are wetter than those of from other tectonic settings [2]. Melt-inclusion studies using XANES have established good positive correlations between water content of primitive melts and their oxidation state ($Fe^{3+}/\Sigma Fe$) [2]. Arc magmas have elevated $Fe^{3+}/\Sigma Fe$ (>0.1 to 0.5), compared to MORB (0.1-0.2) [3,4], and studies of peridotite from the sub-arc mantle [5] also reveal elevated oxidation states compared to non-arc mantle. Still, the site of oxidation of arc magmas is controversial. Redox-sensitive element ratios (V/Sc or Zn/Fe_T) imply oxidation is imposed after magmas leave the mantle wedge [3,6].

Our $\delta^{57}Fe$ data range from -0.2‰ to +0.2‰ (± 0.04), with $Fe^{3+}/\Sigma Fe$ in the range 0.2 to 0.5. $\delta^{57}Fe$ correlates positively with Pb- or Sr-isotope ratios and $Fe^{3+}/\Sigma Fe$ and weakly with age of subducting crust. The trend to heavier iron is not coupled to any correlation with MgO so not driven by olivine or pyroxene crystallisation. A two-fold increase in $Fe^{3+}/\Sigma Fe$ requires >50% olivine crystallization [3] and will only increase $\delta^{57}Fe$ by ~0.06 ‰. As magnetite $\Delta^{57}Fe_{mag\text{-}melt}$ values are ~ +0.30 ‰, they record pre-magnetite conditions.

Results and Conclusions

Our data may reflect differences in oxidation state of the mantle of different arcs. As Fe^{3+} mineral sites tend to have heavier Fe-isotopic compositions [7] and as Fe^{3+} is more incompatible than Fe^{2+}during mantle melting, partial melting of more a oxidized wedge will yield melts with heavier iron isotopes (as will smaller % melting) [7]. Positive correlations with Pb- and Sr-isotopes may be a measure of slab input to the wedge, and that with slab age may indicate that colder, older slab subduction delivers more oxidation capacity to that part of the mantle wedge that yields arc basalt magmas.

Microbes at work: Biogeochemistry in oil sands tailings ponds

JULIA FOGHT*

[1]University of Alberta, Biological Sciences, Edmonton, Canada,
julia.foght@ualberta.ca (* presenting author)

Extraction of surface-mined oil sands ores yields bitumen for upgrading, plus tailings: a slurry of water, sand, silt, clay, unrecovered bitumen and hydrocarbon solvent. These extraction wastes are deposited into enormous tailings ponds where they de-water as the fine particles consolidate very slowly by gravity. After several years the tailings may reach >25% solids, becoming 'mature fine tailings' (MFT). Complex communities of diverse microbes have developed in the ponds (enumerated at 10*6 to 10*8 cells/ml MFT) where they anaerobically degrade labile aliphatic and aromatic hydrocarbons in the solvent (and perhaps low molecular weight components of the bitumen) to produce methane, CO_2 and organic metabolites. This activity has environmental and industrial significance because it affects physical properties of the MFT through unresolved mechanisms, promoting consolidation and de-watering of the MFT ('biodensification'), and generating copious volumes of greenhouse gases, a proportion of which is emitted from the ponds through ebullition. The microbial communities determined using 454 pyrosequencing of 16S rRNA genes comprise hundreds of bacterial genera, many of which represent uncultivated taxa, but only a few methanogenic euryarchaeal lineages. Laboratory enrichment cultures derived from MFT demonstrate methanogenic degradation of short-chain ($<C_{10}$) and long-chain ($>C_{14}$) *n*-alkanes, *iso*- and *cyclo*-alkanes, mono-aromatics (BTEX) and a few polyaromatics. Biodegradation is also observed under sulfate-reducing conditions by amending MFT with sulfate; the community structure shifts in response to C source and electron acceptor availability. However, often the communities are reluctant to 'go to work', sometimes with lag times of 1–2 years in laboratory cultures before biodegradation is apparent. Pure cultures isolated from enrichment cultures are now being studied to infer their roles in situ. Sequencing of functional gene families associated with anaerobic hydrocarbon activation is contributing to understanding biogeochemical potential in the tailings ponds, and full community metagenomic sequencing has provided additional context. Results from this work are contributing to models for predicting the consequences of microbial activity in situ and providing guidance for tailings management and reclamation strategies.

Constraining changes in ocean circulation modes and ^{14}C reservoir ages in the NW Atlantic between 35 and 15 ka BP

J. FOHLMEISTER[1*], J. LIPPOLD[1], M. KUCERA[2], L. WACKER[3], M. BAYER[2]

[1]Heidelberg Academy of Sciences, Institute of Environmental Physics, Germany, jens.fohlmeister@iup.uni-heidelberg.de, (* presenting author),
[2]Department of Geosciences, University Tübingen, Germany,
[3]ETH Zurich, Institute for Particle Physics, Switzerland

The Atlantic Meridional Overturning Circulation plays a key role in the climatic system by redistributing heat and carbon throughout the ocean. Reconstructions of ^{14}C concentrations revealed that large changes in the partitioning of radiocarbon among the main reservoirs on earth must have occurred in the past. Thus, significant effort went into the reconstruction of past ocean circulation and its control on the storage and release of CO_2 as well as its heat supply to higher Northern latitudes.

In our study we focus on a deep sea core from the North-West Atlantic (ODP Site 1063, Bermuda Rise). This core displays very high sedimentation rates (in general > 20 cm/ka), which minimizes bioturbation effects, allowing extraordinaryly high time resolution. For the last glacial the $CaCO_3$ content of this core preserved Heinrich and Dansgaard/Oeschger events. Linking the ODP Site 1063 $CaCO_3$ content to Greenland ice core $\delta^{18}O$ allows constructing a ^{14}C independent age model [1]. We compared sample ages derived from this model with the ^{14}C content of monospecific planktonic foraminifers measured in 35 sub-samples between 15 and 35 ka BP.

The resulting ocean surface reservoir age (R) shows almost constant values (~ 1200 years) during the Last Glacial, while during Heinrich Events (1, 2, 3), R varied between 0 and 2500 years. Additionally, we compare the surface water reservoir age with $^{231}Pa/^{230}Th$ and ε_{Nd} values available for this core [2,3]. In this way, we provide for the first time a data set of three distinct proxies of ocean circulation co-registered from the same sediment core. Comparison of these proxies give evidence of highly variable patterns of ocean circulation during Heinrich Events, characetrised by differences in circulation strength, water mass age and water mass provenance during different times of melt-water hosing in to the North Atlantic.

Behavior of REE in high-alumina alteration zones formed by weathering of felsic volcanic rocks

NORA K. FOLEY[1*]

[1]U.S. Geological Survey, MS 954, Reston, Virginia 20192 USA, nfoley@usgs.gov (* presenting author)

Variation in mineralogy and whole rock chemistry of kaolinite deposits of the Carolina slate belt, USA, are used to study processes leading to remobilization, transport, and concentration of REE and other elements (e.g., Ti, Al, As, Se, Ga, Hf, Zr) during weathering. High-alumina alteration zones are hosted by felsic volcanic rocks of the Persimmon Fork Formation (PFF). The largest deposits (Haile and Brewer, SC) contain reserves of >650,000 metric tons of clay formed by saprolitic weathering of crystal tuff (1). The 554 Ma tuffs have associated feldspar and sericitic alteration and contain epithermal, hot-springs-style deposits of Fe, Au, and other metals produced by acidic hydrothermal fluids that reacted with host volcanic rocks. Chemical weathering of the PFF since the mid-Paleozoic has strongly modified the major and trace element abundances and resulted in a high-quality white clay resource (~35% kaolinite, ~45% quartz, ~20% sericite) with accessory phases including reaction products of the original Ti, Al, and Fe-minerals, a distinctive trace element signature (e.g., Ga~4-36, Se~0-230, As~0-541, ΣREE~30-200 ppm) and diverse secondary minerals formed primarily by weathering of crystal tuff and siliceous-ferruginous sinter, including concretions (layered goethite-Al and kaolinite), Al-REE phosphates, gibbsite, hematite, lepidicrosite, and quartz.

Geochemical traverses across bedrock, saprolite, and clay bodies show that most of the alkali elements and Fe were removed from tuffs during weathering. In contrast, Th, Hf, and Zr contents were generally preserved. Chondrite-normalized REE patterns for variably altered volcanics fall into mineralogically distinct groups. The resultant clay rocks are LREE-enriched at ~50-100x chondrite and have Ce/Yb_N of ~2.0 to 6.6 and La/Sm_N = 1.99 to 5.6. The HREE portion of the pattern is typically flat and ~10-30x chondrite with Tb/Yb_N of ~0.71-1.05. In general, negative Eu/Eu* anomalies of 0.62 to 0.75 characterize the clay rocks. Fe-concretions in clay rocks are enriched by factors of 50 in Se and 25 in As (60-230 ppm Se and 11-511 ppm As) and have ΣREE~150-200. REE mobility did occur in the hydrothermally altered and weathered volcanic rocks; as a group the altered clay rocks and Fe-concretions (normalized to the mean value for unaltered PFF) show depletions in LREE, and slight enrichments in HREE. The changes in the bulk patterns can be explained by the presence of LREE-enriched and HREE-enriched minerals and reflect adsorption onto Fe-oxyhydroides and secondary clay minerals, rather than precipitation of secondary phosphate. Behavior of other trace elements (As, Se, Ga), relative to the parent rock, is also predictable based on the dominant mineralogy of the residual host (clay rock, silicastone, iron oxide concretions and crusts). Elements such as Ga, Hf, and Zr are retained under a combination of acidic hydrothermal and saprolitic alteration processes that result in subtle REE mobility.

Investigating the structural characterization of amorphous mineral precursors for enhanced understanding of contaminant adsorption and incorporation.

SAMANGI ABEYSINGHE AND TORI Z. FORBES*

Department of Chemistry, University of Iowa, Iowa City, IA, USA
tori-forbes@uiowa.edu

Metal oxyhydroxide mineral phases, particularly those containing Fe(III) or Al(III), play an important role in determining the long fate and transport of heavy metals and radionuclides in environmental systems. During rapid hydrolysis of the metal in solution, an amorphous or poorly crystalline precipitate initial forms, which can further transform into a thermodynamically stable mineral phase. During aggregation and flocculation processes, contaminants can adsorb to the surface of the particles, leading to co-precipitation and incorporation. Therefore, understanding the relationship between the soluble molecular precursor species present in solution and the amorphous precipitate is vital for gaining a molecular-level understanding of contaminant uptake by mineral species.

To investigate the structural relationship between the soluble precursors and the amorphous phase, we have begun synthesizing geochemical model compounds to compare to X-ray scattering of the amorphous phase. These model phases are metal oxyhydroxide nanoclusters that are 1-2 nm in diameter that can be packed into an ordered lattice for structure determination via single-crystal X-ray diffraction. The Pair Distribution Function (PDF) analysis of the module compounds can be calculated and compared to experimentally derived spectra. In this presentation we will focus on the relationship between aluminum based nanoclusters and amorphous aluminum hydroxide. In addition, geochemical model compounds with adsorbed contaminants will also be discussed that may provide information regarding possible adsorptions sites within amorphous materials.

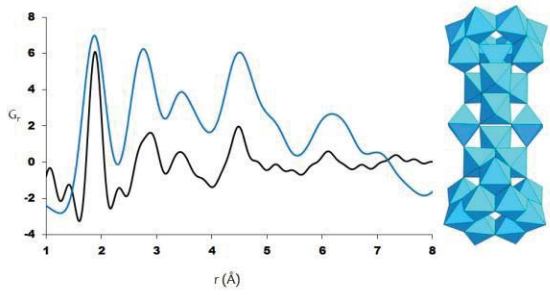

Figure 1. Comparision of the PDF spectra of amorphous metal oxyhydroxide material and the structurally characterized geochemical model compound.

Methane and dissolved inorganic carbon biogeochemistry in the Argentine Basin

M.FORMOLO[1*], N. RIEDINGER[2], J.M. MOGOLLÓN [3], S. HENKEL[4], J. TOMASINI[5], M. STRASSER[6], A. VOßMEYER[7], AND S.KASTEN[3]

The Argentine Basin, located on the continental margin and slope of Uruguay and Argentina, has been well documented as a region susceptible to mass sediment transport processes and high sedimentation rates. These dynamic conditions impact the pore water and dissolved methane biogeochemistry. During Expedition M78/3 (May - June 2009) aboard the RV Meteor sediment and corresponding pore water samples were collected. The methane and pore water constituents provide a unique opportunity to address how sensitive methane and dissolved inorganic carbon (DIC) biogeochemistry are to environmental perturbations in these dynamic continental margin settings.

Adopting the definitions from Hensen et al. [1], for pore water profiles from this region, we have subdivided the sample locations into four profile categories; linear, concave-up, kink, and s-type. Comparisons among these categories allow us to address how methane biogeochemistry responds to sediment movements and variable methane fluxes. Within the Argentine Basin the observed sulfate and methane geochemistry are transitory in nature following mass-flow deposition or variations in methane fluxes. Over time the pore water profiles are constantly returning to a more steady-state situation and information regarding these transient periods can be lost. However, these end member steady-state, transient and non-steady conditions provide an opportunity to model the biogeochemical conditions during these phases. This will provide more detailed information regarding natural biogeochemical response to similar events in marine systems. Integrating pore water CH_4, DIC, and SO_4^{2-} concentrations with $\delta^{13}C$-CH_4 and $\delta^{13}C$-DIC into isotope and reactive-transport models will allow us to address what are the naturally occurring dominant biogeochemical pathways in these sediments and how they respond to perturbations from variable methane fluxes or sediment mass transport events.

Methods for the determination of Te isotope compositions of minerals in the system Au-Ag-Te by MC-ICP-MS

ANDREW P. FORNADEL[1*], PAUL G. SPRY[1], RYAN D. MATHUR[2], SIMON E.JACKSON[3], JOHN B. CHAPMAN[3] AND ISABELLE GIRARD[3]

[1]Iowa State University, Ames, IA, USA, fornadel@iastate.edu (* presenting author); pgspry@iastate.edu
[2]Juniata College, Huntingdon, PA, USA, mathur@juniata.edu
[3]Geological Survey of Canada, Ottawa, Ontario, Canada, Simon.Jackson@nrcan-rncan.gc.ca; John.Chapman@nrcan-rncan.gc.ca; Isabelle.Girard@nrcan-rncan.gc.ca

The high precision of multicollector ICP-MS (MC-ICP-MS) analyses has led to the investigation of stable isotope variability of increasingly heavy elements (e.g., Cu, Se, Hg) found in ore-forming systems. Tellurium is commonly associated with Au and Ag in epithermal and orogenic ore systems. To date, there have been no high-precision studies of the natural variability of tellurium isotopes in ore-forming systems.

Using a micromill, a sufficient mass of telluride or native Te sample can be isolated and extracted from coexisting ore and gangue minerals from ~50 μm wide by ~50 μm deep drilled holes. Dissolution of those samples and subsequent ion exchange chromatography isolates Te from matrix metals, with a tellurium yield of ≥ 95%. The chromatography procedure causes no net fractionation of Te.

MC-ICP-MS analyses were completed using two techniques, both of which employ the doping of samples using Cd to correct for drift in instrumental mass bias. The first method was the introduction of 100 ppb Te bearing solutions (with 100 ppb Cd) using a desolvating nebulizer (DSN). The second method was direct introduction of 2 ppm solutions of Te (with 1 ppm Cd) into the MC-ICP-MS. The average precision using the DSN is ±0.17 ‰, whereas that for the wet method is ±0.08 ‰.

Natural, hypogene tellurides (n = 17) and native Te have shown an isotopic range of $^{130/125}$Te of ~1.9 ‰, demonstrating resolvable disparate isotope ratios between samples, including in samples from the same locality (i.e., Cripple Creek).

The understanding of isotope systematics for Te will lead to a better understanding of the geochemistry of Te, as well as its transport and deposition mechanisms. Systematic spatial variation of Te isotopes within an orebody may serve as an exploration vector for associated Au (as Au only has one stable isotope) and other precious metals.

The relationship between CO_2 and ice-volume on geological timescales

GAVIN L. FOSTER[1*] AND EELCO J. ROHLING[1]

[1]Ocean and Earth Science, National Oceanography Centre Southampton, University of Southampton Waterfront Campus, Southampton, SO14 3ZH (* presenting author); Gavin.Foster@noc.soton.ac.uk; e.rohling@noc.soton.ac.uk

Sea-level is arguably the most serious impact of anthropogenic climage change [1]. Unfortunately, changes in sea-level cannot simply be predicted by numerical climate models because they do not physically describe the dynamics of processes associated with the volume reduction of continental ice sheets. This compounds the issue of long range prediction as retreat of these ice masses will increasingly contribute to sea-level rise as the 21st century progresses. Consequently, the likely magnitude of future sea-level change remains uncertain [1]. One way in which the uncertainty in future sea-level predications can be reduced is to study the behaviour of the ice sheets and sea-level in the past in relation to greenhouse gas forcing.

Here we compile several recent records of pCO_2 and ice-volume from the last 40 million years. A consistent pattern emerges that clearly demonstrates a non-linear relationship between these variables, largely consitent with our understanding based on ice sheet modelling [2]. Given an estimate of the current climate forcing by CO_2 we use the relationship we observe on geological timescales to provide an estimate of the modern long-term equilibrium sea-level. This treatment supports the notion of significantly elevated long-term sea level response to anthropogenic CO_2 forcing even if CO_2 levels are stablised at current levels [3].

Metastable equilibrium in the C-H-O system: Graphite deposition in crustal fluids

DIONYSIS I. FOUSTOUKOS

Geophysical Laboratory, Carnegie Institution of Washington, Washington, DC 20015, United States

The presence of graphite in natural environments is governed by the redox and thermal conditions of C-H-O fluid/mineral equilibrium in hydrothermal veins and metasomatic contacts. The majority of experimental and theroetical studies on the C-H-O system are focused on deriving the thermodynamic properties of species, and on modeling phase relationships under equilibrium conditions. The distribution of C-H-O species in natural systems, however, may also be controlled by metastable equilibria that involves disequilibrium volatile concentrations and deposition of graphitic carbon with different degrees of crystallinity.

Hydothermal experiments were performed to investigate the graphite undersaturated C-H-O system at 600°C – 1 GPa and at supercritical water conditions. Aqueous solutions were reacted in the presence of $Si_5C_{12}H_{36}$ (tetrakis(trimethylsilyl) silane) to generate C-H-O volatiles (e.g. CO_2, CH_4, H_2) in a piston cylinder apparatus. Phase equilibrium relationships were placed along a continuum from highly reducing (iron-wustite) to highly oxidizing (Pt/PtO_2) redox gradient that rendered $CH_{4(aq)}$ and $CO_{2(aq)}$ as dominant species.

Time-series measurements of the dissolved volatile concentrations and mass balance constraints indicate the formation of a metastable non-volatile carbon phase, that attained significant concentrations (up to 0.62 of total carbon) especially during methane oxidation to $CO_{2(aq)}$. The intermediate occurrence of this phase is short-lived and is linked to the precipitation of amorphous graphitic carbon. Indeed, Raman spectroscopic measurements performed on the solid reaction products revealed the presence of poorly-ordered graphite under all the redox conditions investigated. However, the thermometric empirical expressions using the distribution and the shape (FWHH) of the G and D bands in the Raman spectra of graphite failed to accurately estimate the experimental temperature. Thus, the existing Raman geothermometers appear inadequate to address graphite formation under metastable equilibrium conditions and to account for kinetic effects that could greatly affect the degree of crystallinity.

Formation of poorly ordered graphite suggests that the disordered structure of the mineral is more readily deposited than crystalline graphite, and thus it may attain a broader thermodynamic stability field. Exposing this metastable graphitic carbon to high temperatures and pressures could function as a precursor and substrate for the deposition of the well-ordered phase. Such metastable graphite, therefore, may provide an intermediate state that facilitates subduction of carbonaceous material other than crystalline carbonate minerals. This might also have important implications for the formation mechanisms and the carbon isotope systematics of deep seated carbonaceous fluids and minerals such as diamonds.

Steep Rock carbonate platform: an early marine oxygen oasis

PHILIP FRALICK[1] AND ROBERT RIDING[2*]

[1]Lakehead University, Thunder Bay, Canada
pfralick@lakeheadu.ca
[2]University of Tennessee, Knoxville, USA
rriding@utk.edu (*presenting author)

Limestones of Mesoarchean-Neoarchean (~2.8 Ga) age at Steep Rock Lake, Ontario, Canada, are up to 500 m thick and at least 35 km in extent. We suggest that this early example of a thick and relatively well-preserved carbonate platform represents an 'oxygen oasis' that formed in shallow-water adjacent to deeper-water iron oxide and iron carbonate sediments. Anoxic Archean seawater rich in dissolved iron and bicarbonate is expected to have precipitated iron carbonate minerals such as siderite, which is common in banded iron formation (BIF). Dominance of Ca-carbonates over Fe-carbonates at Steep Rock is consistent with relatively low levels of ferrous iron in a suboxic/oxic shallow-water zone above a chemocline. The most likely source of dissolved O_2 to sustain these conditions is oxygenic photosynthesis by cyanobacteria.

Our rare earth element (REE) analyses confirm that oxygen was present in the seawater from which the Ca-carbonate minerals at Steep Rock precipitated. A distinct negative cerium anomaly is present in the limestone and absent in the laterally and vertically adjacent iron formations. Cerium is the only REE with a 4+ valence state, in which it forms an insoluble oxide and is removed from solution. The negative anomaly indicates that seawater at Steep Rock locally encountered sufficient oxygen to remove cerium. Direct evidence for the source of the oxygen is lacking, but two features are consistent with a cyanobacterial origin. First, stromatolites are common in the Steep Rock limestone and cyanobacteria could have been included in their microbial communities. Second, black shales in the basinal iron formation contain up to 30 weight percent organic carbon suggesting the presence of phytoplankton and this community also could have included cyanobacteria.

We conclude that the Archean origin of marine carbonate platforms was closely linked to the transient development of shallow-water 'oxygen oases' at the margins of otherwise anoxic iron-rich seas, and that these were present locally in the mid-Archean, as exemplified at Steep Rock.

Origin and fluxes of dissolved sulphate in the Himalayan system : evaluation and implication

CHRISTIAN FRANCE-LANORD[1*], ANANTA P. GAJUREL[2], VALIER GALY[3], MAARTEN LUPKER[1], GUILLAUME MORIN[1]

[1]CRPG-CNRS U. Lorraine, BP 20 54501 Vandœuvre France cfl@crpg.cnrs-nancy.fr
[2] Tribuhvan U., Kathmandu, Nepal, apgajurel@gmail.com
[3] WHOI, Woods Hole, USA, vgaly@whoi.edu

Continental weathering budget requires careful analysis of dissolved sulphate origin as sulphide oxidation may represent a source of acid auxiliary to CO_2 [1]. In Himalayan rivers the concentration of sulphate is about 10 meq% that of HCO_3^- and previous studies underline the importance of sulphide oxidation processes [2-3]. We present isotopic compositions of dissolved sulphates from various Himalayan basins in Nepal, India and Bangladesh. More detailed data come from the Central Nepal Narayani basin. Isotopic data reveal that $\delta^{34}S$ are low between +6 and -15‰ and $\delta^{18}O$ are between +3 and -10‰. In addition there is a clear correlation between oxygen isotopic compositions of the river water and those of dissolved sulphate. These data confirm that the large majority of dissolved sulphate is derived from sulphide oxidation reactions occurring during erosion. Such reactions appear to be widespread over the Himalayan basin and can be sometime observed in winter as efflorescence of gypsum at the surface of sulphide bearing rocks such as black shale.

The analysis of rivers draining different lithologies in Nepal reveal that while sulphide oxidation is the prevalent source of sulphate it's intensity is highly variable. Assuming that all dissolved sulphate derive from pyrite, chemical erosion of pyrite vary between 10 and 60 t/yr/km^2 in High Himalayan gneisses and in Tethyan Sedimentary Series respectively. Among primary Himalayan basins, the Narayani Gandak and the Siang-Tsangpo rivers are the major sources of dissolved sulphate. Ganga and Brahmaputra in Bangladesh have isotopic compositions comparable to their Himalayan tributaries. The fluxes recorded in Bangladesh suggest that anthropogenic input to the river flux is not dominant in spite of the dense agricultural and industrial activity in the floodplain.

Overall sulphide oxidation processes represent a source of acid for weathering reactions during Himalayan erosion. It's association with Tethyan sediments suggest that sulphuric acid will mostly dissolve carbonates acting on the long term as a net source of CO_2 to the atmosphere.

Particle size dependence on arsenic concentration and bioaccessibility in mine tailings from the Empire Mine, CA

JESSICA M. FRANCIES[1*], NATALIE E. KIWAN[1], CHRISTOPHER S. KIM[1]

[1] School of Earth and Environmental Sciences, Chapman University, Orange, CA, USA, jfranc@chapman.edu

As a result of the historic mining of gold and silver in California, an estimated 47,000 abandoned mine sites exist statewide. Since the halt of mining operations, communities have developed near and around abandoned mine wastes at these locations. This is of great concern because the waste material left over from the processing and extraction of precious metals contains associated toxic metal(loid)s, including arsenic (As), which can be mobilized into surrounding communities, contaminate surface and rain water, and be incidentally ingested by humans. The Empire Mine in the Sierra Nevada mountain range contains areas of varying As contamination. Prelimary studies have discovered a range of As bioaccessibility relative to initial As concentration, indicating that trends in arsenic concentration and bioaccessibility may be a function of particle size, correlations between arsenic and iron, and/or arsenic speciation.

Bulk samples were collected from six different locations at the Empire Mine and separated by particle size through a dry sieving method to generate eleven distinct size fractions. BET surface area analysis and EXAFS spectroscopy was conducted to determine the reactive surface area and arsenic speciation of selected size fractions. Acid digestion and ICP-AES analysis were then conducted to determine the initial concentrations of As and a host of other metals present in each size fraction. Finally, the bioaccessibility of As as a function of particle size was examined by conducting a physiologically based extraction test (PBET) utilizing a simulated gastric fluid (SGF).

The majority of samples collected displayed an inverse relationship between particle size and total arsenic concentration; these same samples also typically showed a strong As-Fe correlation. Conversely, samples without an inverse size-concentration relationship tend to have both low total As concentrations and poor As-Fe correlations. In addition, As concentrations were found to increase by over an order of magnitude as size decreases. In relation to the bioaccessibility tests, 7-10% As was consistently released into the simulated gastric fluid media, suggesting that bioaccessibility is linked with the initial As concitentration of the sample. However, when the percent As released is normalized for surface area in comparison to particle size, a decreasing trend in As as particle size decreased resulted. This indicates surface area also plays a significant role in As bioaccessibility. Furthermore, bulk (unsieved) samples that undergo PBET can underestimate bioaccessibility in fine-grained size fractions, also supporting the possible effect that surface area and particle size play in the degree of arsenic bioaccessibility in mine wastes. These results demonstrate that particle size is an important criterion in determining arsenic transport, concentration, exposure, and future remediation efforts.

Microbial dissolution of Se-jarosite by *Shewanella putrefaciens* CN32

RACHEL FRANZBLAU[1*], NADINE LOICK[1], CHRISTOPHER WEISENER[1]

[1]Great Lakes Environmental Institute for Research, University of Windsor, Windsor, Canada, franzbl@uwindsor.ca*

Introduction

Jarosites form in acidic, low temperature, sulfate-rich environments. Jarosite minerals scavenge trace elements, and are involved in trace metal cycling. Selenium (Se) is a trace element in human and microbial metabolism, but is chronically and actuely toxic in higher doses [1]. In jarosites, Se can completely substitute for the sulfate group ($MFe_3(SO_4)_x(SeO_4)_{2-x}(OH)_6$) [2]. Prior studies have focused on microbial interactions with the two aqueous Se oxyanions, selenate (SeO_4^{2-})and selenite (SeO_3^{2-}) but therie has been limited investigations pertaining to bacterial-mineral chemical pathways [3,4,5]. In this study, the circumneutral dissolution of jarosites with a range of Se-substitution for tetrahedral coordianted sulfate in the presence of *Shewanella putrefaciens* CN32 was examined under anaerobic conditions.

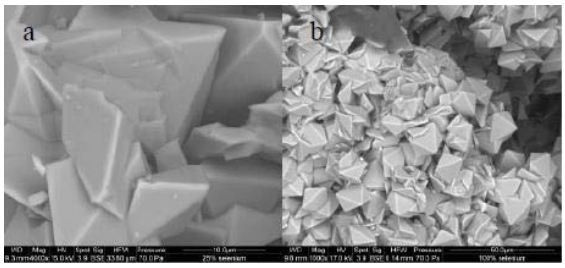

Figure 1: BSE-SEM images of Se-jarosites a) 25% Se substitution b) 100% Se substitution for sulfate

Results and Conclusion

Microbial biomass, ATP, SEM, [Se] and solution chemistry were considered during the experiment to evaluate the influence *Shewanella putrefaciens* CN32 on Se-jarosite dissolution. The reduction and fate of Se will be discussed to provide a better understanding of the interaction of bacteria and Se-minerals in reducing environments.

Yucatán hydroclimate during the Maya 'megadroughts': Speleothem records of multiple hazards and a test of the hurricane masking effect

AMY BENOIT FRAPPIER[1*], AURORA D. PINKEY-DROBNIS[1]

[1]Skidmore College, Department of Geosciences, Saratoga Springs, NY, 12866 USA, afrappie@skidmore.edu (* presenting author)

Severe and persistent megadroughts in the Yucatan peninsula have been associated with the so-called 'collapse' of the Maya high civilization in the Terminal Classic Period (TCP) around 900-1000 C.E. [1] An annual stable isotope record from the Chaac speleothem showed that TCP 'megadrought' was rather a series of 8 severe droughts lasting 3-18 years in the interval betweel 800 and 950 C.E., punctuated by brief moist periods characterized by low $\delta^{18}O$ values[2]. We present a nearby annually-dated multiproxy stalagmite record (CH-1), and compare it to the Chaac stable isotope record as a replication test for a coherent regional climate signal.

The CH-1 stalagmite also contains a conservative record of severe tropical cyclone flooding events, as mud layers embedded within the calcite laminae from cave flooding events [3]. In the 20th century historical period, all flooding events in this low-lying cave are associated with years of local hurricane rain events and associated temporarily high levels of the regional water table. Mud layers in CH-1 thus indicate some years with hurricane rainfall. In the 20th century historical period, the threshold for CH-1 mud layer emplacement varies with pre-existing hydrologic conditions; i.e. mud layers are less likely to be emplaced, even by severe storms, when the pre-existing water table was low due to persistent drought. Likewise, mud layers in CH-1 are more likely when the water table is elevated due to wet conditions and/or repeated hurricane events. Historical hurricanes and droughts are associated with other hazards such as wildfire. We combine stable isotope, stratigraphic, and trace element records from CH-1 to track multiple hazards.

In comparing the two local stalagmite records, we note a curious relation during the TCP between tropical cyclone activity (CH-1 mud layers) and breaks in the megadrought sequence (Chaac $\delta^{18}O$ values). Infiltrating hurricane rainwater, which has an anomalously low stable isotopic composition [6], can depress the $\delta^{18}O$ value of speleothem calcite for months to years after the storm event [5]. If this masking effect from hurricane rainfall has altered the speleothem isotopic record during the TCP, then we would expect that years with high hurricane rainfall would be correlated with years with low calcite $\delta^{18}O$ values. Furthermore, we would expect that during peristent drought, years with low hurricane activity would correlate to times with high speleothem $\delta^{18}O$ values. We present a test of the hurricane masking effect in Yucatan speleothems during the Terminal Classic 'megadroughts', and discuss the implications for tropical speleothem paleoclimatology, and for understanding complex patterns of human-climate interactions during this event.

Understanding Biomarker Records of Terrestrial Paleoecolgy

KATHERINE H. FREEMAN,*[1] HEATHER GRAHAM[2], ANNA HENDERSON[3], CLAY MAGILL[4]

Dept. of Geosciences, The Pennsylvania State University, University Park, PA, USA, 16802, [1]khf4@psu.edu; [2]geozilla@psu.edu; [3]ahenderson@gmail.com; [4]clayton.magill@gmail.com

The terrestrial biosphere is fundamental to the global climate system, influencing albedo, circulation, the water cycle, carbon sequestration and weathering. Paleobotanical records offer detailed insights to plant communities and their changes in response to climate perturbations. Leaf fossils do not lend themselves to high-resolution and continuous records through time, and although continous pollen records can be well preserved, they do not offer physiological insights such as those gained from leaf margins or stomata densities, for example. Plant biomarkers reflect plant phylogeny and functionality, and are well preserved in ancient soils and sediments. Both distributions and isotopic signatures of plant lipids are increasingly used in terrestrial paleoclimate studies.

Recent work on both modern and ancient plant biomarkers offers new ways to understand molecular records of terrestrial paleoecology. Lipid biomarker abundance and distribution patterns within modern plants are influenced both by plant phylogeneic affiliation as well as by functional properties, most notably leaf lifespan. Biomarker carbon-isotope signatures reflect both plant type and environmental factors such as seasonality, water availability, light exposure, and canopy closure. In modern leaves, these factors influence *n*-alkane $\delta^{13}C$ values, chain length distributions of homologs and total abundances in leaf tissue. Such data provide frameworks for interpreting plant-wax carbon-isotope signatures in terms of biome type and ecosystem structure, and provide constraints that aid interpretations of lipid δD signatures.

Understanding how growth environment and phylogenetic relationships influence waxes in modern plants engenders new proxies for past communities. Yet, to be useful to paleoclimate applications, biomarker and isotopic proxies based on modern plants must consider the role of litter flux that can both integrate and filter plant signatures in sedimentary archives. We extend observational data from modern flora with a statistical resampling (bootstrap) analysis to evaluate how variability in plant signatures are integrated by soil and sediment geochemical records.

We will present insights from lipid, leaf, biome and catchment-scale studies that inform our understanding of molecular record of the terrestrial biosphere. These insghts will be illustrated using examples from our studies of Cenozoic terrestrial paleoecology.

CHROMIUM ISOTOPES AS PROXY FOR SURFACE OXYGENATION – RESULTS FROM A ~1.9 GA PALEOSOL DEVELOPED ON OCEANIC CRUST (SCHREIBER BEACH, ONTARIO, CANDADA)

ROBERT FREI[1,2,*] ALI POLAT[3]

[1]Institute of Geography and Geology, University of Copenhagen, Denmark, robertf@geo.ku.dk(* presenting author)
[2]Nordic Center for Earth Evolution (NordCEE)
[3]Department of Earth and Environmental Sciences, University of Windsor, ON, Canada, polat@uwindsor.ca

The chromium isotope proxy is based on isotopic fractionation believed to accompany the oxidative weathering of Cr(III) minerals in soils. At equilibrium, oxidized Cr (Cr(VI) is predicted to be enriched in heavy isotopes, and consequently, one would expect this heavy and mobile Cr to be liberated to solution leaving an isotopically light soil behind.

In order to explore Cr isotope fractionation during soil formation, we investigated a ~ 1.9 Ga subaerial weathering profile at Schreiber Beach, Ontario, Canada. The section developed on Neoarchean (~2.8 Ga) pillow basalts and is unconformably overlain by the Paleoproterozoic (~1.88 Ga) Gunflint Chert and basal conglomerates. There are gradual textural, mineralogical and geochemical changes from unweathered basalts to strongly weathered hematite-bearing basalts with stratigraphic height.

The $\delta^{53}Cr$ value of unweathered basalts (-0.16 +/- 0.05 ‰) is within the range of mantle inventory values [1], whereas weathered brown to green basalts (soils), exhibiting up to 30% lower Cr concentrations compared to unaltered pillow cores, are isotopically lighter ($\delta^{53}Cr$ = -0.35 +/- 0.11 ‰). Red, hematite-rich (lateritic) basalts and hyaloclastites underlying the brown to green basaltic soils, instead are isotopically heavier ($\delta^{53}Cr$ = +0.05 +/- 0.15 ‰). These results speak for a process whereby ferrous Fe and likewise, Cr(VI), was leached from Fe-bearing minerals in upper soil horizons (mostly now eroded), and transported by oxygenated ground waters to lower portions of the profile where it precipitated as iron oxyhydroxides (later transformed to hematite during greenschist metamorphism after the deposition of the Gunflint Cherts) together with back-reduced isotopically heavy Cr(III) originally mobilized as Cr(VI) during surface weathering. An oxidative atmosphere at ~1.9 Ga, as implied by the results from the Schreiber profile, is furthermore supported by positively fractioned Cr isotopes ($\delta^{53}Cr$ = +0.2 +/- 0.05 ‰) recorded in the iron-rich Gunflint Cherts directly above the palaeo-weathered horizons at Schreiber Bay. These values are interpreted to reflect a positively fractionated shallow seawater chromium composition at ~1.88 Ga, a finding which is in accordance with the results of [2].

The potential of the Cr isotope system in ancient paleosols to untangle the presence of oxidative weathering processes makes this system a viable and important tracer for the reconstruction of surface oxygenation in Earth's history.

Reverse weathering in the Okavango Delta, northern Botswana

PATRICK FRINGS[1*], DANIEL J. CONLEY[1], ERIC STRUYF[2] AND MIKE MURRAY-HUDSON[3]

[1]Lund University, 223-62 Lund, Sweden, patrick.frings@geol.lu.se (*presenting author), daniel.conley@geol.lu.se
[2]Antwerp Univeristy, 2610 Antwerp, Belgium, eric.struyf@ua.ac.be

Introduction

Reverse weathering was first proposed to balance elemental budgets in the oceans [1]. The suggestion was thermodynamically possible, but lacked direct observational evidence. Recent field and lab incubations unambiguously show rapid formation of authigenic clay minerals is plausible under certain conditions [2,3]. We present direct and indirect evidence for mineral authigenesis in the Okavango Delta, a shallow, freshwater, tropical wetland bounded by the southern extension of the East African rift valley. Water and sediment samples were collected after peak flood in 2011 along a hydrological gradient from riverine to seasonal floodplain. The watershed hydrodynamics and biogeochemical processing regulate elemental cycling and maintain the Delta as a freshwater system [4].

Evidence for new mineral formation

Direct evidence for rapid mineral authigenesis comes from microscopic, spectroscopic and geochemical analysis of floodplain sediments. Special attention is paid to biogenic silica particles that are known to provide viable substrates for clay precipitation.

Indirect evidence comes from downstream changes in dissolved element concentrations and Ge/Si ratios. PCA of elemental concentrations assessed by ICP-AES or -MS indicates a strong hydro-chemical concentration gradient. Boron acts conservatively and is interpreted as representing the expected enrichment (~12x inflowing concentration) if evapotranspiration was the only process occurring. Other elements show lesser or even negative enrichment (4 – 0.1x inflowing concentrations), suggesting biotic or abiotic removal. A simple mixing model suggests that for many elements involved in clay authigenesis (e.g. Fe, Mn, Mg, K) biotic uptake cannot explain the relative lack of enrichment.

The ratio of Ge to Si (Ge/Si, µmol/mol) is commonly used as a tracer of critical zone weathering processes. A downstream decrease in Ge/Si from ~1 to ~0.2 is interpreted here in terms of in-stream processing. Uptake of Ge relative to Si during biological production is poorly defined but thought to be either unbiased or slightly negative [5]. The observed decrease in Ge/Si ratios must therefore be explained by preferential abiotic Ge removal.

We suggest rapid formation of new mineral phases in floodplain sediments is an important process. Our results show biotic and abiotic processes control element cycling in the Delta and highlight the possibility of reverse weathering in freshwater systems.

Nitrate ($\delta^{15}N$) isotopic distribution in Antarctic Sea Ice,

FRANÇOIS FRIPIAT[1-2*], DANIEL M. SIGMAN[2], JEAN-LOUIS TISON[1]

[1]Université Libre de Bruxelles, Department of Earth and Environmental Sciences, Brussels, Belgium, ffripiat@ulb.ac.be (* presenting author) jtison@ulb.ac.be
[2]Princeton University, Department of Geosciences, Princeton, USA, sigman@princeton.edu

The only study reporting nitrogen isotopic composition ($\delta^{15}N$ vs. Air N_2) in Antarctic Sea Ice pointed out an isotopic distribution for particulate nitrogen (PN) significantly different from the marine counterpart[1-2], respectively 2 to 41‰ vs. -6 ot 6‰. Antarctic sediments from the last ice age are characterized by heavier PN $\delta^{15}N$ (including diatom bound nitrogen)[3]. Since an equatorward sea ice expansion is expected during glacial periods, the potentially higher contribution of sea ice PN in glacial sediment may explain or accentuate such variation.

We have measured $\delta^{15}N$ of nitrate in Antarctic Sea Ice, as a first step toward developing a mechanistic understanding of the processes driving such isotopic difference (sea ice vs. marine realm). The nitrate $\delta^{15}N$ was measured in the brine network both in spring and summer Antarctic pack ice, respectively, in the Bellinghausen Sea (SIMBA, October 2007) and Weddell Sea (ISPOL, December 2005).

The $\delta^{15}N$ range for nitrate measured so far, 2.7 to 13.2‰, falls in the range of previously measured values. The mean $\delta^{15}N$ (± 1sd) is heavier in summer (9.4 ± 2.8‰) than in spring (4.1 ± 1.2‰), in agreement with the seasonal nitrate depletion together with a preferential assimilation of light nitrate into organic matter. An unexpected outcome is that some samples show a $\delta^{15}N$ lower than that of lower circumpolar deep water which is typically 4.7-4.8‰ [2], implying processes in addition of nitrate assimilation. Possible nitrogen source to the nitrate pool include the organic matter and ammonium (NH_4) inside the brine network[4], the nitrification of which could yield low $\delta^{15}N$ nitrate. Indeed, nitrification has been observed to occur in Antarctic Sea Ice[5], implying a regeneration of nitrate inside the brine network. Presumably, the generation of low $\delta^{15}N$ nitrate also causes the ammonium pool to be elevated in $\delta^{15}N$, an inference that we will test with measurements. The implication for the $\delta^{15}N$ of sea ice PN will then be investigated.

Lithium Isotope History of Cenozoic Seawater: Changes in Silicate Weathering and Reverse Weathering

PHILIP N. FROELICH[1,*], SAMBUDDHA MISRA[2]

[1]Froelich Education Services, 3402 Cameron Chase Dr., Tallahassee, FL, 32309. USA. (*correspondence: pfroelich@comcast.net)
[2]Dept. of Earth Sciences; University of Cambridge; Cambridge, UK

A stepwise nine per mil rise in lithium isotope ratios in seawater (^{7}Li / ^{6}Li, δ^7Li_{SW}) over the past 60 million years requires large changes in continental chemical weathering and cation fluxes through the sea, implying episodes of tectonic uplift and CO_2 drawdown. Weathering of uplifted continental rocks plays a central role in controlling both climate and seawater chemistry by consuming CO_2 and releasing cations to the ocean. Lithium isotopes provide a unique record of these changes because lithium, unlike other tracers of ocean chemistry change, is hosted entirely in silicates. This new 68 Ma record of seawater chemical change reveals shifts in global tectonic forces connecting Earth-ocean-climate processes. From the Paleocene (60 Ma) to the Present, δ^7Li_{SW} rose 9‰, requiring large changes in continental forward weathering and seafloor reverse weathering consistent with pulsed tectonic uplift, more rapid continental denudation, increasingly incongruent continental weathering (lower chemical weathering intensity) and more rapid CO_2 drawdown.

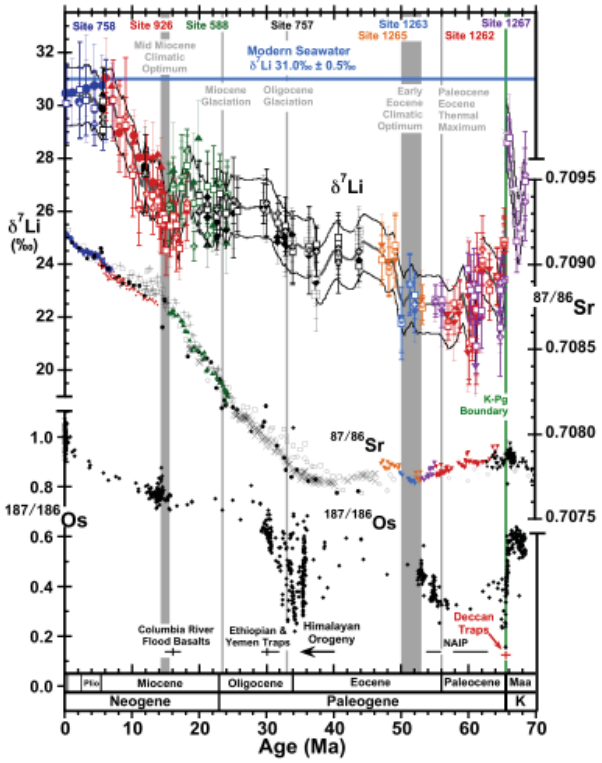

Figure: Li-, Sr-, and Os-isotope records over the past 68 Ma. The Li and Sr isotope records were reconstructed from forams in the same DSDP and ODP drill cores [1]. The Os-isotope data are from Peucker-Ehrenbrink & Ravizza (GTS 2012).

Seawater Lithium Isotope Excursion Across the K-Pg Boundary: Chicxulub Impact vs. Deccan Traps

SAMBUDDHA MISRA[1], PHILIP N. FROELICH[2*]

[1]Dept. of Earth Sciences; University of Cambridge; Cambridge, UK
[2]Froelich Education Services, 3402 Cameron Chase Dr., Tallahassee, FL, 32309. USA. (*correspondence: pfroelich@comcast.net)

A 4‰ drop in the ^{7}Li/^{6}Li ratio of seawater (δ^7Li_{SW}), from about 29‰ in the Late Cretaceous to 25‰ in the Early Paleocene, occurs within less than 0.5 Ma across the Cretaceous-Paleogene boundary (K-PgB, 65.68 Ma). Because δ^7Li_{SW} is sensitive to both very large Li-isotope fractionation factors and to changes in silicate sources and sinks on time scales of the Li residence time in seawater (τ_{Li} ~1.2 Ma) [1], this negative excursion must reflect a large and fast influx of ^{6}Li to the ocean, presumably from continental or seafloor silicates, the primary Li-reservoirs in the Earth's crust. It can not be due to rapid addition of isotopically light Li from (a) the Chicxulub bolide itself nor its impact crater, even if pulverized and instantaneously dissolved in the ocean, or from (b) congruent weathering of the simultaneously erupted Deccan Traps Large Igneous Province (δ^7Li_{Basalt} ~3.4‰). One possibility is that estimates of the volume of Deccan basaltic lavas 'missing" in the Geologic Record is an order of magnitude too low. Another possibility is that the conflagration from the Chicxulub impact deforested large portions of the continents and induced rapid acid-rain chemical weathering of incinerated continental soils that then washed into the ocean. In any event, the cause of this large fast δ^7Li_{SW} drop across the K-Pg boundary remains enigmatic.

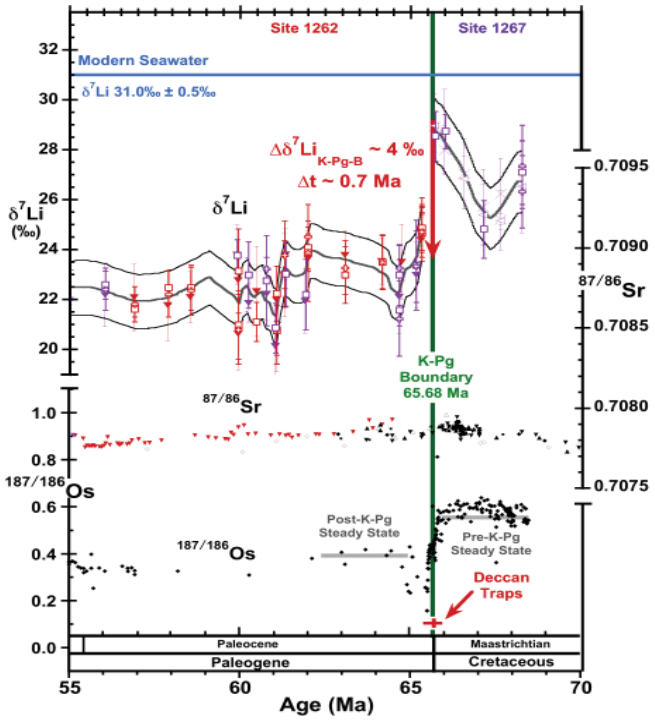

Figure: Li-, Sr-, and Os-isotope records across K-PgB. The lithium and strontium isotope records were recovered from forams in the same drill cores at ODP sites 1262 and 1267 [1]. Osmium isotope data are from Peucker-Ehrenbrink & Ravizza (GTS 2012)

The composition of the lower mantle constrained by experiments on the elasticity of magnesium silicate perovskite

Daniel J. Frost*[1], Julien Chantel[2], Alexander Kurnosov[1], Dmytro Trots[1], Tiziana Boffa Ballaran[1], Yanbin Wang[3]

[3]GSECARS, APS, Argonne, Il , USA , wang@cars.uchicago.edu

Comparison between seismic estimates for S and P wave velocities and similar experimental estimates for appropriate rock compositions is the only rigorous method for determining the composition of the Earth's lower mantle. Magnesium-silicate perovskite is the dominant mineral of the Earth's lower mantle. The composition of silicate perovskite forming within a typical Bulk Silicate Earth composition is dominated by the $MgSiO_3$ component but will also contain sub equal proportions of Al and Fe. The lower mantle may also contain a significant proportion of remnant subducted basaltic crust, from which more Al and Fe-rich silicate perovskite would form. Fe and Al substitution in perovskite will therefore be a significant source of chemical variability in the lower mantle and potentially the main cause of observed seismic heterogeneity in this region.

Using Brillouin spectroscopy we have studied the elasticity of $MgSiO_3$ perovsktie single crystals in the diamond anvil cell to lower mantle pressures. In addition we have examined the elasticity of polycrystalline $MgSiO_3$ perovskite plus samples of the same phase containing Fe and Fe and Al using ultrasonic interferometry in the multianvil. These measurements were performed at the APS synchrotron x-ray source to enable pressure and sample length measurements and were performed up to 25 GPa and 1200 K. The results allow models for seismic wave velocities in the lower mantle to be tested against seismic models and for variations in velocity in the lower mantle to be understood in terms of temperature and composition.

Simulating Arctic Black Carbon with GEOS-Chem/CMAQ Modelling System

JOSHUA S. FU*[1], XINYI DONG[1], KAN HUANG[1], MENGDAWN CHENG[2], AND JOHN STOREY[2]

[1]University of Tennessee at Knoxville, Knoxville, USA, jsfu@utk.edu (* presenting author)

Introduction

Arctic black carbon (BC) is of special interest because it makes a 10-100 times larger climate forcing impact thant a midlatitude source of equal strength[1]. To fully understand the impacts of Arctic BC on both air quality and climate forcing, it is necessary to identify the transport, distribution, and concentrations of Arctic BC within modeling work. However, currently very limited infromation of BC emission inventory over Arctic region is available except for biomass burning which takes about 35% of total BC emission. In this study, GEOS-Chem has been applied to investigate Arctic BC with EDGAR emission inventory for year 2006-2008 with grid resolution of 2x2.5°. With initial and boundary conditions dynamically downscaled from GEOS-Chem[2], Hemispheric-CMAQ is also applied with the same emission inventory but at finer resolutions as 108km and 36km to eiliminate the model discrepancy and uncertainties caused by grid resolutions. Model performances are evaluated against surface network observations from AERONET for 2 sites in US and 2 sites in Russia. GEOS-Chem is found to be able to reproduce BC over US domain generally well with NMB as 4.5% and 7.9% for US sites, and underestimate BC over Russia greatly with NMB of -81.36% and -81.71%. Modelling results from Hemispheric CMAQ will be able to provide more detailed BC information including spatial distributiona and temporal variations, and also the cross-Arctic transport of BC.

Preliminary Summary

Based on our preliminary results, Arctic black carbon emission inventory is underestimated by 285 ~ 2500% over noth Eurasia area in the EDGAR HTAP emission inventory.

Study on Activation Characteristics of Trace Elements in Black Soil Region of Central Jilin Province

Q.FU[1*], D.Y.WANG[1], Y.Y.YANG[1], C. WU[1] AND F.FEI[1]

[1] Jilin University, College of Earth Sciences, Changchun, China, fly19881118@yahoo.com.cn*, wang_dy@jlu.edu.cn, yangyuan52415241@163.com, 178275048@qq.com, flyindance313@hotmail.com

Introduction

Studying available contents of trace elements is the basis of making rational utilization of the land resources and improving soil quality as the effective state of soil elements is the available part in the process of crop utilization and absorption. In recent years, effects of soil trace elements on crop growth and quality have caught more attention, and the previous studies indicate that the consumption of trace elements in soil will increase with the improvement of crop yields, therefore, studying the activation characteristics of soil trace elements and the influence factors is of great significance.

Material, Method, Results and Discussion

This paper analyzes and determines the total contents and available contents of 10 trace elements (As, B, Cr, Cd, Cu, Mo, Mn, Ni, Se, Zn), collected from 62 surface soil samples in black soil region of central Jilin province, NE China, and correlation analyses are done by SPSS both between the total and available contents of trace elements, and between soil pH value and activation indexes of 10 soil trace elements, respectively. Statistics results show that the activation indexes (available contents of elements in soil accounting for total contents) of different trace elements in black soil region of central Jilin province make a great difference and activation index of Mo is 26.19%, reaching the highest while that of Cd is only 0.03% —the lowest. The total and available contents of Cu and Mn exhibit extremely significantly positive correlations while these of As have extremely remarkable negative correlations, and there are no significant correlations between the total and available contents of B, Cd, Cr, Mo, Ni, Se and Zn, respectively. Additionally, the activation indexes of Cr, Cd, Mn, Mo, Ni, Se and Zn have extremely significantly positive correlations with soil pH value, respectively.

Conclusion

Taken together, the above analysis indicates that the total contents of soil trace elements are not the only control factor effecting on the available contents, but soil physical and chemical properties also have some degree influence on activation characteristics of trace elements.

Thus, taking reasonable measures of soil management according to soil characteristics in study area is of vital importance to trace elements management during the agricultural production process.

Mg isotope variation in a ferromanganese crust from Line Seamount in the Central Pacific Ocean

YAZHOU FU[1] AND ZHENGRONG WANG[2*]

[1]State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, China, fuyazhoucas@gmail.com

[2]Department of Geology and Geophysics, Yale University, New Haven, USA, zhengrong.wang@yale.edu

Marine hydrogenous ferromanganese crusts grow slowly (a few mm/Ma) and contain distinctive laminar growth layers which have potential to document the long term evolution of ocean chemistry and/or deep ocean temperatures. In this study, we explored the evolution of Sr and Mg isotope variation in successive layers of a marine hydrogenous ferromanganese crust, MP2D06, from Line Seamount in Central Pacific Ocean.

Eighteen layers from this sample were subjected to a series of incremental leaching steps, using various concentrations of ammonium acetate, acetic acid, hydroxylamine hydrochloride-acetic acid, and hydrochloric acid, to leach out metals from different phases (including surface adsorbed metals, and those associated with carbonate, Fe-Mn oxides, silicates and phosphate phases). Leachates from each independent step were passed through three chromatographic columns to remove interfering metals prior to analysis (particularly Fe, Mn, and Ti). The high-precision isotopic compositions of Sr and Mg for each leachate at every layer were determined by MC-ICP-MS (Neptune) at Yale University.

Preliminary results show that hydroxylamine hydrochloride-acetic acid can dissolve Fe-Mn oxides and leachates after three serial leaching steps contain Sr and Mg associated with predominantly Fe-Mn oxides. Strontium isotopic ratios for leachates from this leaching portion are consistent with seawater $^{87}Sr/^{86}Sr$ ratios, indicating this manganese crust started to grow at about 40 Ma years ago when compared to the standard seawater Sr isotope record. Mg isotope compositions of the leachates are all greater than the contemporary sea water value-the surface layer, for example, is highly enriched in ^{26}Mg compared with contemporary sea water (+1.7 versus -0.82‰ relative to DSM). The $\delta^{26}Mg$ decreases gradually with increasing age. This decrease implies either an increases in ocean bottom temperature and/or decrease of $\delta^{26}Mg$ values of seawater in the last 40-50 Ma years.

Size effect in the adsorption of gold nanoparticles on pyrite surfaces

YUHONG FU, ZONGHUA QIN, SHANSHAN LI, JINKAI XIAO, YI XIAO AND QUAN WAN*

Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, Guizhou, 550002, P.R. China, wanquan@vip.gyig.ac.cn (* presenting author)

Size effect is essential to perhaps all aspects of nanogeoscience. The metal adsorption by minerals is thought to be one important ore-depositing mechanism. Gold nanoparticles (<100 nm) have been ubiquitously found in the Carlin-type deposits, although how they were formed remains elusive. We hypothesize that nanosized gold may be involved in the pathway of ore transportation and enrichment, and therefore have carried out experimental study on adsorption of gold nanoparticles on pyrite surfaces.

Batches of gold nanoparticles in the size range of 10~80 nm were synthesized using the classic Frens method [1]. The monodisperse size of gold particles were controlled through changing the molar ratio of chloroauric acid to sodium citrate. Natural pyrite mineral powders with particle size of tens of microns were obtained through grinding/sieving, and were cleaned with deionized water. Aqueous nano-gold sols (10 ml) of varying gold particle size were mixed (with adequate stirring) at calculated proportions with pyrite powders of varying particle size for 20 hours. Transmission electron microscopy (TEM) was used to characterize the size of the gold nanoparticles as well as their distribution on pyrite surface. Atomic absorption spectroscopy (AAS) was used to monitor the gold concentration in the liquid phase.

We have found that pyrite can strongly adsorb gold nanoparticles. In some cases where sufficient amount of pyrite was present (e.g., 10% of gold coverage on pyrite surface), gold (original concentration ~50 μg/ml) was completely adsorbed from the gold sol to pyrite surface (i.e., zero gold absorbance on AAS after adsorption). This is consistent with the fact that pyrite exists as a major gold-bearing mineral in many gold deposits. Smaller pyrite particle (200~400 mesh) showed higher ability to adsorb gold nanoparticles than larger pyrite particles (100~160 mesh), i.e., more gold (mg) was adsorbed on unit mass of pyrite (g) of smaller particle size. This seems to readily explain the observation that higher concentration of gold was normally found on pyrite of smaller size, however does not necessarily support that gold travelled in either nanoparticle or ionic/complex state. Our data also indicate that more quantity (mg) of gold was adsorbed on pyrite when the size of the gold nanoparticle was larger. While appearing counter-intuitive, this along with other aforementioned results supports a simplified adsorption mechanism that gold nanospheres pack and cover the pyrite surface. Our ongoing work aims to elucidate the detailed thermodynamics and kinetics of gold nanoparticle adsorption on pyrite. It is also worth noting that nanoparticle adsorption by minerals has wider implication beyond the field of ore deposit.

Mineralogy of lacustrine sediment from Darhad basin records the past lake level changes of the paleo-lake.

MADOKA FUCHIZAKI[1*], TAKAAKI YABE[1], HITOMI ABE[1], KEISUKE FUKUSHI[2], NORIKO HASEBE[2] AND KENJI KASHIWAYA[2]

[1]Division of Earth and Environmental Sciences, Graduate School of Natural Science and Technology, Kanazawa University, Ishikawa, Japan (*madoka14@stu.kanazawa-u.ac.jp)

[2]Institute of Nature and Environmental Technology, Kanazawa University, Ishikawa, Japan

Darhad basin in northern Mongolia is located in the continent where is sensitive to the climate change. It has been reported that several hydrologic events with climate changes occurred in this area. Ice dam lake had been formed in Darhad basin by Pleistocene glaciers. There had been several flooded events during warm periods. Darhad basin has many inflows and one outflow (Shishhid Gol river). Limestone is present in southeastrn rim of basin. Granitic rocks are distributed in northern part. There are basalt flows near the valley of the Shishhid Gol[1].

164 m of long drilling core (DDP10-3 core) were obtained from Hodon site (51˚20'11.20" N , 99˚30'04.40" E) in Darhad basin at April 2010. The core was cut into 3 cm. Top 100 m of the sediments were analyzed by X-ray diffraction in order to identify the constituent minerals. Selected samples were observed by scanning electron microscope. Water of several rivers were collected at August 2011. The water quality (pH, electric conductivities, ORP and alkalinities) were measured on site. The concentrations of chloride and sulfate were measured by high-performance liquid chromatography. Those of major cationic species were measured by inductively coupled plasma acrostic emission spectroscopy.

The mineralogical analyses showed that there are the intervals of presence of carbonate minerals and absence of the minerals. In the Some samples during the carbonates absence intervals, the formations of gypsum were observed. The water chemistry of the river samples showed that there are large variations of alkalinities among the inflows. The two inflows came from the southeast carbonate area on the basin have high Ca^{2+} and HCO_3^-. The pH of the rivers ranges from 7.39 to 8.86. The inflow came from northwest has lowest pH and dissolved solid.

The lake must be contacted with southeast limestone area if the lake level was high. The high Ca^{2+} and HCO_3^- of inflows from southeast area were evidence that clastic carbonates were entered in paleo-lake from this region. Therefore, the intervals of presence of carbonate minerals indicate the high lake level of the paleo-lake. In contrast, carbonates must be absent if lake got away from the limestone area. The formation of gypsum found in the carbonates absence intervals indicate the concentration of dissolved solid must be very high because the mineral possesses high solubility. Therefore, the intervals of absence carbonate indicate the periods of low lake level due to the evaporation.

Electrochemical precipitation of gold from a hydrothermal fluid in the Black and Kimberley Reefs, South Africa

SEBASTIAN FUCHS[1*], ANTHONY WILLIAMS-JONES[2] AND WOJCIECH PRZYBYLOWICZ[3]

[1]McGill University, Earth and Planetary Sciences, Montreal, Canada, sebastian.fuchs@mail.mcgill.ca (* presenting author)
[2]McGill University, Earth and Planetary Sciences, Montreal, Canada,
[3]iThemba, Laboratory for Accelerator Based Sciences, Somerset West, South Africa

The Witwatersrand hosts the largest known gold resource on Earth, however, the genesis of the gold mineralization is still a matter of considerable debate (opinion is divided over the relative importance of detrital sedimentary and hydrothermal processes). In the Kimberley Reef (Upper Witwatersrand Supergroup) and the Black Reef (Lowermost Transvaal Supergroup), gold is locally enriched in areas proximal to underlying gold-bearing Witwatersrand reefs. Gold concentration in the Kimberly and Black reefs correlates strongly with hydrocarbon content. The gold occurs as angular to sub-angular, native gold particles in the interstitial space between pyrite and arsenic-bearing sulphides, in fractures cutting pyrite, in irregularly shaped pores within pyrite and in hydrocarbon nodules.

Particle-induced X-ray emmision (PIXE) analyses were performed on native gold grains and nearby grains of pyrite and other minerals. Quantitative element maps prepared from these analyses show that pyrite adjacent to gold grains is invariably zoned in respect to As (unless there is also an adjacent arsenic-bearing mineral) with the highest concentrations occurring adjacent to gold grains. The concentration of As varies from 86 ppm (+/- 20) to 7850 ppm (+/- 130). The chemical zoning of As is interpreted to correspond to a change from n-type (low As) to p-type (high As) conduction. This behaviour leads to large differences in the electric potential of the surfaces of growing pyrite crystals [1].

The evidence presented above suggests strongly that the gold grains discussed here are hydrothermal in origin. Assuming this to be the case, and based on data suggesting that temperature did not exceed 350 ºC and pH was < 5 [2], gold would have been transported mainly as $AuHS^0$ and $Au(HS)_2^-$ [3]. We propose that the close spatial association of gold with As-bearing pyrite reflects the electrochemical precipitation of gold onto the p-type pyrite because of the transfer of electrons from its surface to the gold species, thereby reducing Au^+ to Au^o and releasing HS^-. A similar interpretation is proposed for gold grains in contact with other arsenic-bearing minerals. In view of the strong evidence for the hydrothermal origin of the gold and its spatial association with underlying Witwatersrand gold reefs, we conclude that the gold in the Kimberly and Black reefs was hydrothermally remobilized from Witwatersrand gold reefs.

Ab initio study of Zn isotope fractionation in aqueous compounds

TOSHIYUKI FUJII[1]*, FRÉDÉRIC MOYNIER[2], MARIE-LAURE PONS[3], AND FRANCIS ALBARÈDE[3]

[1]Research Reactor Institute, Kyoto University, Osaka, Japan, tosiyuki@rri.kyoto-u.ac.jp
[2]Department of Earth and Planetary Sciences, Washington University in St. Louis, St. Louis, USA
[3]Ecole Normale Supérieure de Lyon, Lyon, France

Isotopic variability of Zn in natural samples has been well documented by multi-collector ICP-MS [1]. The interpretation of these data is limited by our knowledge of isotope fractionation during chemical reactions. Intramolecular vibration of isotopologues is the major origin of chemical isotope effect for non-heavy elements [2]. Analysis of model molecules by *ab initio* methods is helpful to estimate magnitude of isotope fractionation. In the present study, isotope fractionation factor of various Zn species was calculated. Orbital geometries and vibrational frequencies of Zn(II) species were computed using density functional theory (DFT) as implemented by the Gaussian03,09 codes (Gaussian Inc.). The DFT method and basis set employed here are B3LYP and 6-311+G(d,p).

Isotope fractionation factor ln β (‰) for $^{66}Zn/^{64}Zn$ was estimated from the calculated vibrational frequencies of isotopologues for hydrated Zn ion, chlorides, sulfides, sulphates, carbonates, phosphates, citrates, and malates [3,4]. For the common species, our results are consistent with those of Black *et al*. [5]. With a site-averaged ln β value of 3.43‰ at 298 K, citrates are enriched in heavy isotopes with respect to the hydrated Zn^{2+} aqua ion $Zn(H_2O)_6^{2+}$, the dominant form of Zn in natural water. ln β was found to be 0.2-1‰ larger than that of Zn^{2+} for carbonates, phosphates, and sulphates, and 0.1-1‰ smaller for chlorides and sulfides. This suggests that strong oxygen donor ligands, notably phosphates and carbonates, are enriched in heavy Zn isotopes.

The present results provide a consistent framework for the interpretation of Zn isotope data in plants [6,7], with Zn phosphates in the root system being isotopically heavier than Zn malate and phosphate in the aerial parts. They also explain the heavy Zn isotope compositions of human and animal bones. The role of phosphates explains the isotopically light Zn in residual soils and isotopically heavy Zn in FeMn-nodules. It is anticipated that potential threats of aquifer pollutions by heavy metals and phosphates upon pH variations could also be monitored by Zn isotopes.

Catchment-wide denudation rates from the Murrumbidgee River, Murray-Darling Basin, SE Australia, using *in situ* cosmogenic ^{10}Be

TOSHIYUKI FUJIOKA[1*], ANTHONY DOSSETO[2], PAUL HESSE[3] AND CHARLES MIFSUD[1]

[1]Australian Nuclear Science and Technology Organisation, Sydney, Australia, toshiyuki.fujioka@ansto.gov.au (* presenting author), charles.mifsud@ansto.gov.au

[3]Department of Environment and Geography, Macquarie University, Sydney, Australia, paul.hesse@mq.edu.au

Abstract

The Murray-Darling Basin (MDB) is a large inland basin in southeast Australia (draining one seventh of the continent), and is by far the most important agricultural centre of the country. Sustainable use of the basin resources is a significant national agenda where the balance between two contrasting aspects - ecological preservation and industrial/agricultural development - has been long-debated. To evaluate the impact of human land use, it is required to understand the natural response of the basin to various external forcing such as climate and CO_2 fluctuation. This study is the first part of a larger investigation on the behavior of different river systems within MDB in response to past climate changes. Here, we present a study of the Murrumbidgee River catchment for the estimate of catchment-wide denudation rates using *in situ* cosmogenic-nuclide measurement in sediments. The Murrumbidgee River is among the longest (length ~1485 km) of the MDB rivers. Four stages of paleo-channel systems were identified and dated previously by thermoluminescence [1]. The paleo-denudation rates were calculated from the measured ^{10}Be corrected for post-depositional nuclide production. Results show remarkably constant nature of catchment-wide denudation rate (12-15 m/Ma) for the last 100 ka. The average rate of 14 ± 1 m/Ma (n = 8) is much slower than the global mean ^{10}Be-based basin denudation rate of 218 ± 35 m/Ma (n = 1149) [2]. At such low rate, time-averaging of denudation rate estimate is c. 50-70 ka, and our data integrate over the entire glacial or interglacial period. Overall, our results suggest that catchment-wide denudation in the Murrumbidgee River catchment has not been changed dramatically for the last two glacial-interglacial cycles. The result here is somewhat in contrast to U-series comminution ages of the same deposits, where interglacial sediments exhibit relatively longer residence time (c. 100-500 ka) over sediments deposited during the glacial periods (<50 ka) [3], which implies changes in weathering or erosion regimes between the two periods. Finally, response to certain climatic conditions may have been significantly different between rivers within the MDB, and our ongoing project will address this issue by comparing temporal variations in fluvial activity, denudation rates, and sediment residence times between different catchments within the basin.

Monitoring microbially induced calcite precipitation in the subsurface

YOSHIKO FUJITA[1*], TSIGABU GEBREHIWET[2], JAMES R. HENRIKSEN[1], JOANNA L. TAYLOR[2], BAPTISTE DAFFLON[3], SUSAN S. HUBBARD[3] AND ROBERT W. SMITH[2]

Microbially induced calcite precipitation (MICP) has gained interest for a number of subsurface applications, such as contaminant remediation, flowpath modification for energy resource recovery and management, and improvement of soil shear strength. A specific example is the immobilization of the radionuclide ^{90}Sr by co-precipitation in calcite, where calcite precipitation is accelerated by microbial ureolysis. Previous work has shown that ureolytically driven calcite precipitation can be mediated by indigeneous subsurface microorganisms at numerous sites, and that nutrient addition can accelerate the process and thereby increase Sr partitioning. A critical need for the further development of this approach into a field-ready technology is the ability to verify and track the progress of the relevant biogeochemical processes.

Recently we have been conducting field experiments of MICP and testing various approaches for monitoring the effects of our perturbations of the subsurface biogeochemical environment. In an experiment at the Integrated Field Research Challenge site in Rifle, Colorado, USA, we injected urea and molasses into groundwater for 12 days, with a continuous recirculation system between two wells located approximately 4 meters apart. During the recirculation, water samples were withdrawn at various locations within and outside of the recirculation zone for analysis of chemical and isotopic (^{13}C) composition and of microbial ureolytic potential (cell counts, urease gene quantitation, and/or ureolysis rate estimations), and incubated solids were sampled for evaluation of the attached microbial community. Cross borehole geophysical data were collected prior, during, and after the amendment addition. Followup water sampling occurred periodically for almost a year after active recirculation. Ten months after the cessation of nutrient injection, core was collected from within the recirculation zone.

The urea and molasses treatment enhanced *in situ* ureolytic activity as evidenced by increases in *ureC* gene copies and estimated urea hydrolysis rates, as well as long-term observations of ammonium in the injection, extraction and downgradient monitoring wells. Isotopic analyses showed a decrease in the δ^{13}C of the dissolved inorganic carbon in the recirculated water, consistent with hydrolysis of the isotopically light urea. Permeability changes and increases in the calcite saturation indexes in the well field suggest that mineral precipitation occurred; core samples are being examined for evidence. Joint interpretation of radar, seismic and electrical data suggest that these techniques can track the spatiotemporal progress of the urea hydrolysis and calcite precipitation processes.

Chemical processes of zinc in aerosols inferred from the speciation and isotopic analyses

MASATOMO FUJIWARA,[1] MASAHARU TANIMIZU,[2,1] AND YOSHIO TAKAHASHI[1*]

[1]Hiroshima University, ytakaha@hiroshima-u.ac.jp; [2]Japan Agency for Marine-Earth Science and Technology (JAMSTEC);

Supply of Zn from atmosphere to earth's surface is important considering possible deficiency of zinc (Zn) for phytoplanktons in open oceans and also toxic effects of excess Zn to various organisms in surface environment. Relative concentration of zinc (Zn) in aerosols is very high compared with the crustal abundances normalized by aluminum for other elements, showing that Zn in aerosols is originated exclusively from anthropogenic sources. In addition, Zn is largely found in finer particle fractions, since the main process of the emission is combustion in refinery factories etc. Another possible source of Zn is its emission as particles by the ablation of polyorganic materials containing zinc such as tire wears.

When Zn is provided by gaseous species into the atmosphere, finer particle of Zn in aerosol is finally formed by condensation of vapor released by the combustion, the fraction of which exhibits lighter Zn isotopic ratio enriched feature [1]. For this reason, Zn isotopic analyses may be able to quantify the contribution of Zn emitted by the volatlization. On the other hand, Zn speciation is changed in the atmosphere during long-range transport due to the reactions with water and other ligands such as sulfate and oxalate in the atmosphere. Thus, the speciation of Zn in the aerosol by X-ray absorption fine structure (XAFS) can reflect the source and behavior of Zn in the atmosphere. However, there have been no studies conducted based on both speciation and isotopic analysis for Zn in the aerosols.

In this study, aerosol samples were collected at Tsukuba, Japan. We applied XAFS to identify the speciation in the aerosols coupled with ICP-AES or ICP-MS to determine total concentration of each Zn species at each particle size. In addition, we also measured isotopic ratio of Zn using multi-collector inductively-coupled plasma mass spectrometer (MC-ICPMS; Neptune) to examine the relationship between Zn species and their isotopic ratios.

For the particles larger than 3.3 μm, ZnO and ZnS were mainly observed, which may be released from tire wear and other materials emitted originally as particles into the atmosphere. Zinc isotopic ratios in the particles are not fractionated because there is no process to induce isotopic fractionation such as volatilization for Zn when they are prduced originally as particles.

For the finer particles, main zinc species were $ZnCl_2$, Zn sulfate, and Zn oxalate. A negative correlation between zinc concentration in the atmosphere and its isotopic ratios was observed. This result suggested that most of zinc in the finer particles is anthropogenic, and that most of zinc has been emitted by the vaporization during combustion.

Tellurium Isotope Analysis in Sequential Acid Leachates of Carbonaceous Chondrites

YUSUKE FUKAMI[1*] AND TETSUYA YOKOYAMA[1]

[1] Department of Earth and Planetary Sciences, Tokyo Institute of Technology, fukami.y.aa@m.titech.ac.jp (* presenting author)

Nucleosynthetic isotope anomalies found in primitive chondrites give us clues for understanding the origin of materials from which our solar system has formed. Precise determination of isotopic compositions for various trace elements in meteorites now suggests heterogeneous isotopic distribution in the protosolar nebula (e.g. Cr, Ti, Mo, Ru, Sm [1-3]), yet some limited elements support isotopic homogeneity in the early solar system (e.g. Zr, Te, Os [4-6]). The inconsistent isotopic signatures would be the result of incomplete mixing and/or destruction of some "selected" presolar materials in the early solar system. To investigate this, it is important to determine the main presolar phases for individual elements that have contributed to the solar system. However, it is difficult to directly measure isotope ratios in individual presolar grains for trace elements where concentrations are at ppm level. In contrast, sequential acid leaching of bulk chondirtes enables chemical mineral separation, and it has been commonly used for detecting isotope anomalies of trace elements. Tellurium is one of the intriguing elements for the study of nucleosynthetic isotope anomalies in meteorites. It has eight stable nuclides produced by nucleosynthesis of p-process (^{120}Te), s-process ($^{122, 123, 124, 125, 126}$Te) and r-process ($^{125, 126, 128, 130}$Te). The isotopic composition of Te is also affected by the extinct nuclide of ^{126}Sn that decays to ^{126}Te with a half-life of 234.5 kyr [7]. In this study, we present preliminary data of Te isotopic compositions in acid leachates of Murchison meteorite (CM2) and Tagish Lake meteorite (C2-ung), which were subjected to the sequential acid leaching procedure described in [8] that was used for Os isotope analysis.

Te isotope analysis was performed by using thermal ionization mass spectrometry in negative mode (N-TIMS). The typical analytical reproducibility was 310 ppm for ^{126}Te/^{124}Te ratios when measured by using Faraday cups. The Te isotopic compositions in all the acid leacahtes from Murchison and Tagish Lake were not resolvable from terrestlial standard within analytical uncertainties. This is contrasting to Os isotopic results which showed larage nucleosynthetic anomalies in acid leachates of Murchison, while bulk chondrites possess no Os isotope anomalies [6, 8]. This inconsistency might indicate that dominant presolar phases carrying Te were thermally or aqueously unstable compared to those containing Os. The difference of volatility might have acted to produce not only planetary but also minral-scale isotopic homogeneity for Te, which was not the case for Os and other elements.

Background and abstract

Throughout geologic time, variations in carbon fixation by photosynthesis have been associated with climate changes. During glacial periods, strengthened productivity and an efficient biological pump in the North Pacific, equatorial Pacific, and Southern Oceans may have contributed to low pCO_2 [1-4]. However, there is still some controversy as to whether marine productivity was high everywhere during glacial periods, and whether intensification (or weakening) of marine productivity contributed to a decrease (or increase) of atmospheric pCO_2 during the last deglaciation. Resolving this controversy requires more data from many regions regarding temporal changes in past export fluxes of biogenic materials.

Thorium 230 (^{230}Th) normalized fluxes of biogenic components from sediment cores collected at 36ºS off central Chilean covering the past 22 kilo years (ka) (PC-1) and at 52ºS near the mouth of Strait of Magellan, Pacific side over the past 13 ka (PC-3). The ^{230}Th-normalized fluxes of TOC at the PC-1 site was relatively low between 22 and 15 calendar ka (cal ka), and a substantial increase was observed after ~13 cal kyr BP. The ^{230}Th-normalized flux of TOC at the PC-3 site was relatively low from 13 to 6 cal kyr BP, thereafter increased during the late Holocene. Our ^{230}Th normalized fluxes suggested that biological pump would not have fully worked throughout 22–14 kyr BP and the early Holocene in the central–south Chilean and from 13 to 6 kyr BP at southern most Patagonia. Therefore, biological pump in the eastern South Pacific including this study area, may have not contributed to low pCO_2 during the last glacial and deglacial periods, and intensification of marine productivity occurred after 6 kyr BP at southern most Patagonia. We will also present the ^{230}Th-normalized fluxes of biogenic components recorded in the sediment core collected from the Drake Passage.

Origin of the jadeite-quartzite from Yorii area, the Kanto Mountains, Japan

MAYUKO FUKUYAMA[1*], MASATSUGU OGASAWARA[2], KENJI HORIE[2], AND DER-CHUEN LEE[4]

[1]Akita University, Akita, Japan, mayuko@gipc.akita-u.ac.jp (* presenting author)
[2]Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan, masa.ogasawara@aist.go.jp
[3]National Institute of Polar Research, Tokyo, Japan, horie.kenji@nipr.ac.jp
[4]Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan, dclee@earth.sinica.edu.tw

The petrological, chemical, and isotopic characteristics for the jadeite-quartzite in the serpentinite mélanges [1] from Yorii, Kanto Mountains, Japan have been examined in order to study the tectonic link between jadeite-quartzite and the Jurassic accretionary complex in Japan. The mineral assemblage of the jadeite-quartzite is mainly of jadeite, albite, and quartz, with minor aegirine-augite, zircon, and titanite. Mineral texture shows that the jadeite-quartzite has recorded the reaction: albite = jadeite + quartz. Zircon crystals exhibit two distinct characteristics (Type I and II), based on their morphology and REE abundance. Type I zircon is prismatic, and has REE pattern similar to that of the magmatic zircon, but with higher total REE contents. Thus, Type I zircon is considered to be formed with the influence of fluid. In contrast, Type II zircon is porous and with REE pattern of typical hydrothermal origin. The U-Pb age for both types of the zircon is 162.2±0.6 Ma (MSWD=1.4), and at this time, Japan was still a part of the eastern margin of the Asian continent. In the Jurassic, the Pacific oceanic plate subducted and formed a Jurassic accretionary complex, the Mino-Tanba-Chichibu complex, in Japan. The age suggests that the jadeite-quartzite was formed in a deep subduction zone contemporaneous to the formation of the Jurassic accretionary complex near the trench. Whole rock elemental data show that the jadeite-quartzite contains high concentrations of Zr and Nb and low LILE (large ion lithophile elements) contents. This indicates that the jadeite-quartzite may have acquired the HFSE (high field strength element) before the fluid moved up to the mantle wedge. Typical arc volcanic rocks are depleted in HFSE. Therefore, the high HFSE found in the jadeite-bearing rock is consistent with the fluid was stripped with HFSE before it got involved in the formation of arc magma. Although the occurrence of the jadeite-bearing rock is rare, it could be quite abundant in the subducted slab. [1] Hirajima (1983) *J. Japan. Assoc. Min. Petr. Econ. Geol.***78**, 77-83.

Solution chemistry controls multisite sorption of ^{137}Cs on micaceous soils

ADAM J. FULLER[1*], SAMUEL SHAW[1], CAROLINE L. PEACOCK[1], DIVYESH TRIVEDI[2], AND IAN T. BURKE[1]

[1]School of Earth & Environment, University of Leeds, UK eeajf@leeds.ac.uk (*presenting author)
[2]National Nuclear Laboratory, UK

Accidental releases of radioactive material have led to elevated levels of the hazardous radionuclide ^{137}Cs at a number of sites, notably: Fukushima, Japan; Chernobyl, Ukraine; Hanford, USA and Sellafield, UK. Once present in soils the mobility and bioavailability of ^{137}Cs is governed by its sorption to clay minerals [1]. This behaviour is influenced by the soil's mineralogy, solution pH, nature of competing cations, and the Cs concentration. We investigated the multi-site sorption behaviour of Cs on micaceous soils, as a function of Cs concentration and solution chemistry (pH and ionic strength).

This work used batch experiments to investgate sorption of Cs onto bulk 1 mm sieved micaceous soils from near Sellafield, W. Cumbria, UK. The amphoteric sorption behaviour of Cs is strongly controlled by its solution concentration (Fig. 1). At very low concentrations (10^{-11} M) Cs sorption is unaffected by pH. However as the concentration of Cs is increased pH becomes an important controlling factor on sorption.

At low concentrations, where sorption is pH independant, Cs selectively sorbs to the highly specific Frayed Edge Sites (FES) of illite. At increased concentrations (10^{-4} M) the FES become saturated and the excess sorbs to the basal plane [2]. This is a cation exchange process and is controlled by solution pH. At excessive Cs concentrations (10^{-1} M) the clay's sorption sites are saturated and any amphoteric behaviour is masked.

This study shows the complexity of the Cs sorption process on micaceous soils. It is governed by an interrelationship between solution chemistry and the availability of multiple sorption sites, as controlled by Cs solution concentration. It is important therefore to ensure that experiments are conducted at environmentally relevant Cs concentrations and that chemical variables are carefully controlled.

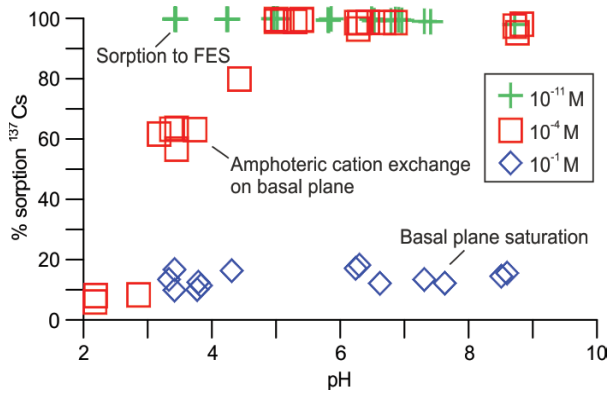

Figure 1 Sorption of Cs as a function of pH and Cs concentration

Isotope dilution analysis of Se and Te in chondritic meteorites

CLAUDIA FUNK[1*], FRANK WOMBACHER[1], HARRY BECKER[2], AND ADDI BISCHOFF[3]

[1]Institut für Geologie und Mineralogie, Universität zu Köln, Germany. cfunk0@uni-koeln.de (*presenting author)
[2]Institut für Geologische Wissenschaften, Freie Universität Berlin, Germany
[3]Institut für Planetologie, Westfälische Wilhelms Universität Münster, Germany

Introduction

The moderately volatile elements Se and Te have similar equilibrium (50%) condensation temperatures (697 and 709 K, respectively) at 10^{-4} bar for a gas of solar-system composition [1]. While the purely chalcophile element Se is exclusively hosted in sulfides [e.g. 2], the siderophile element Te can be incorporated in alloys, but also in sulfides due to its strong chalcophile affinity [1]. In CK and R chondrites and refractory inclusions in CV chondrites Te additionally forms noble metal-rich tellurides such as chengbolite ($PtTe_2$) and moncheite ($PtTe_2$) [e.g. 3, 4]. To further constrain early cosmochemical processes that led to (primary) depletion and fractionation processes affecting these two elements, precise Se and Te abundences were determined for different groups of primitive chondrites.

Analytical approach

^{77}Se and ^{125}Te enriched spikes were added to typically 50 mg of meteorite sample powder which was subsequently dissolved by HF-HNO_3 acid digestion. Chemical separation of Se and Te followed by using thiol cotton fiber (TCF). Mass spectrometric measurements were performed by multi collector ICP-MS, hydride generation and background substraction.

First Results

The presented method provides accurate and precise Se and Te abundances for chondritic samples. Concentrations were so far determined for a number of bulk carbonaceous chondrites (CI, C2 ungr., CM1, CM2, CO3, CV3, CR2, CH2), enstatite chondrites (EL3), ordinary chondrites (H3.3, L3.0), and Rumuruti chondrites (R3). Selenium and tellurium abundances are in general agreement with literature values [e.g. 2, 5]. Uniform Se/Te ratios were found for CI, C2 ungr. (Tagish Lake), CR2, CM1, and in one of the CM2 chondrites (Nogoya), whereas other CM2s, CV3, CO3.2 and CH2 chondrites show slightly lower Se/Te ratios. Ordinary, enstatite, and Rumuruti chondrites have consistently higher Se/Te ratios than carbonaceous chondrites. The data suggests that the CI chondrite Se/Te ratio is slightly higher than previously estimated by [1], and that Se/Te ratios discriminate ordinary, enstatite and Rumuruti chondrites from carbonaceous chondrites. Furthermore a weathered piece of Allende appears to confirm the suggestion that Se in chondrites is easily affected by terrestrial weathering [e.g. 2, 4].

Growth rate effect on oxygen isotope fractionation between aragonite and fluid at 24°C by *in situ* analysis

RINAT I. GABITOV[1*]

[1]University of California, Los Angeles, USA, gabitr@ucla.edu (* presenting author)

Introduction and Methodology

Oxygen isotope compositions ($\delta^{18}O$) of biogenic and inorganically precipitated calcium carbonate minerals are being used to reveal marine and terrestrial temperatures from the past. However, experimental and natural observations show that factors other than temperature control $\delta^{18}O$ in $CaCO_3$ via disequilibrium fractionation [1,2, etc.]. Among these factors are crystallization rate, solution pH, and saturation state of the fluid with respect to $CaCO_3$ phase (Ω). Previous experimental assessments of disequilibrium effects for $\delta^{18}O$ were focused on controlling pH and Ω of the experimental solution, followed by bulk analysis of $\delta^{18}O$ in multicrystalline precipitates. The precipitation rates in those works are usually being reported as amount of precipitated $CaCO_3$ per surface area and time (or simply amount per time) [3,4]. Because of this, inter- and intra-crystal isotopic variability has remained unknown.

In this work, I used the alternative approach of *in situ* Secondary Ion Mass Spectrometry (SIMS) at lateral spatial resolution of ~10 μm to determine isotopic and chemical variability of precipitated aragonite. The standard deviation of ten SIMS analyses of clear-beige natural aragonite (Belice, Bohemia) was 0.3 ‰ (1σ); the bulk $\delta^{18}O_{VPDB}$ in this reference aragonite was determined by stable isotope mass spectrometry as -7.79 ‰. Hemispherical bundles of aragonite crystals (spherulites) were precipitated by diffusion of CO_2 from ammonium carbonate into NH_4Cl-$MgCl_2$-$CaCl_2$ solution at 24°C. Spherulite growth (extention) rate (V) was monitored by sequentally spiking the growth medium with rare earth element (REE) dopants. After performing $\delta^{18}O$ analyses with a Cs^+ primary beam the same spots were revisited to determine their REE/Ca using an O^- beam. pH was measured in periodically sub-sampled fluids where aragonite nucleated and crystallized between starting and terminal pH of 8.3±0.1 and 8.63±0.02, respectively.

Results

SIMS spot analyses demontrate that nucleation centers of aragonite spherulites are depleted in $\delta^{18}O$ relative to their edges by as much as 4 ‰. REE/Ca profiles show decreasing V in the spherulites with time (i.e., spherulites edges advanced at slower rates than centers). $\delta^{18}O$ increases by 2.4 ‰ with decreasing V between 3 and 0.1 μm/hr. Because of a large fluid to crystal molar ratio (~4000) $\delta^{18}O$ of the fluid unlikely changed significantly during aragonite crystallization. Analysis of fluid sub-samples for $\delta^{18}O$ is ongoing and will permit to accurately calculate the dependence of the fractionation factor ($\alpha^{18}O$) on aragonite growth rate.

Phase equilibrium constraints on the genesis of wehrlite cumulates at mid-ocean ridges and the origin of the clinopyroxene paradox

GLENN A GAETANI[1*], JOHN MACLENNAN[2]

[1]Department of Geology and Geophysics, Woods Hole Oceanographic Institution, Woods Hole, MA, 02543, USA (ggaetani@whoi.edu)

[2]Department of Earth Sciences, University of Cambridge, Downing Street, Cambridge, CB2 3EQ, UK (jcm1004@cam.ac.uk)

A longstanding gap in our understanding of ocean crust accretion is the occurence of pyroxene-bearing ultramafic cumulates near the base of the crust in ophiolites [1]. A similarly unresolved issue in the evolution of mid-ocean ridge basalts (MORB) is a compositional signature for clinopyroxene crystallization in abyssal tholeiites that are pyroxene saturated only at upper mantle conditions (the clinopyroxene paradox) [2]. Melting experiments conducted on lava from the Borgarhraun flow in the Theistareykir segment of Iceland's Northern Volcanic Zone provide new insights into both of these issues. Our results, combined with those of Winpenny and Maclennan [3], indicate that wehrlites nodules in the Borgarhraun flow crystallized at moderate pressures and relatively low temperatures from highly depleted magmas. This is consistent with an origin for wehrlite cumulates by crystallization of late-stage melts generated in the upper portions of the ascending mantle. The eventual mixing of these magmas with melts formed deeper the melting column imparts a clinopyroxene crystallization signature on erupted MORB.

Experiments were carried out on primitive (Mg# ~0.72) Borgarhraun lava at 1 bar and 1190 to 1320ºC by suspending rock powder from Re loops in a vertical gas-mixing furnace, with oxygen fugacity controlled at ~1.5 log units below the fayalite-magnetite-quartz buffer. Experiments were also conducted at 1.0 to 1.4 GPa and 1260 to 1370ºC, in graphite capsules, using a solid-medium piston-cylinder device. All run products were analyzed for major elements by electron microprobe. Trace elements were analyzed in a subset of the experiments by secondary ion mass spectrometry.

The 0.1 MPa liquid line of descent for Borgarhraun lava is typical of MORB, with olivine on the liquidus at ~1310°C, followed by olivine + plagioclase at ~1220°C. Clinopyroxene appears at ~1205°C. At 1.2 GPa Olivine + clinopyroxene crystallize together on the liquidus at ~1360°C. Clinopyroxenes in the wehrlite nodules studied by Winpenny and Maclennan [3] are compositionally distinct from those in our high-pressure experiments. The former are characterized by higher Mg# and CaO, and are strongly depleted in incompatible elements. A likley parent magma for the wehrlite cumulates is, therefore, a late-stage partial melt formed at relatively shallow depths. Dantas et al. [4] proposed a similar origin for pyroxenite cumulates from the Southwest Indian Ridge, suggesting that this process may be common at mid-ocean ridges.

Me/Ca Proxies and Foram Biomineralization: The Role of Cation Transport

ALEXANDER GAGNON[1,2*], JAMES DEYOREO[2], DONALD DEPAOLO[1], HOWARD SPERO[3], ANN RUSSELL[3] AND ANTHONY GIUFFRE[4]

[1]Earth Science Division and [2]The Molecular Foundry, LBNL, Berkeley, USA, acgagnon@lbl.gov

The Mg/Ca paleothermometer is a widely used technique and a powerful tool to reconstruct past sea surface temperatures from the tests of planktic foraminifera. However, the presence of unexplained diurnal Mg/Ca bands in these same tests [1] stands as a reminder of how little we know regarding the mechanistic details of biomineralization. During skeletal growth Mg/Ca and other proxies are controlled by a host of biological and physical factors including ion transport, aquatic speciation, surface chemistry, thermodynamic partitioning, crystal growth kinetics, and mineralization pathways. To build accurate environmental reconstructions we need to separate the impact of each parameter and use these data to build a chemical-scale understanding of biomineralization. In this study we isolate and characterize cation transport in cultured planktic foraminifera using stable isotope spikes and microanalysis. We then test if ion transport can explain diurnal Mg/Ca banding and develop a general model for the impact of ion dynamics on skeletal composition.

Living planktic foraminifera (*O. universa*) were placed in seawater enriched with stable isotopes of Mg, Ca, and Li. After 48 hours the forams were returned to natural abundance seawater. Imaged using NanoSIMS, the skeletal records of isotope uptake and efflux during this experiment reflect ion transport rates. We found that the calcium pool used for skeletal growth exchanges with the surrounding seawater with a turnover time of less than two hours. Furthermore, we observed no evidence for distinct day or night cation pools. Finally, magnesium, calcium, and lithium all showed identical dynamics suggesting direct and rapid seawater transport to the site of calcification rather than ion specific pathways. Thus selective calcium or magnesium pumping into the site of calcification cannot be used to explain diurnal Mg/Ca banding. Specific pumping of magnesium out from the site of calcification is still consistent with our data, however, and may explain banding. Combining ion transport rates and skeletal growth rate measurements from the same forams, we build a general analytical model to quantify the impact of ion dynamics on test composition. This transport model complements ongoing work on mineral growth rate effects in calcite and contributes towards a holistic and chemical-scale understanding of proxy behavior in foraminifera.

Toward a quantitative model of metamorphic nucleation

FRED GAIDIES

Department of Earth Sciences, Carleton University, Ottawa, ON, K1S5B6, Canada

Mineral reactions in rocks take place as the result of a complex interplay between various atomic scale processes including dissolution, chemical diffusion, nucleation, and crystal growth. It is generally assumed that the product of a mineral reaction forms if the formation of that phase lowers the Gibbs free energy of the effective chemical system. However, even when that phase is part of the thermodynamically stable mineral assemblage, it may not necessarily nucleate. A certain departure from equilibrium is required to gain energy for the formation of the interface between reactants and products. This energy is referred to as interfacial energy, and only little is known about its magnitude during rock formation. In addition to this energy that has to be provided to initiate crystallization in rocks, chemical elements have to be transported between the sites of reactant dissolution and product nucleation, and attachment and detachment processes at the interfaces have to be efficient for crystallization to proceed. Knowledge of chemical transport and interface reaction rates in rocks are scarce but it is known that their interplay controls the microstructure and texture of rocks with important implications for the derivation of the conditions of rock formation relevant for the interpretation of past and future tectonic processes of Earth.

In this talk, a simple numerical model will be presented that accounts for the departure from equilibrium required for interface-controlled mineral nucleation [1]. The model simulates interface processes during metamorphic mineral reactions by which nuclei and crystals form on a molecular level based on classical nucleation and reaction rate theory and Gibbs free energy dissipation in a multi-component model system. Modeling results will be shown that allow to explore the interplay of several key parameters that impact on crystallization kinetics during petrogenesis such as the relative influences of interfacial energy and interface mobility on mineral content, mineral chemistry, and texture of rocks accounting for different rates of pressure – temperature changes during crystallization.

The comparison of nucleation simulations of contact-metamorphic garnet with analytical data obtained through XR-CT and EPMA provides first estimates of the order of magnitude of interfacial energies during metamorphic crystallization. It suggests furthermore that the interfacial energy has a first-order control on the departure from equilibrium required for mineral reactions if attachment and detachment processes at the surface of the product phase limit the overall crystallization rate. The influence of the heating rate on thermal overstepping is found to be negligible. A significant feedback is predicted between chemical fractionation associated with garnet formation and the kinetics of nucleation and crystal growth of garnet giving rise to its commonly lognormal – shaped crystal size distribution.

Chronic toxicity of metals/metalloids in mammals is mediated by their effect on Se-metabolism

JŰRGEN GAILER[1], GRAHAM N. GEORGE[2], AND INGRID J. PICKERING[2]

[1]University of Calgary, Calgary, Canada, jgailer@ucalgary.ca (* presenting author)

[2]University of Saskatchewan, Saskatoon, Canada, g.george@usask.ca; ingrid.pickering@usask.ca

The etiology of numerous human diseases, including autism and type 2 diabetes, the incidences of which are rising globally, is not well understood. Conversely, the concentration of toxic metals and metalloids, such as As, Cd, Hg and Pb in human blood of the average population is well established, but strikingly little is known about the role that these inorganic pollutants might play in the etiology of human disease processes [1]. Hence, the establishment of functional connections between the chronic exposure to inorganic pollutants and the etiology of certain diseases remains one of the great challenges in the post-genomic era. This requires us to uncover hitherto unknown biomolecular mechanisms which must explain how exceedingly small doses of a toxic metal/metalloid compound (low µg per day) – or mixtures thereof – may eventually result in a particular human disease. The biological complexity that is associated with mammalian organisms, however, makes the discovery of relevant mechanisms a monumental challenge. Recent findings suggest that a better understanding of the bioinorganic chemistry of inorganic pollutants in the bloodstream represents one fruitful strategy to unravel pertinent biomolecular mechanisms [1, 2]. In particular, the adverse effect(s) that toxic metals/metalloid compounds exert on the transport of the essential ultratrace element selenium to organs has emerged as highly relevant [3, 4]. An overview of the effect that As^{III} and Hg^{2+} exert on the mammalian metabolism of selenite will be presented and the health relevance of these findings will be discussed.

The igneous contribution to atmosphere chemistry

FABRICE GAILLARD[1]*, BRUNO SCAILLET[1]

[1] CNRS-INSU, Université d'Orléans, ISTO, UMR 7327, 45071, Orléans, France, gaillard@cnrs-orleans.fr; bscaille@cnrs-orleans.fr (* presenting author).

We intend here to discuss the relationships between volcanic degassing and atmosphere chemistry in a (comparative) planetary perspective, with a particular emphasis on the atmospheric oxygenation that occurred on Earth, at the Archean-Proterozoic transition [1].

Igneous rocks and volcanic exhalations are moderately reduced [1]. For several reasons, secular variations in their redox state have been proposed [2] but so far no evidence of this has been found [3]. The only clear large scale modification of mantle redox state occurred at the end of the core formation at about 4.45 Ga. But it is only two billions years later that Earth's atmosphere became oxidized. This timelag between the mantle and the atmosphere great oxidation events [4] may possibly reflect changes in the conditions of volcanic degassing [5,6] that, in turn, may have been conditioned by large scale geodynamic modifications [7]. We will pursue here this analysis by evaluating alternative scenarii leading to changes in volcanic gas compositions. This includes changes in the intrusive/extrusive ratios and variations of the depth of melting. We will also discuss wether the great oxidation event (GOE) is unique to Earth or a common planetary process. The fact that Mars atmosphere is oxidized with an oxygen content comparable to that of the Earth's atmosphere after the GEO must be considered in the light of a possible GOE on Mars. The observation that Martian basalts show redox conditions much more reducing than that on Earth should also be incorporated in our contemplation on the role of igneous input to atmosphere chemistry. The fact that Venus atmosphere is reduced and may be comparable to that of Earth before the great oxidation event is also intriguing.

Because sulfur is an important component in volcanic processes and because of the diversity of its possible redox states, sulfur plays a dominant role in redox processes impacting oxygen abundance in planetary atmospheres [5,8]. We suggest that the efficiency of sulfur transfer from planetary interiors to their atmospheres is playing a major role in atmospheric oxygenation on Earth, and elsewhere.

Denudation of the Lesser Antilles

JÉRÔME GAILLARDET[1*], ERIC LAJEUNESSE[1], SETAREH RAD[2], . CELINE DESSERT[1], PASCALE LOUVAT[1], KARINE RIVÉ[1], PIERRE AGRNIER[1], ELIMIE LLORET[3] ET MARC BENEDETTI[1]

We report in this paper the results of a multidisciplinary project aiming at determining the rates of chemical and physical denudation in the Lesser Antilles and the carbon fluxes exported to the ocean in a volcanic arc setting (Guadeloupe, Martinique, Dominica). Chemical denudation rates, determined by using river dissolved load range from 30 to 600 t/km2/yr, are extremely variable as a result of highly variable runoff and of the variable input of groundwaters influenced by volcanic acids [1], [2]. Physical denudation was estimated using different methods. Temporal monitoring of selected watershed gives a first estimate over a relatively short observation period. Based on the chemistry of the bottom sands transported in rivers, we calculated the physical denudation rates expected for a weathering system at steady state by solving a mass budget between source rocks and erosion products. Results show that the volcanic relief of Guadeloupe is eroding both chemically and physically at rates ranging between 100 mm/kr and more than 1000 mm/yr from the northern (and older) part of the Island to the southern (and younger) part respectively. These rates are important at a global scale and show that volcanic arc islands are "hot spots" of chemical and physical denudation on Earth. The denudation of the Lesser Antilles Arc is 2-3 higher that the eruptive rate, or island construction rate, meaning that volcanic arc islands have a limited lifetime (of typically 1 to a couple of million years) at a geological time scale. In addition to be a locus of intense sediment production to the ocean, the Lesser Antilles have a significant role of carbon export to the ocean. In terms of atmospheric carbon sequestration, first results show that the sequestration of organic carbon (in both dissolved and suspended load) may be about the same order of magnitude than inorganic sequestration [3]. Hydrology, and particularly orographic precipitation are proposed to be the main drivers of the weathering and denudation of tropical volcanic islands. Progresses have to be done primarily to establish proper water budgets of volcanic island to separate the effect of surface waters from groundwaters and to monitor over long periods of time the exportation of solids and particulate carbon.

Non-traditional isotope variations in the Cordillera del Paine pluton

N. GAJOS[1*], C.C. LUNDSTROM[1] AND P.J. MICHAEL[2]

[1]Dept. of Geology, Univ of Illinois, Urbana, Il 61801 lundstro@uiuc.edu

[2]Dept. Geosciences, Univ of Tulsa, Tulsa, OK 74104 pjm@utulsa.edu

Non-traditional isotope systems provide unique insight into magma differentiation processes. We present new Fe and U isotope analyses (along with traditional Sr and Pb isotope data) on samples from the Cordillera del Paine igneous complex to assess relationships with differentiation. The Cordillera del Paine complex consists of a 1 km vertical exposure of relatively homogenous granite overlying a nearly contemporaneous and possibly cogenetic 0.5 km mafic gabbro suite. The mafic suite includes a small zone of diorites underlain by hornblende gabbros at the base of the exposure.

Samples previously characterized by Michael (1984, 1991) [1,2] were analyzed by MCICPMS. Fe isotope data shows a hyperbolic trend of increasing δ^{56}Fe with increasing SiO_2 in the pluton. Results show a strong correlation between $^{87}Sr/^{86}Sr$ and silica. Ten mafic suite samples average $^{87}Sr/^{86}Sr$ 0.7043(±)0.0004 and eleven granites average $^{87}Sr/^{86}Sr$ 0.70527(±)0.0004. In contrast, Pb isotopes are remarkably constant hovering ~ $^{208}Pb/^{204}Pb$ 38.72, $^{207}Pb/^{204}Pb$ 15.64 and $^{206}Pb/^{204}Pb$ 18.83. Finally, preliminary U isotope data show a trend of increasing $^{238}U/^{235}U$ with increasing SiO_2 (ranging from -0.37 to -0.26) although these data are only marginally outside of analytical error.

We assess four possible processes responsible for fractionating Fe isotopes during magma differentiation: 1) thermal migration and thermal gradients [3]; 2) crustal contamination, 3) fractional crystallization and 4) late stage fluid removal [4]. Quantitative assessment of #3 & #4 awaits results of experiments in progress to measure mineral-melt fractionation factors. The correlation of $^{87}Sr/^{86}Sr$ with silica as well as δ^{56}Fe suggests crustal contamination could be important to all isotope systems. This is reinforced by the Pb isotope data which fall very close to nearby Chile trench values [5]. On the other hand, fractionation of the heavy Fe and U isotope ratios with differentiation is also consistent with thermal migration and thermal gradient laboratory experiments. Further tests of other non-traditional stable isotope systems, such as Si, will help to assess the plausibility of this mechanism.

Upper ocean deoxygenation and denitrification at the end of the last ice age

ERIC GALBRAITH[1*] AND SAMUEL JACCARD[3]

[1]McGill University, Montreal, Canada, eric.galbraith@mcgill.ca (* presenting author)
[2]ETHZ, Zurich, Switzerland, samuel.jaccard@erdw.ethz.ch

The solubility of gases in the ocean decreased at the end of the last ice age, as ocean temperatures gradually rose, which would be expected to have increased water column denitrification rates. However, proxy records from marine sediments have shown that changes in oceanic oxygen contrations across this interval were not globally uniform, implying an important role for accumulated changes in oxygen consumption through the respiration of settling organic matter. A global compilation of marine sediment proxy records reveals that the upper ocean generally deoxygenated, but this included pauses and even reversals, consistent with changes in both temperature and oxygen consumption. [1] A new global nitrogen isotope compilation is consistent with a doubling of the rate of denitrification in the anoxic cores of oxygen-minimum zones across the deglaciation. This compilation is also consistent with a deglacial increase of nutrient supply via leakage from nitrate-rich upwelling regions, most notably the Southern Ocean, as previously suggested [2]. It seems likely that this increased nitrate supply contributed to the deglacial de-oxygenation by enhancing export and oxygen consumption, while also intensifying denitrification in anoxic waters. This analysis suggests that the nutrient flux across the thermocline is a key determinant of oxygenation and denitrification, in addition to temperature-driven solubility changes.

Being able to compute the thermodynamics and reactivity of carbonate minerals and their solution species from atomistic simulation has long been a goal of geochemical modelling. The objective of this presentation is to address the question of how far can we go towards achieving this with present models and resources? Here a number of problems in carbonate geochemistry will be examined to demonstrate to what extend we can reproduce experimental data for the solid state and therefore be predictive for more complex environments, such as those for solution speciation.

A first test for any theoretical method is the polymorphism of crystalline calcium carbonate where the thermodynamics is well known. Examination of the performance of various first principles methods shows that reproducing the relative stabilities of calcite, aragonite and vaterite is sensitive to the choice of functional. Beside the quantitative thermodynamics, such methods offer new insights into the disorder within vaterite [1]. While there are also many force field models for carbonate minerals in the literature, most also fail to yield accurate thermodynamics unless explicitly considered during fitting [2]. If care is taken, force field models are found to provide a good description of cation-mixing in carbonate solid solutions.

More challenging than the bulk is the interface between carbonates and solution, including the influence of pH. Here the thermodynamics and reactivity of calcium carbonate in solution can be accurately predicted by atomistic methods. Computed free energies for ion pairing and formation of stable pre-nucleation clusters [3] are found to agree well with data from experimental speciation models [4]. Furthermore, simulations predict that nanoparticles of amorphous calcium carbonate are more stable than their crystalline counterparts below a critical size, depending on the degree of water incorporation [5]. The final challenge is to be able to compute rates of growth and dissolution for carbonates; this is now feasible with the use of enhanced sampling techniques [6].

Simulation of non-classical crystallization of carbonate minerals

RAFFAELLA DEMICHELIS[1], PAOLO RAITERI[1], JULIAN D. GALE[1*], DAVID QUIGLEY[2] AND DENIS GEBAUER[3]

[1]Curtin University, Chemistry, Perth, WA, Australia, J.Gale@curtin.edu.au (* presenting author)
[2]University of Warwick, Physics, Coventry, UK, D.Quigley@warwick.ac.uk
[3]University of Konstanz, Physical Chemistry, Konstanz, Germany, Australia, Denis.Gebauer@uni-konstanz.de

The crystallization mechanisms of carbonate minerals have long attracted significant interest and none more so than calcium carbonate. Ion pairs have long been known to exist in carbonate solutions [1], while the existence of a range of $CaCO_3^0{}_{(aq)}$ species of varying hydration was proposed [2]. Recently, the demonstration that these pre-nucleation species are actually stable has sparked considerable interest in the non-classical nucleation of carbonates [3,4]. How this relates to the observation of amorphous states, such as Polymer Induced Liquid Precursors (PILP) [5] and Liquid Amorphous Calcium Carbonate (LACC) remains an open to debate [6].

In the present work we have utilized molecular dynamics simulation, based on both reactive [7] and conventional atomistic force fields, to identify the nature of the stable pre-nucleation clusters as being rapidly varying hydrated supramolecular polymers labelled as Dynamically Ordered Liquid-Like Oxyanion Polymers (DOLLOP) [8]. These DOLLOPs consist primarily of 1, 2 and 3-coordinate calcium and carbonate ions, leading to linear or branched polymer chains. However, ions remain in equilibrium with the solution through rapid exchange. The evolution and lifetime of the DOLLOP species depends on the size of the cluster; once a critical size is reached the properties are found to alter while remaining distinct from ACC. A preliminary examination of the influence of the presence of species other than calcium, carbonate and bicarbonate on the behaviour of DOLLOP has also been carried out.

U(VI)-organic phosphate complex formation studied by ESI-FTMS

CATHERINE GALINDO[1], MIRELLA DEL NERO[1*], OLIVIER COURSON [1] AND SYLVIA GEORG[1]

[1]Institut Pluridisciplinaire Hubert Curien, UMR 7178 UdS/CNRS, Strasbourg, France
mireille.delnero@iphc.cnrs.fr (* presenting author)

Introduction

Complexation studies using model molecules with P=O and P-OH functionalities are highly required to assess to which extent organic phosphorus, present in the humic fraction of natural organic matter as derivatives of phospholipids, phosphonic acids, phosphoric esters, is involved in the binding of uranyl ions by humic acids. Electrospray ionization-Fourier transform mass spectrometry (ESI-FTMS) was used to investigate the formation of uranyl complexes in native solutions containing phenylphosphonic acid (H_2L) or phenylphosphoric acid and U(VI) at trace concentration level (µmolar range). Positive identification of the species was achieved, thanks to the high resolving power, high mass accuracy and reliability in ion abundance of the linear ion trap/orbitrap hybrid mass spectrometer.

Results and conclusion

Two types of complexes of stoechiometry of 1:1 (UO_2HL^+) and 1:2 ($UO_2(HL)_2$) were identified in native solutions at pH 3 containing U and phenylphosphonic acid, and the stability constants were evaluated. The technique was also successfully applied to elucidate the interactions between U(VI) and phenylphosphoric acid in native solutions with pH values favouring the hydrolysis of the organic ligand. Evidence was given for the presence of U(VI)-phenylphosphate complexes and for the formation of uranyl complexes with the degradation by-products of the ligand, with the relative contributions of species varying with time.

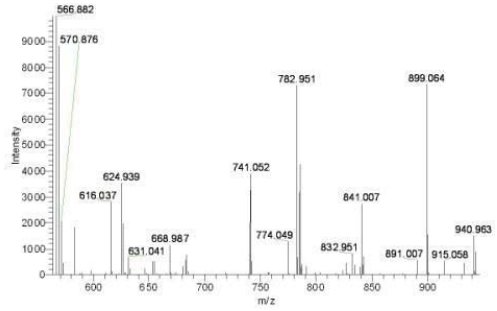

Figure 1: Negative ion mode ESI-FTMS spectrum showing presence of uranyl-phenylphosphonate complexes (detected as clusters formed with ClO_4^- electrolyte ions during ionization).

Studies of native solutions by means of ESI-FTMS has provided structural and quantitative information on the complexes formed between U(VI) and model molecules with P=O and P-OH functionalities. A complete speciation model was obtained for the uranyl - phenylphosphonic acid system, which is useful to model the binding of U by humic acids. The study was performed for trace level concentration of U, which is important for the applicability of the model to the speciation of uranyl in soil systems.

[2]Durham University, Department of Earth Sciences, Durham, UK

The isotope system of nickel (Ni) has recently achieved some attention as a possible tracer for low-temperature processes [1]. However, although Ni is a ubiquitous element in the mantle the behaviour of Ni isotopes in high-temperature environments is yet to be investigated. In this study we have measured the mass-dependant isotope composition of Ni ($\delta^{60/58}$Ni, relative to the Ni metal standard NIST-SRM986) in a variety of mantle derived rock samples by MC-ICPMS using double-spike correction (long-term external reproducibility on silicate samples < 0.07‰) [2].

MORB glasses from different ocean ridges (Mid-Atlantic Ridge, Indian Ocean Ridge, and East Pacific Rise) and of different spreading rates were analysed for their Ni isotope compositions. The samples from the faster-spreading East Pacific Rise are heavier on average than those from the slower Mid-Atlantic and Indian Ocean Ridges, although all samples are significantly lighter (up to –0.4‰, δ^{60}Ni) in their isotope composition relative to peridotite samples. It is therefore possible that partial melting of the upper mantle cause fractionation of Ni isotopes, with the lighter isotopes being preferably extracted into the melt.

The Ni isotopic compositions of intraplate basalt (OIB) samples from widely different locations were also measured. Although the δ^{60}Ni-values for these basalt samples were spread over ~0.2‰, the values are within error of the isotopic composition of peridotites and Tertiary komatiites, which indicates that there is essentially no isotopic fractionation between mantle rocks and intraplate basalts. These preliminary results suggest that basalts may have small differences in their Ni isotopic composition depending on their origin, with MORBs appearing lighter than intraplate basalts.

Whether these results depend on differences in degree of partial melting between the MORB and OIB samples, or if their differences are due to the source's original chemical composition is difficult to say without further analyses. However, if partial melting causes fractionation of Ni isotopes between solid and melt in the mantle to the same extent in both OIBs and MORBs, resulting in the melt being slightly lighter than the residual solid, then the deep mantle may contain an undepleted reservoir of heavier δ^{60}Ni than measured in peridotite and komatiite samples.

The French National Plan on the Management of Radioactive Materials and Waste launched a survey of some former uranium mines, worked in France between 1948 and 2001 to detect potential effects on the environment. We present preliminary data on the supergene evolution of waste rock piles generated during mining operations in the Saint-Sylvestre leucogranite complex (northwestern Limousin, French Massif Central) a granite intruded at 324 ± 4 Ma. This two-mica granite hosts an important U-ore mineralization deposited at 270-280 Ma, due to sustained hydrothermal circulation. In the Bellezane area, later lamprophyre dykes also cut the granite and suffered extensive low-T alteration. Mining operations have generated waste rock piles of granitic rocks, exposed to meteoritical weathering since the mining time. Biotites are a useful indicator of the type and intensity of alteration, showing chloritic or kaolinitic evolution. Low-T weathering is indicate by the presence of smectites. Fe-migration gives rise to the formation of Fe3+-phosphates and sulphates. Primary U-minerals mostly consist of pechblende and coffinite. Primary and secondary phosphates consist of monazite and crandalite, sometimes intergrown. is frequently observed. Secondary phases such as autunite of U-bearing smectite contribute to decrease U-mobility during meteoritic weathering.

The formation of carbonaceous material by abiotic processes is an important standing issue. This process depends on redox conditions and fluid/rock interactions. Subduction zones are major interfaces between the surficial and the deep Earth carbon reservoirs where complex processes affecting carbon transfers are still poorly known.

Here, we studied the geochemistry of carbon (reduced and oxidized) in siliceous-marbles at the direct contact with serpentinites in the Alpine eclogitic meta-ophiolithic units of northern Corsica (France). We applied spectroscopic (Raman) and isotopic techniques to characterize the carbonaceous and carbonate reservoirs in the rocks across a reaction front where the reaction $CaCO_3+SiO_2+2H_2=CaSiO_3+C+2H_2O$ is evidenced.

The reaction zone consists in a centimeter-thick pale nephrite layer lying at the contact with serpentinites, overlaid by a thin wollastonite layer and a 5 to 20 cm thick dark zone composed of wollastonite, carbonaceous material (CM) and quartz. No carbonate could be evidenced in that reaction zone. There is a sharp (<0.5cm) transition between this reaction zone and the overlying "primary" metasediment, which is composed of calcite+quartz and contains significantly less CM. Raman spectroscopy shows that CM is much more graphitic in the reaction zone than in the "primary" metasediment. Significant isotopic differences are observed between the reaction zone and the overlying "primary" metasediment: $\delta^{13}C$ values are around -15‰ and 1.3‰ for CM and calcite respectively in the "primary" metasediment far from the reaction zone, whereas $\delta^{13}C$ (CM) is around -1‰ in the reaction zone.

We interpret the graphitic CM in the reaction zone as formed by the destabilization and reduction of calcite subsequently to the diffusion of reducing fluids from the underlying serpentinite unit. Mass balance calculations support this hypothesis and shows that a complete reduction of carbonates may have occurred. The timing of the formation of this abiotic macromolecular and graphitic C, and the possible role of catalysts is discussed. The geological importance of this process in the subduction zone carbon cycling will be critically assessed.

Constraints on the Mg initial isotopic composition of the solar system from CM & CR chondrite

A. GALY[1,*], C. GÖPEL[2], J.-L. BIRCK[2,3]

[1]Department of Earth Sciences, University of Cambridge, UK, albert00@esc.cam.ac.uk (* presenting author)
[2]Institut de Physique du Globe de Paris, France, gopel@ipgp.fr
[3]birck@ipgp.fr

The recent evaluation of the Al-Mg systematic in undifferentiated and differentiated meteorites at high precision using MC-SIMS or MC-ICPMS has returned conflicting information about the heterogeneity in the initial abundance of short-lived ^{26}Al (half-life of 0.73Ma) and in the Mg isotopic composition of the solar nebula (SN) [1-4]. Heterogeneity in the initial abundance of ^{26}Mg ($\delta^{26}Mg^*_0$) would prevent the use of olivine for dating the last thermal event [4] while $^{26}Al/^{27}Al$ heterogeneity would preclude any dating with Al-Mg.

Here, we report data, on the DSM3 scale, for Tafassasset, an equilibrated CR chondrite and for Paris, a well preserved CM chondrite. Sequential dissolution steps of bulk rock powder were performed but also separated minerals of olivine (Forsterite and Fayalite?) in Paris, accessory chromite (Tafassasset) and an aliquot of the bulk rock were analyzed for Al/Mg systematic. These fractions correspond to aliquots from the detailed Mn/Cr systematic study that suggested an age of 4.8±0.4 and 7.8±0.6 Ma older than the angrite LEW Cliff 86010 for the CR and the CM, respectively [5]. In Tafassasset, the Mg isotopic composition is homogeneous with $\delta^{26}Mg$= - 0.30±0.05‰ and $\delta^{26}Mg^*$= - 0.002±0.015‰ ($2\sigma_{mean}$, N=5) except for the chromite with a $\delta^{26}Mg$= 0.24±0.07‰ and a $\delta^{26}Mg^*_{Bulk\ CR}$<0.038‰ at 95% confidence level. This would suggest a $^{26}Al/^{27}Al \leq 2\times10^{-6}$ at the time of the thermal equilibration of the chromite with the rest of the chondrite. The difference in the $\delta^{26}Mg$ suggests an Mg equilibrium temperature of 1180-1450°K [6]. Assuming a homogeneous and initial $^{26}Al/^{27}Al$ of 5.23×10^{-5} for the SN, a $^{26}Al/^{27}Al \leq 2\times10^{-6}$ would only be compatible with the Mn-Cr age if the difference in age was > 9.5Ma between LEW Cliff 86010 and CAIs. Such an old age for the CAIs is also required from Hf-W systematic [7] and the chronological agreement between CAIs, CR and LEW Cliff 86010 for Al-Mg, Mn-Cr and Hf-W would support a homogeneous SN with respect to ^{26}Al [1-2]. In that case, the measured value implies $\delta^{26}Mg^*_0$= - 0.040±0.015‰ assuming a chondritic Al/Mg ratio for this CR. In Paris, the olivine fractions returned different Mg isotopic compositions. Their $\delta^{26}Mg^*$ are different by 0.064‰ just outside the $2\sigma_{mean}$. Given the old Mn/Cr age of this CM chondrite, the $\delta^{26}Mg^*_0$ is estimated to be - 0.006±0.039‰ ($2\sigma_{mean}$, for 4 objects defining the Mn-Cr isochron [5]). Altogether these data are more suggestive of small (~0.05‰) heterogeneity in the initial abundance of ^{26}Mg than of ^{26}Al in the SN. Attempt of detailed Al-Mg will be discussed but the small measured range of $\delta^{26}Mg^*$ (<0.15‰ at 95% confidence) is likely to prevent accurate determination of the $^{26}Al/^{27}Al$ for this CM.

Reactive Transport Model

Alberta Oil Sands mining has introduced intensive petrochemical processing into an environmentally sensitive boreal landscape. The resulting tailings ponds are considered an environmental risk for contaminant emissions to surrounding environments. A reactive transport model has been developed along two transects of wells in order to quantify the fluxes of metal and organic contaminant emissions from a large tailings pond into surrounding ground and surface waters, including the Athabasca River. Here we report the results of the inorganic portion of that study, including lead and zinc isotopic signatures as a method for discriminating natural from anthropogenic contaminant emissions.

Metal concentrations in both ground and surface waters surrounding the tailings pond are lower than current environmental guidelines. Dissolved metal contaminant concentrations demonstrate a strong attenuation profile down gradient from the tailings pond. PHREEQC modelling, SEM observations, and precipitate monitoring all indicate groundwaters are strongly supersaturated in iron and manganese oxyhydroxides throughout the well profiles. Sorption of metals by actively precipiting oxyhydroxides can account for the subsurface attenuation profiles. Modelling suggests that the rate of subsurface metal sequestration along the groundwater flow path are ~10 µg/L Zn, ~0.5 µg/L As; ~1 µg/L Pb; ~20 µg/L Ni. These are calculated from a temporally limited suite of samples that may not represent long-term averages.

The metal isotopic dataset is from Athabasca River water, McMurray Formation, and groundwaters downflow of the active area of metal sequestration. The data fall on a mixing line between Athabasca River and McMurray Formation end-member signatures, suggesting that this technique has significant potential for discriminating natural from anthropogenic sources. However, there is minor scatter in the groundwater data that suggests further research is required to better characterise other potential end-member isotopic signatures (e.g. Clearwater and Waterways formations).

Conclusions

The flux of metal contaminants from the tailings pond reaching the Athabasca River is low due to the active sequestration process. Hydrogeological modelling to be completed shortly will determine the flux of subsurface metal sequestration, and will help assess the utility of metal isotopic analyses for monitoring metal contaminant emissions in this area.

Stable isotopes reveal biogeochemical processes in a shallow, eutrophic lake

C. H. GAMMONS[1*], WILLIAM HENNE[1], AND S. R. POULSON[2]

[1]Montana Tech, Geological Engineering, cgammons@mtech.edu (* presenting author), whenne@mtech.edu

[2]University of Nevada-Reno, Geological Sciences and Engineering, poulson@mines.unr.edu

Recent research has shown how the isotopic compositions of dissolved inorganic carbon (δ^{13}C-DIC) and dissolved oxygen (δ^{18}O-DO) can be used to track biogeochemical processes in rivers [1] and shallow groundwater [2]. This study uses the same approach to examine processes occurring under ice cover in Georgetown Lake, a shallow, eutrophic lake in western Montana, USA. The results have implications for survival of fish during winter hypoxia.

After the onset of ice (Nov-2010), DO concentrations decreased sharply with depth and time at two monitoring sites, while δ^{18}O-DO increased (Fig. 1B, Trends III, IV). Conversely, DIC concentrations increased with depth and time, while δ^{13}C-DIC initially decreased (Fig. 1A, Trend I). These trends are consistent with a respiration: photosynthesis ratio > 1. The lower slope of Trend IV vs. Trend III indicates a higher rate of photosynthesis (which produces isotopically light DO) at Site 2, which partly counteracts the effects of respiration (which preferentially consumes light DO). Photosynthesis in the top 1-2 m of the water column provides enough DO for trout and land-locked salmon to survive the 6-month winter.

Late in the winter, the deeper waters at both sampling sites (especially Site 2) saw a continued increase in DIC concentration and an increase in δ^{13}C-DIC (Fig. 1A, Trend II). Trend II is best explained by a shift in the dominant microbial pathway in the deeper water column and underlying sediment from organic-C oxidation to organic-C disproportionation, the latter yielding a mixture of isotopically heavy CO_2 and isotopically-light CH_4 [3]. Work is in progress to measure CH_4 and dissolved organic carbon concentrations and isotopic compositions to confirm this hypothesis.

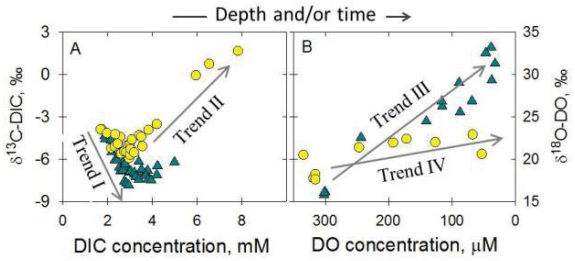

Figure 1: Seasonal changes in the concentration and isotopic compositions of (A) DIC and (B) DO between Nov-2010 and May-2011. Triangles are Site 1 (max. depth = 9 m); circles are Site 2 (max. depth = 6 m). Depth in the water column and elapsed time increase from left to right in both diagrams.

Intrinsic Proton Activity of Surface Hydroxyl Groups of Single-crystal (Hydr)oxide Minerals: Insights from Recent AFM Studies

YANG GAN*

Harbin Institute of Technology, Chemical Engineering, China, ygan@hit.edu.cn (* presenting author)

Regardless of intensive interests in the surface chemistry of (hydr)oxide minerals, the surface charging behavior in aqueous solution is still not well understood. Using skillfully both AFM high-resolution imaging [1] and reliable colloidal probe technique [2, 3], we showed unambiguously that the basal plane of gibbsite developed significant net positive charge in the acidic pH range (Fig. 1) [4], and that the PZC of polished corundum single-crystals was sensitive to the change in off-cut angle of samples [5]. These results demonstrated that using samples with well-defined structures was essential towards a better understanding of the charging properties of gibbsite and corundum, particularly the intrinsic proton activity of surface hydroxyl groups like Al_2OH and AlOH [6].

Preparation contaminant-free surface of single-crystal corundum substrates, without resorting to vacuum annealing, is the prerequisite for studying the charging properties of corundum/water interface; however, after critical evaluation we found that existing wet/UV/plasma cleaning methods were not valid in terms of removing both organic and particulate contaminants. We proposed a modified RCA method which is reliable for producing contaminant-free surface with well-defined surface structures [7,8].

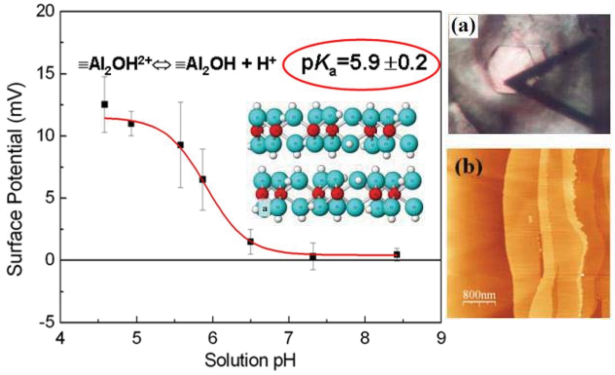

Figure 1: Diffuse layer potential of gibbsite (001) basal plane (the sample and an AFM image are shown on the right) in 1 mM NaCl at various pH obtained from fitting the AFM force curves. The red solid line is the fitting result based on a single-pKa protonation model shown in the inset (pKa=5.9). Also shown in the inset is the structural mode of gibbsite.

Determination of trace mercury in geological samples by photo induced chemical vapour generation with isotope dilution inductively coupled plasma mass spectrometry determination

XIAFENG XIA[1], YING GAO[1*], AND FURONG YUE[1]

[1]College of Nuclear Technology and Automation Engineering, Chengdu University of Technology, Sichuan 610059, China, ying.gaoy@gmail.com

Abstract

Mercury is ubiquitous in the environment. Anthropogenic activities take the major responsibility for the significantly elevated mercury emission as a result of more and more human activities[1]. Much concern has been attracted to the determination of mercury due to their high toxicity and biomagnification[2]. The increasing mercury emission directly resulted in sediment and soil Hg contamination. To assess the toxicity and health risks of mercury, the accurate determination of Hg in sediment and soil is of great importance. However, the extremely low concentration of mercury and the complex sample matrix of soil and sediment samples make the accurate mercury determination troublesome. Furthermore, the severe memory effect of mercury determination by ICP MS is a rather difficult problem to overcome.

A simple, rapid and selective method was developed for the accurate determination of trace mercury in soil and sediment samples by photo induced chemical vapor generation (PVG) with isotope dilution inductively coupled plasma mass spectrometry determination (ID ICPMS). After microwave assisted acid digestion, sample solution was subjected to UV irradiation in the presence of formic acid. Mercury was thus efficiently converted into Hg^0 without the addition of any other reductants. Subsequently, the generated mercury vapor was rapidly separated from the matrix by an argon flow and swept into ICPMS for quantification. Under the optimal experimental conditions, the limit of detection of 0.6 ng L^{-1} was obtained. Compared to traditional CVG, the PVG systems have superior detection sensitivity and tolerance ability to transition metal ions. Up to 5000 folds of Cu^{2+}, Co^{2+}, Ni^{2+}, Mn^{2+}, Fe^{3+}, and Zn^{2+} have no significant interferences for mercury determination. The method was applied to the determination of mercury in geological samples with satisfactory results.

Elemental sulfur nanoparticle coarsening kinetics and changes in Raman and voltammetric signals

ANGEL A. GARCIA[1*] AND GREG K. DRUSCHEL[1,2]

[1]University of Vermont, Burlington, Vermont, angel.garcia@uvm.edu (* presenting author)

[2]Indiana University-Purdue University Indianapolis, Indianapolis, Indiana, gdrusche@iupui.edu

Elemental sulfur exists is a variety of forms in natural systems, from dissolved forms (noted as S^0, or in ring form as in $S_{8\ (rings)}$) to bulk elemental sulfur (most stable as α-S_8, but existing in at least 180 different allotropes and polymorphs). Elemental sulfur can form via a number of biotic and abiotic processes, many of which would begin with single S^0 molecules that aggregate into larger and larger forms; this process is explained by the following pathway: $S^0 \rightarrow S_{8\ (rings)} \rightarrow S_{8\ (nano)} \rightarrow S_{8\ (\alpha\text{-}S_8)\ (bulk)}$. Formation of elemental sulfur has been done in the lab via two primary techniques to create an emulsion of liquid sulfur in water called sulfur sols that approximate some mechanisms of possible elemental sulfur formation in natural systems. These techniques produce Wiemarn (hydrophobic) and Raffo (hydrophilic) sols [1]. These sols begin as single S molecules, but quickly become nanoparticulate and coarsen into micron sized particles via a combination of Ostwald ripening and aggregation processes. In an effort to investigate fundamental questions related to elemental sulfur particle size in natural systems, we conducted a series of experiments to study the rate of elemental sulfur particle coarsening using dynamic light scattering analysis under different physical and chemical conditions. Results showed that coarsening of $S_{8(nano)}$ is partly pH dependent (with faster coarsening at pH 3 than at pH 7 or 10), and strongly temperature dependent (Figure 1). The addition of surfactants to emulate biotic mechanisms to transport elemental sulphur inside the cell shows a significant reduction in the rate of aggregation, in addition to known effects of these molecules on elemental sulphur solubility [2]. Initial cryo-SEM results additionally suggest coarsening is largely a product of ripening processes rather than particle aggregation. Raman spectroscopy and voltammetry (using Au-amalgam and mercury drop electrodes) signals change as a function of size and surfactant use..

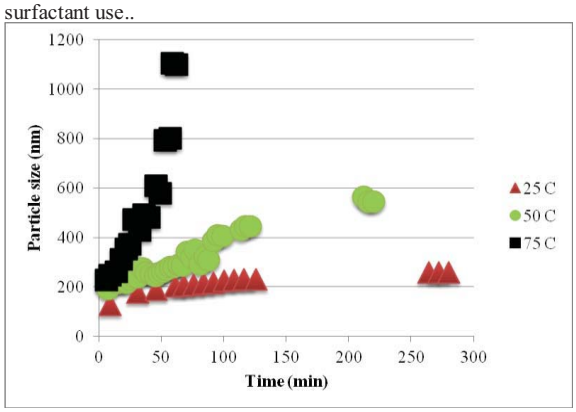

Figure 1: Elemental sulfur particle coarsening. Nanoparticles form from S^0 and $S_{8(rings)}$ in seconds, followed by coarsening (ripening and aggregation) that is strongly T-dependent.

Large magnesite vein and fracture formation in peridotite rocks

PABLO GARCÍA DEL REAL[1]*, KATE MAHER[1], DENNIS K. BIRD[1], AND GORDON E. BROWN, JR.[1,2,3]

[1]Department of Geological & Environmental Sciences, Stanford University, Stanford, CA 94305, USA. gdelreal@stanford.edu (* presenting auhor)

[2] Department of Photon Science and Stanford Synchrotron Radiation Lightsource, SLAC National Accelerator Laboratory, Menlo Park, CA 94025, USA

[3]Department of Chemical Engineering, Stanford University, Stanford, CA 94305, USA

Large monomineralic cryptocrystalline magnesite ($MgCO_3$) vein deposits hosted in ophiolitic peridotite provide insights into the chemical, structural, and temporal constraints on subsurface carbonation processes. The magnesite veins record the upward migration of deep mineralizing solutions to shallow crustal depths, which bear relevance to two fundamental problems important to industrial geologic sequestration of CO_2 in peridotite rocks: (1) the kinetics of magnesite formation—the target carbonate for CO_2 mineralization and (2) the generation of permeability required for modally abundant carbonate formation. Our field site, the Red Mountain Magnesite Mining District in the Diablo Mountain Range, California, provides information about these processes and a framework for comparison with the results of experimental and modeling studies of carbonation of Mg-silicates.

Mines at the Red Mountain Magnesite District, California, reveal more than 20 homogenous magnesite veins up to 40 m thick and >100s of m in length hosted in the variably serpentinized peridotite lithology of the Del Puerto ophiolite. The carbonate mineralization occurs primarily as cryptocrystalline magnesite veins with sharp mineralogic or structurally sheared/brecciated contacts with the host peridotite rock. Rapid, low-temperature mineralization is inferred from chemical, isotopic, and textural homogeneity of magnesite, and the lack of metasomatic reaction zones along the peridotite-magnesite interface. Opaline silica occurs as relatively small late-stage veins paragenetically distinct from the magnesite mineralization and the peridotite host rock. Silica expected from extensive peridotite dissolution and relic textures of peridotite in the carbonate are absent in the observed exposures, indicating that Mg was supplied from dissolution of Mg-bearing rocks below the mineralization zone and that silica did not inhibit magnesite precipitation. This suggests that the rates of Mg-silicate dissolution are decoupled from the rates of magnesite precipitation. At Red Mountain, magnesite precipitation was both effective and pervasive, implying that the experimental problems in magnesite formation (primarily slow nucleation kinetics) have been overcome in nature. These observations highlight both the complexity of natural analogues and the limitations in the chemical and temporal scope of dissolution-carbonation experiments in replicating natural systems. The magnesite veins evidence a structurally and paragenetically different carbonation mechanism than that proposed for carbon sequestration (direct Mg-silicate dissolution and creation of permeability via carbonate growth). Geochemical and geochronological work on the magnesite, silica, and peridotite rocks further constrain models of fracture-vein initiation and closure related to the carbonation at Red Mountain.

Evaluation of ^{224}Ra as a SGD tracer in Long Island Sound

GARCIA-ORELLANA, J.[1*], COCHRAN J.K.[2], DANIEL J.W.R.[2], RODELLAS V.,[1] BOKUNIEWICZ H.[2] AND HEILBRUN C.[2]

[1]Departament de Física – ICTA, Unversitat Autònoma de Barcelona, Bellaterra, Spain, jordi.garcia@uab.cat, valenti.rodellas@uab.cat

[2]School of Marine and Atmospheric Sciences - SUNY, Stony Brook, NY - US, kcochran@notes.cc.sunysb.edu, jwrdaniel@gmail.com, hbokuniewicz@notes.cc.sunysb.edu, cheilbrun@notes.cc.sunysb.edu

Introduction

In this work we present the Ra mass balance used to evaluate the importance of the submarine groundwater discharge (SGD) in Long Island Sound (NY, US). Long Island Sound is a large estuary on the east coast of the U.S. located between Long Island and Connecticut. It has a mean depth of 20m and tidal ranges up to 2 m with mud deposits that cover 67% of the western basin. In summertime, it is affected by hypoxia in the western basin. Three surveys were conducted between April 2009 and August 2010 where 25 water stations were sampled for Ra isotopes, oxygen concentration and Mn. Stations were oriented along 4 transects: one axial extending from the western to eastern Sound and three longitudinal transects in the western, central and eastern Sound.

Results and Conclusion

The inventory of ^{224}Ra in the water column in summer was two times higher than in winter pointing out an increased ^{224}Ra flux to the Sound in summer. A mass balance for ^{224}Ra was constructed considering tidal exchange and the inputs from rivers, desorption from particles, diffusive fluxes (including bioirrigation) and the loss due to radioactive decay. Diffusive fluxes of ^{224}Ra from bottom sediments have been measured by incubating cores in a continuous flow mode such that the overlying water was circulated through a Mn-oxide fiber to maintain a constant activity of ^{224}Ra. Diffusive fluxes from muddy sediments are about five times greater than those from sandy sediments. The Ra balance shows a net input of Ra to the Sound that could be attributed to fresh SGD, tidal recirculation through the beach sands or seasonal difference in the diffusive flux from sediments. ^{224}Ra values within 100 m of the shore were ten times those in the open sound. Radium concentrations were elevated in the pore water of the coarse beach sand along the Long Island and Connecticut coasts, suggesting that tidal recirculation through the beach face is an important source of Ra to the Sound. Seasonal variation in this source seems unlikely and we conclude that the variations seen in the ^{224}Ra inventories are probably produced by variations in sediment fluxes due to seasonal changes in bioirrigation and/or redox cycling of Mn.

Tourmalinites of the Brusque Group in the São João Batista-Tijucas area, Santa Catarina State – Brazil

MIGUEL A.S. BASEI[1], GIANNA M. GARDA[1*], FABIO BRENTAN[1]

[1]Instituto de Geociências da Universidade de São Paulo, São Paulo, Brazil, giagarda@usp.br (* presenting author)

Introduction

The Dom Feliciano Belt is the most important geotectonic unit of the southern portion of the Mantiqueira Province in southern Brazil. In eastern Santa Catarina State, it is represented by the Itajaí and Brusque groups and the Florianópolis Batholith.[1] The basal Rio do Oliveira Formation of the Brusque Group is constituted from top to bottom by metapsammitic, metapelitic, metavolcanic-exhalative and metabasic/calc-silicate units. Within the metavolcanic-exhalative unit, a discontinuous tourmalinite sequence stretches out for approximately 14 km, from São João Batista to Tijucas.

The tourmalinites of the São João Batista-Tijucas area

Two types of tourmalinites are distinguished in the São João Batista-Tijucas area. Those cropping out along the Oliveira River are banded, very fine-grained, and are composed of greenish yellow tourmalines. In contrast, those cropping out in the Morro do Carneiro are coarse-grained and massive to slightly foliated. The tourmalines are typically zoned, with a transparent core, a darker intermediate zone, and a greenish rim.

Electron probe microanalyses showed that the tourmalines of the Oliveira River tourmalinites are Al- and alkalis-rich, whereas those of the Morro do Carneiro tourmalinites are Mg- and Ca-rich. The Morro do Carneiro tourmaline color zoning corresponds to an increase in Mg# and decrease in Al, alkalis and Fe contents from the light core to the greenish rim. The sharp increase in Ca contents from core to rim may be explained by Ca input from the surrounding calc-silicate rocks. On the other hand, the Oliveira River tourmalines are Ca-poor and Al-rich.

Geochronological studies by LA-ICPMS helped distinguish four zircon age groups.[2] Detrital zircons from the Rio do Oliveira Formation basal rocks yielded ages in the 2101-2150 Ma interval, interpreted as those of the source rocks for the Brusque Group metasediments. A second zircon population yielded 1090 ± 230 Ma, age characteristic of the 'adjacent' Namaqua Metamorphic Complex (in Western Gondwana). The zircon age obtained for the Rio do Oliveira Formation basal amphibolites is 639 ± 11 Ma, which is considered the maximum age of the overlying banded tourmalinites. Younger ages, between 608 and 581 Ma, correspond to the thermal event associated with the Neoproterozoic granitic magmatism. These ages may correspond to the age of formation of the Morro do Carneiro massive tourmalinites.

Conclusions

The Rio do Oliveira tourmalinites formed by selective substitution caused by B-rich exhalative fluids affecting the sediments of the metavolcanic-exhalative unit, whereas metasomatic/igneous fluids led to the formation of the Morro do Carneiro massive tourmalinites. Zircon dating showed that the Rio do Oliveira tourmalinites are somewhat older than the Morro do Carneiro massive tourmalinites.

Abstract

Carbonaceous chondrites are considered as amongst the most primitive Solar System samples available, because of their enrichment in volatile elements. The mineralogy of CM and CI chondrites is dominated by serpentines and montmorillonite type clays, respectively but mineralogy of CR chondrites is poorly constrained so far. Here, in order to characterize and quantify the abundance of hydrous minerals in carbonaceous chondrites, we performed thermogravimetric analysis (TGA) of fragments of Tagish Lake (TL, UCC), Murchison (CM2.5), Orgueil (CI) and EET 92159 (CR2).

Chunks of meteorites were extracted for TGA analysis following [1]. In the case of the CR chondrite, a matrix-enriched fraction of the sample was prepared and compared to a bulk rock fragment. TGA experiments were performed with TGA/SDTA 851^e Mettler Toledo under the following conditions: sample mass of about 15 mg, platinum crucible of 150 μl, heating rate of 10 °C min^{-1}, and inert N_2 atmosphere of 50 ml min^{-1}. About 15 reference minerals were analyzed as standards.

All meteorites studied show significant endothermic mass loss below 200°C. Two distinct peaks are present on the first derivative curve corresponding to adsorbed H_20 (peak at 70°C) and water molecules trapped in mesopores (peak at 130°C), in agreement with IR study [2]. The total amount of this "exchangeable" water is 2.8, 6.0, 7.8 and 3.9 wt % for Murchison, TL, Orgueil and the matrix of the CR, respectively.

In the case of Orgueil, a significant amount of mass loss is centered at 250°C, likely related to the decomposition of ferrihydrite, confirming previous studies [3]. In addition, mass releases are observed at 570°C and 730°C, attributed to Fe and Mg-rich phyllosilicates. In the case of Murchison, the occurrence of Mg-rich serpentine is suggested by the presence of a mass loss at 730°C, together with cronstedtite (mass loss at 380°C and 545°C). TL shows a particular behaviour since Mg-serpentine appears to be absent and the first derivative curve shows a mass loss occuring at 570°C with a shoulder at 520°C. In the case of EET 92159, a significant mass loss occurs between 200° and 900°C (7,5 wt %) indicating that the matrix is hydrated. The amount of hydration of the matrix suggests a very high proportion of phyllosilicates. Numerous peaks are present in the derivative curve indicating a complex hydrated mineralogy dominated by phyllosilicates

Hydrothermal vents as a source of pyrite and trace metal- containing mineral nanoparticles to the oceans

AMY GARTMAN [1*], MUSTAFA YÜCEL [2], GEORGE W. LUTHER, III[1]

[1]School of Marine Science and Policy, College of Earth, Ocean and Environment, The University of Delaware, Lewes, DE 19958, USA (*agartman@udel.edu)

[2] Université Pierre et Marie Curie, Banyuls—sur--mer, France, yucel@obs-banyuls.fr

The mechanisms by which metals from hydrothermal vents may be transported through the ocean are still largely unknown. We demonstrate that pyrite nanoparticles as small as 4nm, and aggregated into clusters of 50-350nm, are emitted from high temperature black smokers at Lau Basin. These nanoparticles, which contain other metals, are characterized via chemical methods as well as by using a combination of physical chemical techniques (TEM, SEM-EDS and EELS). Laboratory experiments show that synthesized pyrite nanoparticles are stable in oxic seawater for months, and thus provide a potential transport mechanism for iron far from vent sources. All these nanoparticles as well as others including iron silicates, which are present, likely influence the transport of iron and other elements from the hydrothermal environment to the ocean. Hydrothermal vents may serve as nanoparticle 'factories' that fertilize the ocean.

Isotopes and geochemistry of rock-water interaction, Chalk River, Ontario

MEL GASCOYNE [1]* , KAREN KING-SHARP[2], LEONID NEYMARK[3], ZELL PETERMAN[3] AND SHAUN FRAPE[4]

[1]GGP Inc ., Pinawa, Manitoba, Canada, gascoyne@granite.mb.ca (*presenting author)
[2]AECL, Chalk River Laboratories, Chalk River, Ontario, Canada
[3]USGS, Denver, CO, USA
[4]University of Waterloo, Waterloo, ON, Canada

A five-year pre-project study under the Nuclear Legacy Liabilities Program was undertaken to assess the suitability of the bedrock at the Chalk River Laboratories (CRL) site to safely host a proposed Geologic Waste Management Facility (GWMF) for Atomic Energy of Canada Limited's low- and intermediate-level radioactive waste (LILW) at CRL. The site investigations involved the disciplines of geology, hydrogeology, geochemistry, geomechanics and microbiology.

The authors have investigated certain geochemical parameters in the groundwater (e.g. redox, pH, Fe, U, isotopic data) and the mineralogy of the host rock. The geochemical composition of the groundwater and rock pore water at repository depth may affect the performance of the repository barrier system and ideally should be favourable to retarding radionuclide movement. Characterization of the groundwater was also identified as important in determining its residence time ('age') and origin.

This talk will summarize isotopic data (^{3}H, ^{18}O, ^{13}C, ^{14}C, ^{36}Cl, $^{87}Sr/^{86}Sr$ ratio, U-series) from CRL crystalline rocks, porewaters, groundwaters and fracture minerals. The application of heavy element isotope systematics (Rb-Sr, U-Pb and U-series) was also studied in selected bulk-rock samples from CRL. Currently, information is being obtained from isotope systematics based on past fluid chemistry, isotopic composition, and pressure and temperature conditions during paleohydrogeological events (such as metamorphic and glacial episodes). Other data for examination include age dates of rocks and groundwater that may indicate recent U mobility and transitions from oxidizing to reducing groundwaters effects of rock-water interactions.

The geochemical composition of the groundwater and the rock pore water is consistent with low hydraulic conductivity of rocks. It further indicates limited fracture-matrix interaction and implies that solute movement in the rock matrix in this area is diffusion controlled. The Rb-Sr & U-Pb isotope systematics indicate no geologically recent U mobility (<100 Ma) and most U isotopic data show secular equilibrium, and, therefore, no U loss/gain in the last 1 Ma.

Ureolytic $CaCO_3$ Precipitation in the Presence of Non-ureolytic Bacteria

DANIELLA GAT [1*], MICHAEL TSESARSKY [2,1] AND ZEEV RONEN [3]

[1]Ben-Gurion University of the Negev, Geological and Environmental Sciences, Beer-Sheva, Israel, mizdani@bgu.ac.il (* presenting author)
[2]Ben-Gurion University of the Negev, Structural Engineering, Beer-Sheva, Israel, michatse@bgu.ac.il
[3]The Zuckerberg Institute for Water Research, the J. Blaustein Institute for Desert Research, Ben-Gurion University of the Negev, Sede-Boqer, Israel, zeevrone@bgu.ac.il

Microbially induced $CaCO_3$ precipitation (MICP) is recently being studied due to its various potential applications, such as: sequestration of soil contaminants [1]; and mitigation of seismic liquefaction [2], among others. Some of these applications involve *in-situ* treatment of soils, and therefore require a better understanding of the interactions between microbial ecology and aquatic geochemistry.

Hydrolysis of urea, catalyzed by the enzyme *urease*, is one of the most common pathways for MICP [3]. Hydrolysis of urea produces ammonium and carbonate: $CO(NH_2)_2+2H_2O \rightarrow 2NH_4^+ + CO_3^{2-}$, thus increasing surrounding alkalinity. In the presence of dissolved calcium this process will result in the precipitation of $CaCO_3$: $Ca^{2+} + CO_3^{2-} \rightarrow CaCO_3$.

In order to study the interactions between ureolytic and non-ureolytic bacteria we performed a MICP experiment in artificial groundwater medium, inoculated with two model bacteria: *S. pasteurii* (ureolytic bacteria) and *B. subtilis* (non-ureolytic bacteria), and supplemented with Nutrient Broth and urea. Control was inoculated with *S. pasteurii* alone. The experiment lasted 10 days, during which NH_4^+, Ca^{2+}, pH, dissolved inorganic carbon and optical density (OD) were measured.

Results are summarized in Table 1. Most of the $CaCO_3$ precipitation took place until the 80th hour of the experiment. During which time, pH values and carbonate ion concentrations in the presence of non-ureolytic bacteria were lower than in their absence. However, measured Ca^{2+} concentrations indicates that $CaCO_3$ precipitation was accelerated in the presence of non-ureolytic bacteria, despite less favorable chemical conditions. Bacterial growth, as infferred from OD measurements was significantly higher in samples containing non-ureolytic bacteria. Therefore, we suggest that $CaCO_3$ precipitation in the presence of non-urealytic bacteria was accelerated due to addition of nucleation sites in the form of bacterial cells.

	Control	Both Bacteria
pH	**7.49-8.45**	**7.50-8.21**
CO_3^{2-} (mM)	**0.005-0.132**	**0.005-0.087**
OD	**20 hr. lag phase**	**6 hr. lag phase**
$CaCO_3$ precipitation	**100% in 123 hours**	**100% in 80 hours**

Table 1: Results summary.

Studies of submarine groundwater discharge (SGD) have been focused on passive margins with large floodplains [1]. SGD from active margins without substantial sediment cover remains unknown, but it is in the rapidly eroding highlands along these margins that the feedback between climate and weathering is most effective [2].

In Taiwan, measured erosion and silicate weathering rates are amongst the highest in the world. In a representative section of the northeast coast of Taiwan, at the outlet of the Liwu river, we have explored the possible magnitude and pattern of SGD, and its implications for weathering budgets. The river drains 4 km of emergent mountain relief, with a further 5 km of submarine relief above the Pacific abyssal plain. In the Liwu catchment, 16±1% of the river discharge (averaged over 37 years of record) comes from a deep groundwater reservoir, and deep seated chemical weathering of silicates accounts for 38% of the riverine silicate weathering flux [3]. It is likely that the large inland hydraulic head drives submarine discharge from this deep groundwater reservoir and weathering reactor.

We have used the radium quartet (^{228}Ra, ^{226}Ra, ^{224}Ra, ^{223}Ra) along with Temperature-Salinity (T-S) profiles on two 50 km West-East marine transects off the NE coast of Taiwan (<2000m water depth) to search for SGD. Stable isotopes, major elements, and Ra isotopes in water samples were analyzed to constrain the hydrogeology of rivers and two types of groundwater: sandy shallow aquifers (<200 m deep) and a deep bedrock aquifer (~400m deep).

Radium activities were measured using RaDeCC. Preliminray results show that the ^{224}Ra and ^{228}Ra activities at the sea surface exceed those in the average deep coastal water column. ^{228}Ra activities are also slightly elevated in some stations at 400-600m depth, below the Kuroshio current. These stations have anomalously low salinity, when compared to regional hydrographic profiles. Given the strong density barrier presented by the Kuroshio current, these Ra and salinity excursions at depth are not likely to result from downward mixing of surface seawater. They may be related to groundwater discharge from submerged mountain bedrock.

The T-S and Ra-isotopes data suggest that there may be active SGD across the structural dip of the active margin of East Taiwan. Using both transects and the deep groundwater characteristics, we will add constraints on sediment/water interactions and the occurrence and spatial extent of SGD in the area.

[4] NASA GSFC, Solar System Exploration Division, Greenbelt, USA

In this work [1] we present mid- and far-Infrared absorption spectra of Titan's aerosol analogues produced in the PAMPRE experimental setup.

We provide a complete dataset regarding the influence that the concentration of methane vapor in the gas mixture has on the tholins spectra. Among other effects, the intensity of the 2900 cm^{-1} pattern (attributed to methyl stretching modes) increases whith the methane concentration. On the opposite, tholins produced with low methane concentrations seem to be more amine based polymers (see Fig. 1).

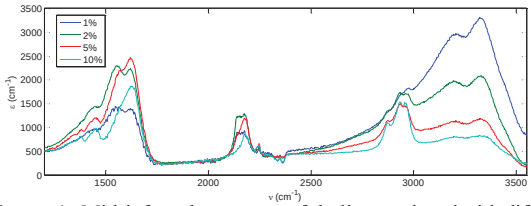

Figure 1: Mid-infrared spectrum of tholins produced with different methane concentrations

Moreover, we compare tholins spectrum with observation of Titan's atmosphere (see Fig. 2).

It is shown that the position of the bands around 2900 cm^{-1} depends on the chemical environment of the methyl functional group. We conclude that the presence of these absorption bands in Titan's atmosphere, as measured with the VIMS instrument onboard Cassini [2] is in agreement with an aerosol contribution.

In the far-infrared, tholins spectrum presents many similarities with the spectra of Titan's aerosols derived from recent Cassini-CIRS observations [3].

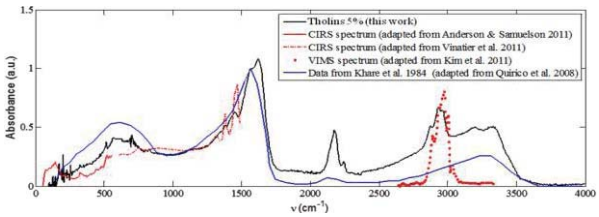

Figure 2: Far- and mid-infrared spectrum of tholins (black) compared to Cassini VIMS and CIRS observations (red)

HSE and Os isotope systematics of mantle pyroxenites from the Lherz and Lanzo ultramafic massifs.

T. GAWRONSKI[1]*, H. BECKER[2]

[1*]Institut für Geologische Wissenschaften, Freie Universität Berlin, Germany, gawronsk@zedat.fu-berlin.de

[2]Institut für Geologische Wissenschaften, Freie Universität Berlin, Germany, hbecker@zedat.fu-berlin.de

Mantle pyroxenites provide direct evidence for mantle heterogeneity and magma transport in the mantle. These rocks may form by crystal accumulation at high pressures from mantle derived magmas, melt-peridotite reaction or partial melting of basic rocks in the mantle [1]. Pyroxenites are also useful to study fluxes and fractionation of highly siderophile elements (HSE) during transport in the mantle and to assess the influence of pyroxenites in magma genesis.

The peridotite massifs at Lanzo (northern Italy) and Lherz (southern France) provide the opportunity to study pyroxenites that have equilibrated at different P-T-conditions. The spinel facies Lherz peridotite contains spinel websterites, orthopyroxenites, garnet-clinopyroxenites.The plagioclase facies Lanzo peridotite massif includes spinel and plagioclase websterites, clino- and orthopyroxenites up to several dm in thickness. Aluminum poor websterites at Lherz and Lanzo display highly siderophile elment (HSE: Os, Ir, Ru, Rh, Pt, Pd, Au and Re) patterns similar to fertile lherzolite. In contrast, Lherz clinopyroxenites show more strongly frationated HSE patterns compared to Lanzo clinopyroxenites. with a stronger depletion in Os, Ir, Ru, Rh and Pt relative to Pd, Au and Re. These differences likely reflect different extent of reaction of parental melts with peridotite or different compositions of precursor materials (e.g. recycled oceanic crust). Re-Os data for pyroxenites from Lherz scatter around a 1.7 Ga reference line. This data is consistent with the Re-Os model ages obtained on peridotites [2] and hints that the refertilization of the Lherz body may have occurred in the Proterozoic. These results support the view that the Lherz body is indeed a fragment of Proterozoic continental lithospheric mantle and not Mesozoic oceanic mantle that contains ancient heterogeneities.

[3]Dep. of Geological Sciences, Brown University, Providence, USA

[4]Dep. of Earth Science, Rice,University, Houston, USA

[5]Dep. of Terrestrial Magnetism, Carnegie Institution, Washington, USA.

The Big Pine Volcanic Field (BPVF) is an ideal location for constraining the mantle melting conditions westernmost region of the Basin and Range. This work is the first to report H_2O and CO_2 concentrations in Big Pine magmas and fO_2, which are necessary for accurate estimates of the melting conditions. Melt inclusions trapped in primitive olivines (Fo_{82-90}) record surprisingly high H_2O contents (1.5 to 3.0 wt.%) for a location not currently above active subduction. The combined H_2O-CO_2 data are consistent with closed-system degassing from >5 kb (~ 20 km) to the surface. Estimates of the oxidation state of BPVF magmas are also surprisingly high (FMQ +1.0 to +1.5), based on constraints from V partitioning between melt and olivine and melt inclusion S contents (up to 5000 ppm), yielding Fe^{3+}/Fe_T ratios of 23 - 30%. While lithospheric mantle xenoliths from BPVF record low H_2O concentrations (whole rock <75 ppm). Pressures and temperatures of melt equilibration of the BPVF magmas indicate a shift over time, from higher melting temperatures (~1320 °C) and pressures (~2 GPa) for magmas that are >500 ka, to cooler (~1220 °C) and shallower melting (~1 GPa) conditions in younger magmas. The depth of melting also correlates strongly with some trace element ratios in the magmas, with deeper melts having higher Ce/Pb (14-21) and Ba/La (20), closer to typical upper mantle asthenosphere values, and shallower melts having lower Ce/Pb (<14) and variable Ba/La (20-30), more typical of subduction zone magmas, and within the range of the available lithospheric mantle xenolith data from BPVF. The correlated melting conditions and geochemical stratification of the mantle melts are consistent with seismic observations of a shallow lithosphere-asthenosphere boundary (~55 km depth). Combined trace element and cryoscopic melting models yield self-consistent estimates for the degree of melting (~5%) and source H_2O concentration (~1000 ppm). We suggest two possible geodynamic models to explain small convection necessary for magma generation. The first related with the Isabella seismic anomaly, either as a remnant of the Farrallon Plate or lithospheric foundering. The second scenario is related to slow extension of the lithosphere.

Towards an understanding of the non-classical nucleation of $CaCO_3$

DENIS GEBAUER

University of Konstanz, Physical Chemistry, denis.gebauer@uni-konstanz.de

Introduction

Nucleation of calcium carbonate from aqueous solution can proceed via an alternative pathway that involves stable pre-nucleation clusters [1] and results in the initial precipitation of amorphous calcium carbonate (ACC) nanoparticles, which may subsequently transform into crystalline species. This pathway is referred to as "non-classical nucleation", because it challenges the major concepts and assumptions made by classical nucleation theories [2]. Additive-free ACC formed in this manner exhibits distinct short-range structural features, which (depending on pH) can relate to the long-range order of different crystalline $CaCO_3$ polymorphs [3]. The presence of such proto-structures in ACC is well-known from biogenic, though additive-containing specimens [4], and may be the clue to a novel understanding of polymorph selection and control.

The atomistic background underlying non-classical nucleation of calcium carbonate should thus offer an explanation for at least three major experimental observations; (i) the thermodynamic stability of pre-nucleation clusters, (ii) the existence of a distinct barrier for nucleation separating solution (pre-nucleation) and solution/solid (post-nucleation) states, and (iii) the possibility of different structures in precipitated ACC.

Results and Conclusions

The non-classical pre-nucleation behavior of calcium carbonate can be rationalized by means of results obtained from computer simulation in combination with re-evaluations of experimental data [5], which show that stable pre-nucleation clusters are highly dynamic, liquid- and chain-like structures of $CaCO_3$ ion pairs. Various experimental observations [6–9] are put into context with this theoretical speciation, eventually allowing for speculations about what happens at the point of nucleation.

It appears that solid calcium carbonate can only be nucleated from homogeneous solutions if pre-nucleation clusters aggregate and coalesce to build larger entities above ca. 20 nm in size [8]. In turn, these considerations suggest that the classical pathway via ion-by-ion growth of un- and metastable nuclei may indeed be blocked under the conditions that have been investigated so far. Finally, implications of these findings for additive-controlled crystallization of calcium carbonate are outlined.

[3]Istituto Nazionale di Geofisica e Vulcanologia Sezione di Napoli - Osservatorio Vesuviano, Naples, Italy, lucia.pappalardo@ov.ingv.it

The Campi Flegrei volcanic district (Naples region, Italy) is a 12 km wide, restless caldera system that has erupted at least six voluminous ignimbrites throughout the late Pleistocene, including the >300 km^3 Campanian Ignimbrite (CI), originated by the largest known volcanic event of the Mediterranean region. One of these deposits, the Breccia Museo (BM), a petrologically heterogeneous and stratigraphically complex volcanic deposit extending over 200 km^2 in close proximity to Campi Flegrei [1], has long remained contentious regarding its age and stratigraphic relation to the CI. Here, we present crystallization and eruption ages for BM plutonic ejecta clasts that were determined via uranium decay series and (U-Th)/He dating of zircon, respectively. Plutonic clasts were examined by scanning electron microscopy, and zircon crystals were extracted for geochronologic analysis. Despite mineralogical and textural heterogeneity of these syenitic clasts, their U-Th zircon crystallization ages are indistinguishable with an average age of 49.2±3.0 ka (2σ errors; mean square of weighted deviates MSWD = 1.2; n = 34). Disequilibrium-corrected (U-Th)/He zircon ages for three plutonic clasts average 42.2±2.6 ka; MSWD = 0.7; n = 10). One exception is a single clast where zircon crystals yielded older (U-Th)/He ages of 50.6±3.9 ka (MSWD = 1.6, n = 6) that overlap with the U-Th zircon crystallization ages. The limited range in U-Th zircon ages indicates rapid crystallization within the plutonic margins of the pre-CI magma system. For most clasts, the limited range of (U-Th)/He ages suggests complete resetting during the eruption, or lack of pre-eruptive ^{4}He accumulation due to high ambient temperatures. Only in one instance we suspect that the explosive eruption that ejected the BM plutonic clasts may not have heated zircon sufficiently to completely degas pre-eruptive ^{4}He. There, the close overlap between crystallization and (U-Th)/He ages would imply very rapid cooling within the shallow intrusive complex. Our (U-Th)/He zircon eruption age overlaps with published ^{40}Ar/^{39}Ar sanidine ages for BM which, however, display considerable variation (i.e., plateau ages ranging between 34.2 and 41.0 ka; [1]). It is marginally older than the commonly cited ^{40}Ar/^{39}Ar CI eruption age (39.5±0.1 ka; [2]), but significantly pre-dates published ^{14}C ages for BM (17.9 ka [3]) and CI (between 42 and 27 ka reported in [4]). These results underscore the potential of combined U-Th and (U-Th)/He zircon geochronology for high-accuracy chronostratigraphy, and reconstruction of the thermal history of the magmatic feeder systems of supereruptions.

Synthesis and isotopic characterization of high-pure ^{12}C nano-calcite

ANTOINE GEHIN[1*], GERMAN MONTES-HERNANDEZ[1] AND LAURENT CHARLET[1]

[1] ISTerre, Maison des Geosciences, 38041 Grenoble, France, (correspondence antoine.gehin@ujf-grenoble.fr, german.montes-hernandez@ujf-grenoble.fr and charlet38@gmail.com)

In the present study, we report a simple and innovative synthesis route for high-pure ^{12}C nanosized calcite particles. Herein, $Ca(OH)_2$ nanoparticles portlandite were directly carbonated with high-pure $^{12}CO_2$ (99,99% ICP-MS certfified) gas using a static bed reactor under anisobaric conditions (initial $^{12}CO_2$ gas pressure = 20 bars and T = 303 K).

Calcite nature and particle size (including its morphology) were controlled by X-ray diffraction (XRD) and field emission gun scanning electron microscopy (FESEM), respectively. Its isotopic characterization by isotopic CO_2 Cavity Ring-Down Spectroscopy (CRDS from Picarro) analyzer has confirmed the very low negative delta of the ^{13}C (**Figure 1**), i.e. higher content in ^{12}C with respect to standard (measured against Vienna Pee Dee Belemnite *VPDB*).

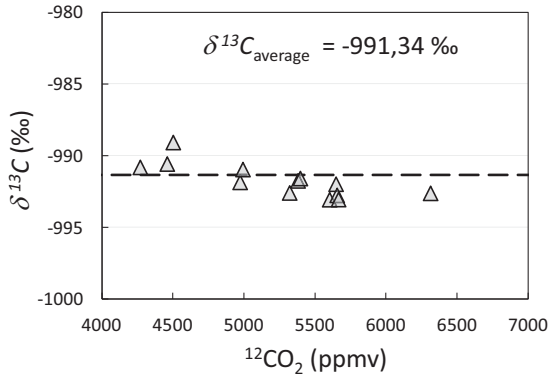

Figure 1: $\delta^{13}C$ value of $Ca^{12}CO_3$ as a funtion of $^{12}CO_2$ (in ppmv). The dashed line shows an average value of $\delta^{13}C$ = -991,34 ‰.

To the best of our knowledge, this is the first time ever that such $\delta^{13}C$ measurement is reported for a synthetic material. Remarking that $\delta^{13}C$ are expressed in permil and are typically in the range from -100 to +100. This new high-pure ^{12}C nano-calcite opens new possibilities to investigate on the carbon ^{12}C-^{13}C dynamic exchange at the calcite-fluid interfaces with relevance in natural and artificial systems.

Si isotope fractionation during silica precipitation in flow-through experiments

SONJA GEILERT[1*], MANFRED VAN BERGEN[1], PIETER VROON[2], PHILIPPE VAN CAPPELLEN[3]

[1]Department of Earth Science, Utrecht University, Utrecht, The Netherlands, s.geilert@uu.nl (* presenting author), m.j.vanbergen@uu.nl

[2]Department of Petrology, VU University, Amsterdam, The Netherlands, p.z.vroon@vu.nl

[3]Department of Earth and Environmental Sciences, University of Waterloo, Waterloo, Canada, pvc@uwaterloo.ca

Silicon isotopes are a promising proxy for (near-) surface processes and conditions. However, an unequivocal interpretation of isotope signatures in natural silica deposits is often hampered by the lack of quantitative constraints on isotopic fractionation for the environment of interest. To help alleviate these limitations, we performed precipitation experiments using flow-through reactors wherein silica precipitated from a saturated solution in the 10-60°C temperature range. Principal objective was to determine the sign and magnitude of silicon isotope fractionation during controlled precipitation of amorphous silica induced by a temperature drop.

A starting solution, brought to saturation in amorphous silica at 90°C, was forced to pass flow-through reactors containing seeds of amorphous silica powder. The reactors were placed in a water bath with a pre-set cooler temperature. Time-series results, obtained through monitoring the Si concentration in output solutions, were used to optimize the experimental conditions under which steady-state deposition could be achieved. This comprehensive set of test runs exposed strong effects from flow-rate, surface area of the seeding material and degree of supersaturation in the reactors.

Silicon isotope ratios ($^{30}Si/^{28}Si$ and $^{29}Si/^{28}Si$), measured in input and output solutions using a Thermo Neptune MC-ICPMS, showed a systematic time-dependent behaviour as well. Isotope shifts in initial run products, expressed as $\Delta^{30}Si_{out\text{-}in}$ ($\delta^{30}Si_{output}$ - $\delta^{30}Si_{input}$), ranged between -2.0 and +0.1‰, mainly depending on temperature and surface area of the silica seeds. Long-term runs (up to 2 month) were required to approach a steady isotopic signal in the output solution, which is taken to reflect equilibrium. In these cases, the output results are consistent with preferential incorporation of the light isotope in the precipitating silica, in qualitative agreement with expected fractionation behaviour. Our experimental results obtained so far yielded a maximum $\Delta^{30}Si_{out\text{-}in}$ value of +1.4‰, which was found when the precipitation temperature was lowest. The magnitude of fractionation tended to increase with decreasing temperature.

Our experimental set-up mimics a submarine hydrothermal vent system where silica deposition is associated with a steep temperature gradient. The results corroborate the potential of $\delta^{30}Si$ signatures of (precursors of) cherts as a paleo-proxy for ambient conditions, but question their robustness as indicator of paleo-temperatures alone.

Carbonatite extraction and seismic anomalies in the Galápagos plume

D. GEIST[1*], D.R. TOOMEY[2], D. VILLAGOMEZ[3], AND E. HOOFT[4]

[1]*University of Idaho, Moscow ID USA, dgeist@uidaho.edu
[2] University of Oregon, Eugene OR USA, drt@uoregon.edu
[3] University of Oregon, Eugene OR USA, emilie@uoregon.edu
[4]University of Oregon, Eugene OR USA, darwin7@gmail.com

Conventional models of plume-ridge action call on plume material (either melt or solid mantle) flowing along the base of the lithosphere toward the ridge. This model is inconsistent with a number of seismic and geochemical paradoxes in the Galápagos Archipelago. Although the Galápagos Spreading Center is contaminated with plume Sr, Nd, and Pb, there is no plume He in GSC lavas. Many of the northern Galapagos volcanoes have less of a plume isotopic signal than any GSC lava from within 400 km of the Galapagos hotspot. GSC magmas contain water from the Galapagos plume; there are no data bearing on whether the plume is richer in CO_2 than the GSC or whether plume CO_2 contaminates the GSC.

Combined surface and S-wave tomography reveals 4 velocity zones in the Galapagos plume: a 1 to 2% slow zone extending from 400 to 100 km, a normal velocity zone from 100 to 80 km, a zone 2% slow zone from 80 to 15 km, and the crust. The deep slow zone is unlikely to be due to hydrogen in olivine or temperature, owing to the magnitude of the velocity anomaly. Instead, we propose that it is due to a carbonatite melt that is produced at depths >400 km. A reasonable estimate of the carbon concentration of the Galapagos mantle is 500 ppm (as CO_2), which could yield a ~0.1% carbonatite melt. This melt is likely to extract the noble gases from the rock and ascend vertically to Fernandina's magmatic system. The zone with normal seismic velocity at 100 to 80 km may represent the intersection of the plume with the water-bearing solidus, as the removal of water from olivine is likely to result in an increased seismic velocity. For example, 150 ppm H_2O would depress the anhydrous solidus by about 55 km (Hirschmann, 2006). The shallower slow zone is likely caused by more extensive partial melting of the silicate phases in the garnet facies, producing a basaltic melt. Fernadina's high $^3He/^4He$ magmas result from mixing of the carbonatite and silicate melts above the plume axis, and trace element models are consistent with this hypothesis.

We propose that plume material is carried to the GSC by deep return flow of the asthenosphere toward the GSC (>100 km depth), not along the base of the lithosphere. Flow at this depth will incorporate plume material that is depleted in He and carbon, accounting for the lack of these signals in GSC lavas. Also, the shallow asthenosphere might be flowing with the plate, away from the GSC. Magmas from the northern Galapagos then are created by melting of mantle that has already had melt extracted at the GSC, accounting for their more depleted compositions. Carbonatite may be the cause of deep (>100 km) seismic anomalies in plume provinces on a worldwide basis.

Engineered nanoparticle sorption onto mineral surfaces

A. GÉLABERT[1,*], Y. SIVRY[1], C. SOARES PEREIRA[1], C. AUBRY[2], N. MENGUY[3], J.-P. CROUÉ[2] AND M.F. BENEDETTI[1]

The strong increase in the use of engineered nanoparticles (NPs) during the last decade may ultimately result in their release in environmental settings as predicted for different types of NPs by Gottshalk et al.[1]. As part of previous modeling works, it has been showed that soils and sediments were able to accumulate high amounts of NPs while waters were acting as a dispersion agent. Thus, in order to be able to predict the fate of NPs in natural systems, an accurate understanding of the interactions involving the mineral surfaces is highly required. This study aims to estimate the NPs sorption properties onto model mineral substrates, to depict the molecular scale processes at work, and to assess the impact of the NPs physico-chemical properties, such as the NPs agregation state.

For this study, the bulk structure of commercial ZnO NPs have been investigated using XRD analysis in combination with high-resolution TEM observations. The physico-chemical properties of the NPs surface were estimated from zeta potential measurements and XPS spectrocopy. And the NPs agregation state was measured using DLS and cryo-TEM techniques. The sorption kinetics of ZnO NPs on mica surfaces and Al_2O_3 (1-102) oriented single crystals have been measured using atomic force microscopy (AFM) in 0.01M $NaNO_3$ solution. This revealed a fast sorption, in the order of minutes, followed by a slower evolution of the system during few hours. Furthermore, sorption studies on synthetic microsized goethite and alumina have been conducted at pH 7.0 in 0.01M $NaNO_3$ solutions. The time of exposure has been fixed at three hours and various mineral/NPs ratio have been tested. The obtained sorption isotherms could only be described using the Temkin equation, thus revealing a decrease in NPs affinity for the mineral surface with an increase in the total NPs sorption rate. This trend can be partly explained by TEM and cryo-TEM observations that showed a preferential sorption of agregated NPs on the mineral surfaces compared to individual NPs. Finally, the NPs aggregation state appears to be one of the major controls of the NPs sorbing properties.

This study constitutes an essential step to understand the fate of NPs in soils, and demonstrates the importance of the NPs physico-chemical properties during their interaction with mineral surfaces.

The Rusty Sink: Iron Promotes the Preservation of Organic Matter in Sediments

YVES GÉLINAS[1]*, KARINE LALONDE[2], ALFONSO MUCCI[3], ALEXANDRE OUELLET[4]

The biogeochemical cycles of iron (Fe) and organic carbon (OC) are strongly interlinked. In oceanic waters, organic ligands have been shown to control the concentration of dissolved Fe [1]. In soils, solid Fe phases provide a sheltering and preservative effect for organic matter [2], but the role of iron in the preservation of OC in sediments has not been clearly established. Here, we determine the amount of organic carbon, associated with reactive iron phases in sediments of various mineralogies collected from a wide range of depositional environments, using an iron reduction method previously applied to soils [3]. Our findings suggest that 21.5 ± 8.6 per cent of the organic carbon in sediments is directly bound to reactive iron phases, representing a global mass of 19 to 45 × 10^{15} g of organic carbon in surface marine sediments [4]. This pool of OC is different from the rest of sedimentary OC, with ^{13}C and nitrogen-enriched organic matter preferentially bound to Fe which suggests that biochemical fractionation occurs with OC-Fe binding. We propose that these organic carbon-iron associations, formed primarily through co-precipitation and/or direct chelation, promote the preservation of organic carbon in sediments. Since reactive iron phases are metastable over geological timescales, they serve as an efficient "rusty sink" for OC, a key factor in the long-term storage of organic carbon and thus contributing to the global cycles of carbon, oxygen and sulphur [5]. New data showing Fe-OC interactions in water column suspended particles will also be presented.

O isotopes in the Azores: mantle melting versus AFC

FELIX S. GENSKE[1,2]*, CHRISTOPH BEIER[1,2], STEFAN KRUMM[1], KARSTEN M. HAASE[1], SIMON P. TURNER[2]

[1]GeoZentrum Nordbayern, Universität Erlangen-Nürnberg, Schlossgarten 5, D-91054 Erlangen, Germany
[2]CCFS, GEMOC, Department of Earth and Planetary Sciences, Macquarie University, Sydney NSW 2109, Australia (*correspondence: felix.genske@mq.edu.au)

The Azores archipelago in the central North Atlantic has been studied wideley over the last few decades, one reason being its formation history that is related to a slow-upwelling mantle plume. The plume sources identified in these ocean islands are predominantly inferred from Sr-Nd-Pb-(Hf) radiogenic isotope data along with major and trace element geochemistry. Contrastingly, few studies have dealt with the variability in stable isotopic composition. Here, we present a detailed isotopic study of oxygen isotope ratios ($^{18}O/^{16}O$) in olivines, clinopyroxenes and plagioclases that allow to infer on the quantiative and qualitativey involvement of altered oceanic crust (AOC) during ascent of the magmas. This is particularly important when aiming to place constraints on the primary O isotopic composition of the mantle plume source. Furthermore, such estimates can be combined with other newly availabe isotope data of boron (B) and Lithium (Li) of the Azores lavas.

We provide a comprehensive data set of phenocryst O isotope data obtained by laser fluorination along with their individual mineral chemistry measured by electron microprobe on the same grain. The phenocrysts originate from lavas from the entire archipelago, namely Faial and Pico (central Azores) and São Miguel (east Azores), and, for the first time, include data for the two islands west of the mid-Atlantic ridge (MAR), Flores and Corvo. The samples were selected from geochemically well characterised host lavas such that the newly obtained O data are placed in a tight geochemical and petrological background.

Our data indicate that the eastern Azores lavas are characterized by O ratios (i.e. $\delta^{18}O_{(ol)}$ 4.7-5.2 ‰) slightly lighter than the primitive mantle range ($\delta^{18}O_{(ol)}$ ~ 5.2±0.2 ‰), while the western lavas fall within the latter range. However, we find that decreasing forsterite contents in olivines are tightly correlated with decreasing $\delta^{18}O$. Such systematic is also observed in Hawaii', which is explained by assimilation of hydrothermally altered material during the crystallization-differentiation process [1]. We test whether assimilation fractional crystallization (AFC) models sufficiently describe the $\delta^{18}O$ systematic of the Azores lavas, and if the highest forsterite olivines can be used to distinguish the $\delta^{18}O$ signal of the plume source. Our data are also compared with those of the MAR [2] to better evaluate the nature and distribution of enriched components in the north Atlantic mantle.

Acid mine drainage multi-step passive treatment system: the Lorraine case study

THOMAS GENTY[1]*, BRUNO BUSSIÈRE[1], CARMEN NECULITA[1], MOSTAFA BENZAAZOUA[1], AND GÉRALD J. ZAGURY[2]

[1]Université du Québec en Abitibi-Témiscamingue, Institut de recherche Mines et Environnement, Thomas.genty@uqat.ca (*presenting author), Bruno.bussière@uqat.ca, Carmen.neculita@uqat.ca, Mostafa.benzaazoua@uqat.ca

[2]École Polytechnique de Montréal, Département de génie civil, géologique et des mines, gerald.zagury@polymtl.ca

Introduction

At the closure stage of a mine site, passive treatment systems are an interesting alternative to reduce environmental impacts of acid mine drainage (AMD) [1] because they require low investments and maintenance, and natural organic materials (like manure and compost) or by-products (like wood ashes) can be used to build them. However, passive treatment of AMD with high iron concentrations is still a major challenge for system efficiency.

The Lorraine site is an AMD generating site in Quebec province reclaimed in 1999. Although the reclamation strategy is effective to limit the generation of new AMD, contaminated water (especially characterized by a high iron loading of 2020 mg/L) in the tailings pores will take time before being leached out. Laboratory studies have shown that a system composed of only one unit passive treatment system, such as sulfate-reducing passive biofilter (SRPB) or anoxic limestone drain, is not efficient to treat this type of AMD [2,3]. Therefore, a multi-step treatment system was designed and built [3]. The first step is a SRPB (containing 50%wt limestone and 50%wt mixture of chicken manure, vegetable compost, wood chips, and sand), which allows pH increasing and a partial dissolved metal removal. The second step is a wood ash filter, for iron removal, mainly. The third step consists of a second SRPB, which allows the removal of sulfates and residual metals.

A 120 m^3system (40 m long x 3 m wide x 1 m high) was built in August 2011 and allows treating 1L/min (Figure 1).

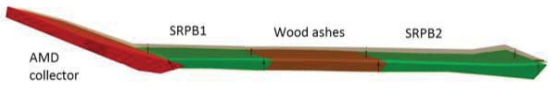

Figure 1: Multi-step treatment system design

Preliminary results

Results from the first four months of operation (see Table 1) showed a promising removal percentage for iron and sulfates (respectively 93% and 59% on average).

Parameter	pH	Fe (mg/L)	SO_4^{2-} (mg/L)
AMD	5.5	2020	4784
After treatment	6.4	150	1992

Table 1: Average water quality after treatment

Silicon Isotopes – A Global Weathering Proxy?

R.B. GEORG

Water Quality Centre, Trent University, Peterborough, Ontario, K9J 7B8 (rgeorg@trentu.ca)

Silicon stable isotopes are one example of the large group of so called "novel stable isotope tools" that became routinely available over the past decade. Advances in mass-spectrometry, especially ICP-MS and gas source mass-spectrometry, provided the technical means for determining Si isotope ratios with unprecedented precision and accuracy. These technical advances opened up new ways to study low-temperature processes, such as weathering reactions, in greater detail. Silicon is ubiquitous in the environment and the isotope system is therefore predestined to be a useful tracer for processes controlling the Si budget in the weathering zone.

Two major fractionation pathways have been identified; (1) biological uptake of Si and (2) the formation of secondary weathering products. Both of these fractionation processes discriminate against the heavier isotopes and produce dissolved Si in surface waters that is usually enriched in heavy Si isotopes. The global runoff has a δ^{30}Si of about +1.1‰ (De La Rocha et al 2005, Georg et al 2009), which reflects isotope fractionation due to a combination of biological processes and weathering processes. The interesting questions would be: which of the two major fractionation pathways dominates and produces the positive isotope composition of the global runoff?

The biological part of the continental Si cycle is often being perceived as the dominant one resulting in large biogenic Si fluxes. A fast turnover of biogenic silica, however, mitigates larger fractionation effects on the dissolved Si load in rivers. The formation of secondary clays represents a more effective way of removing Si from the weathering zone and therefore causing a much greater net fractionation.

I will present a fractionation model of the continental Si cycle that takes into account the interactions between various Si pools and isotopic evolution as a function of the two major fractionation processes. Results show that the formation of secondary minerals is the main driver behind the positive isotope composition in rivers. Although more Si is cycling through the biosphere, the fast turnover means that the biological Si cycle is mostly self-supporting and does not require larger inputs of fresh Si from weathering. Hence the net isotope fractionation is mitigated when biogenic silica is returned to the soil system. The biological cycle has a larger net effect only when significant amounts of biogenic silica are stored in long-term sinks (phytoliths). The typical positive Si isotope composition can only be achieved when significant proportions of Si are being locked-up in clays. In other words, the positive isotope composition of the global runoff reflects a slightly dominating inorganic Si cycle, e.g. dissolution of crustal material and formation of secondary weathering products. There appears to be some systematic change in the isotope composition of the runoff with weathering rates and intensities and in periods with extensive recycling of previously weathered materials, the Si isotope composition of the global runoff can be expected to be lighter than the modern value.

Silicon isotopes could potentially be used to track changes in continental weathering over time, providing a suitable archive exists, such as marine shales (see Savage et al – session 12c).

Re-Os shale ages constrain onset and duration of Late Jurassic anoxia, Barents Shelf

S. GEORGIEV[1,2], H.J. STEIN[1,2,3], J.L. HANNAH[1,2,3], B. BINGEN[1], H.M. WEISS[4]

[1] Geological Survey of Norway, 7491 Trondheim, Norway, georgiev@colostate.edu (* presenting author)
[2] AIRIE Program, Colorado State University, Fort Collins, CO, USA
[3] Physics of Geological Processes, University of Oslo, Norway
[4] SINTEF Petroleum Research, 7465 Trondheim, Norway

Organic-rich marine shales with excellent oil-generation potential were deposited in abundance during the Late Jurassic. These include the Kimmeridge Clay Formation, the main source rock for North Sea oils, and areally extensive black shales in North Alaska, Arctic Canada, the Barents Shelf and Northern Siberia [1]. One of them, the Hekkingen Formation, is the most widespread, though variably mature, hydrocarbon source rock on the Barents Shelf. We report high precision Re-Os isotopic data and geochemical data for three intervals from a condensed section of Hekkingen Formation in the Nordkapp Basin, southwestern Barents Sea.

We sampled shales of the Hekkingen Formation from two shallow drillcores [2], previously subject to detailed biostratigrahpic studies [3]. Shales at the base of the lower Alge Member yield a Re-Os age of ~158 Ma with an initial $^{187}Os/^{188}Os$ ratio of ~0.45. Up section, shales of the overlying Krill Member yield a Re-Os age of ~147 Ma and initial $^{187}Os/^{188}Os$ ratio of ~0.63.

Rock-Eval pyrolysis shows that the organic matter is thermally immature (T_{max} ~400 to 410 °C) and of mixed marine-terrestrial origin (kerogen type II/III predominates). The high total organic carbon (9-19 wt%) and lack of bioturbation, combined with unusually high enrichment in redox-sensitive trace elements Re, Os, Mo, U, Se and V, indicate deposition of the Hekkingen shales under oxygen-free bottom water conditions. Extreme enrichment in Ag, Zn, Ni, Cr, Cu, Cd, Sb, As and Tl, even for black shales, may stem from a high degree of anoxia combined with slow sedimentation in a distal setting with minimal clastic input.

The Re-Os ages provide time pins for the onset (~158 Ma) and duration (at least 11 m.y.) of Late Jurassic anoxia in the Barents Shelf, and for sedimentation rates of organic-rich muds with extreme trace metal concentrations. Additionally, comparison of Re-Os ages with detailed biostratigraphy provides new radiometric constraints for the age of the Kimmeridgian-Tithonian boundary. Rising initial Os isotope ratios from the Oxfordian to the Kimmeridgian shales mirror rising seawater Sr isotope ratios throughout the latest Jurassic [4]. These parallel trends suggest that the initial $^{187}Os/^{188}Os$ of shales records the $^{187}Os/^{188}Os$ of contemporaneous Late Jurassic seawater. The trend toward more radiogenic Sr isotope ratios may reflect decreasing mid-ocean ridge production [4], rather than changes in continental weathering rates.

Intrabasaltic Regoliths in the Deccan (India) and Karoo traps (Lesotho): witnesses of volcanic quiescence and environmental links.

MARTINE GERARD[1*], FREDERIC FLUTEAU[2], VINCENT COURTILLOT[2] AND MAUD MOULIN[3]

[1] IMPMC, IRD, Université Pierre et Marie Curie, Paris, France, martine.gerard@impmc.upmc.fr (* presenting author)
[2] IPGP, Université Paris Diderot, Paris, France
[3] Dpmt de Géologie, Université Jean Monnet, Saint Etienne, France

Large igneous provinces (LIP) are often synchronous with major mass extinctions. Intertrappean layers ("red boles") correspond to periods of volcanic quiescence. Their study complements other methods, and may help to quantify how volcanic activity translates into major environmental perturbations. Geomagnetic secular variation recorded by lavas can be used as a relative time proxy (1,2), providing an estimate of the time needed to generate these regoliths. We have studied a 1200m thick stack of flows in the Deccan and Karoo LIPs. In the Deccan, 22 red boles occur between volcanic flows. Most consist in 5-10cm thick red clayey material filling joints and diaclases at flow contact, located in the frontal part of flow lobes. Only 5 red boles are thicker, but their lateral extent (less than 1km) prevents a stratigraphic reconstruction. The more mature regoliths (a few meters thick) correspond to weathering profiles of massive basalts. Red compact silty clay with relics of feldspars and voids grades into orange silty clay with friable vesicular relics of blocks of basalts, overlaying brown clay jointed lava and massive altered lava. Mineralogical parageneses and micromorphological observations indicate strong hydrolysis and also (deuteric or metasomatic) hydrothermal alteration. No organic relics were found. The duration of formation is likely much less than 10000 years for the more evolved regoliths, when compared to similar paleosols affected by hydrothermalism. Most red boles we observed in the top part of the Deccan lava pile were probably formed in less than 1000 years, consistent with the magnetostratigraphic study [1].The Karoo intra-basaltic regoliths are much less developed and numerous [2]. The red weathered horizons and hydrothermalized contacts always occur within lava lobes, more easily affected by alteration and topographic irregularities. At the base of the section, more or less baked sandstone interbeds have recorded a minor mineralogical signature of weathering from the surrounding lava flows. The altered bases of the overlying lava flows and the baked sediments suggest humid lacustrine conditions. The weathering profiles in the upper part of the section are basaltic saprolites with a summital horizon of smectites-hematites. Within a few profiles, silty quartz may also suggest colluvial paleosols. As is the case for the Deccan regoliths, zeolitic parageneses suggest a strong impact of hydrothermalism. Compared to the Deccan, the Karoo intertrappean layers suggest much more arid climatic conditions that would have drastically limited the occurence of weathering.

Apparent crustal growth due to disequilibration of the Lu-Hf isotope system during crustal melting

AXEL GERDES[1]

[1]Goethe University, Frankfurt am Main, Germany, gerdes@em.uni-frankfurt.de

The combined U-Pb-Hf analysis of zircon is a powerful, widely-used tool for studying the evolution of the continental crust though time. It allows for estimates of the proportions of new, primitive crust relative to the recycled, older continental crust for separate time slices from the Hadean through to the present.

While the general concept appears clear and straight forward, individual data sets generally need careful evaluation before interpretation. Various issues have an important influence on the isotopic data, such as the complexity of natural zircon grains, demanding careful spot selection and high spatial resolution during isotope analyses. Other analytical problems are the possible disturbance of the U-Pb system and the substantial interference correction during Hf isotope analyses.

This study will discuss the possibility that many crustal melts do not reflect the isotopic composition of their source. Most granitic rocks contain inherited zircon in their zircon population commonly preserved as cores overgrown by newly crystallized rims. The Hf isotope composition of the rims usually represents that of the magma, which is either a mixture between mantle magma and crustal components or of pure crustal origin. Even in the latter case, the $^{176}Hf/^{177}Hf$ of the melt, as reflected by the zircon rim composition, will be more radiogenic than that of their average crustal source, as unradiogenic Hf is stored in the inherited cores. The effect will increase with the percentage of inherited, non-dissolved zircon and with the time since last isotope equilibration of the crustal source. This is because new ^{176}Hf formed from Lu-decay usually readily enters the melt, as Lu is incorporated in phases other than zircon that are reactants in the melting process, while only a fraction of the Hf stored in zircon will be dissolved. Assuming a time span of 0.5-1.0 Ga since the last isotopic equilibration and that 40-60% of zircon from the source dissolve in the melt, the Hf isotope composition of the melt will be about 3-11 εHf(t) (t= time of melting) units lower than that of the source. Using 4 different examples from the recent literature, inherited zircon cores have at time of granite generation a mean εHf(t) of -3±3, -13±20, -22±19, and -21±20, which is in average about 6-20 εHf units lower than that of their magmatic rims. This correlates well with the mean age of the cores, which are about 0.46 to 1.5 Ga older than that of their rims. Notably is also that the overall isotopic variation of the inherited cores is about 5-40times higher than that in the magmatic rims (e.g., ±0.5, SD).

As a consequence, estimation of the average crustal residence time (e.g. T_{DM} ages) based on the composition of the magmatic zircon will be too young and will thus overestimate the contribution of juvenile magmas to the system. Although granite magmas probably do not fully equilibrate with their sources, the data imply that crustal melting stimulates isotopic and chemical homogenisation of the crust.

Protracted tectonometamophic history at the base of an orogenic channel in the southeastern Canadian Cordillera

We tested the recently proposed model of channel flow[1] by mapping key outcrops in the northern Monashee Mountains of the southeastern Canadian Cordillera. The structural and metamorphic continuity of this area constitute the main challenges for this controversial model. Our fieldwork revealed the existence of a major SE-striking, reverse-sense shear zone, named Hellroar Creek Shear Zone (HCSZ). It is characterized by a large volume (>60%) of highly sheared leucogranite and leucosome, whereas leucogranite in its footwall, although locally as abundant, forms a heterogeneous mesh of highly discordant intrusions. The HCSZ separates a low-strain domain with preserved stratigraphic polarity and dominated by SW- to W-verging structures in its footwall, from a high-strain domain with rocks recording complete transposition by top-to-the-NNE to top-to-the-E shearing in its hanging wall.

One migmatitic pelitic schist, one prekinematic, and one synkinematic leucogranite dykes from the hanging wall of the HCSZ, as well as one postkinematic leucogranite dykes from its immediate footwall were dated for U-(Th)-Pb monazite and zircon geochronology. Collectively, the near continuous record of monazite and zircon growth from 104 to 57 Ma in these samples indicates an exceptionally long tectonometamorphic history for this reverse-sense shear zone.

The presence of a major shear zone with a protracted history of ductile deformation in an area previously mapped as continuous supports the channel flow model. In addition, the timeframe of shearing coincides with the timing of flow derived from the pattern of younger cooling ages recorded from the front to the rear of the proposed channel.[1] The HCSZ is thus interpreted as the base of a channel flow system that was active for >40 Myr in the Late Cretaceous.

21g. Process-based reactive transport modelling of aquifer remediation and natural attenuation

Volatile organic compounds may cause major contamination problems in groundwater and soil. Their presence in air can create a hazard to public health. However, limited remedial options exist in controlling the vapour transport of these compounds in the unsaturated zone.

In this study, batch experiments were carried out to investigate the oxidation of TCE, ethanol, and toluene vapour in air by potassium permanganate. For each compound, three experiments with different combinations of vapour concentration and mass of potassium permanganate grains were performed. The objectives of these batch tests were (1) to evaluate the ability of solid potassium permanganate to transform contaminants in the gas phase to harmless compounds and (2) to determine the kinetic parameters. Experimental results have revealed that solid potassium permanganate is able to remove these harmful compounds from the vapour phase. We found that the removal efficiency for TCE and ethanol oxidation is higher than for toluene.

To obtain kinetic parameters, the reaction rate was assumed to be related nonlinearly to the concentration of the targets compounds and the amount of permanganate:

$$\frac{dC}{dt} = kA C^{\alpha} M^{\beta}$$

where k denotes the rate constant ($mol^{1-\alpha}\ L^{3\alpha+3\beta-5}\ M^{-\beta+1}\ T^{-1}$), A is the specific surface area of potassium permanganate ($L^2\ M^{-1}$), C is the vapour concentration of the compound (mol L^{-1}), M is the mass of potassium permanganate per volume of gas (M L^{-3}), α and β are constant parameters. We made sure that $KMnO_4$ was abundantly present so it was assumed that its consumption did not affect the reaction rate. This equation was fitted to experimental data in order to determine k, α, β for each compound. Results of the simulations are given in table1.

Compound	α	β	k($mol^{1-\alpha}\ L^{3\alpha+3\beta-5}\ M^{\beta+1}\ T^{-1}$)	R^2
TCE	0.9	1	6.92×10^{-7}	0.99
Ethanol	1.09	1	5.68×10^{-7}	0.99
Toluene	0.94	1	2.99×10^{-8}	0.99

Table1: kinetic parameters for target compounds

Conclusion

This study shows that TCE and ethanol in vapour phase can be rapidly oxidized by solid potassium permanganate. Toluene, however, is degraded much slower. A nonlinear reaction formula simulates results of experiment satisfactory. While, potassium permanganate shows promise for the remediation of TCE and ethanol vapour, further investigation of its applicability for toluene is needed.

Evaluation of Zr in rutile geothermometry for pelitic rocks from the Mica Creek area, British Columbia.
